postoperative organ dysfunction.[13] Metabolic indices must be routinely monitored (ie, every 30–60 minutes), and a successful resuscitation should include a pH approaching normal values (ie, pH >7.3),[14] decreasing serum lactate (ie, lactate clearance of 10% per hour),[15] base deficit greater than –2.0, partial pressure of carbon dioxide ($Paco_2$) of 35 to 40 torr, and a core body temperature of greater than 35°C.[16] Temperature management and avoidance of hypothermia are critical in an acutely injured trauma patient and may be achieved by active means such as fluid warmers or intravascular warming devices or with passive convection warming devices. Extracorporeal devices, such as extracorporeal membrane oxygenation or renal replacement therapy, may be used to rewarm patients with critical hypothermia (ie, temperature <32°C).

If cardiovascular physiology deteriorates as evidenced by continued bleeding in the operative field and/or acute hemodynamic decompensation, the anesthesia team should request for temporary surgical hemorrhage control with pressure packing, vascular clamps, or REBOA inflation until adequate intravascular volume is restored. Newer techniques, such as REBOA[17] (see Chapter 13) or emergency preservation and resuscitation trials,[18] carry associated physiologic impacts that require additional anesthesia education and collaborative management protocols.[19] Hypotension and bradycardia in an acutely hemorrhaging patient should alert the resuscitation team to imminent cardiovascular collapse. At times, intraoperative damage control techniques should be expedited, followed by resuscitation to reverse the shock in an intensive care unit (ICU), prior to surgical reexploration and definitive repair. When blood replacement needs exceed surgical blood loss, consideration of other sites of hemorrhage should be discussed and explored. For patients with a tourniquet in place, a pelvic binder, or inflated REBOA, the planned complete or partial release of hemorrhage control devices must be communicated to the anesthesiologist to allow for monitoring and treatment of sudden hypotension and negative inotropy from decreased preload and reperfusion of acidic metabolites. At times, vasopressor administration may be indicated. Although retrospective evidence has suggested that early vasopressor use following traumatic hemorrhagic shock is associated with increased mortality,[20] recent investigations suggest that norepinephrine administration does not adversely affect mortality.[21] Single-center, prospective, randomized data also demonstrated that continuous infusion of vasopressin to patients in hemorrhagic shock was associated with decreased transfusion requirements.[22] However, large doses of vasopressors should be critically evaluated and every effort made to restore intravascular volume prior to vasopressor use (Table 20-2).

While injury leading to hemorrhage is of primary focus, many other alterations in normal physiology can occur in the injured patient and must be rapidly diagnosed and treated in the operating room. For example, brain injury with consequential increases in intracranial pressure (ICP),[23] coagulopathy and arrhythmias, airway and thoracic injuries with subsequent difficulty oxygenating and ventilating, and spinal cord injuries with resultant hypotension unresponsive to volume replacement[24] must all be concurrently considered by the anesthesiologist and should dictate therapeutic interventions. Advanced Trauma Life Support training, education in management of nonhemorrhagic injury and morbidity (found in other chapters in this book), and simulation are vital in preparing the trauma anesthesiologist to manage the entire patient.

Finally, disposition from the operating room must also be formulated (ie, Does the patient require ICU admission? Is further imaging required? Does hemorrhagic control require damage control management via interventional angiography?). These decisions and communication should all occur in conjunction with the anesthesiologist, trauma surgeon, and critical care intensivist. The emphasis on perioperative vigilance as the core of anesthetic practice cannot be more accurate when caring for the multisystem severely injured trauma patient.

ANESTHETIC MONITORING AND PLANNING

Monitors and Machines

The American Society of Anesthesiologists (ASA) has established standards to ensure appropriate and safe physiologic monitoring during all anesthetics.[25] These include monitoring of oxygenation, ventilation, circulation and hemodynamics, and temperature. During general endotracheal anesthesia,

TABLE 20-2: Vasopressor Activity, Risks, and Benefits

Vasopressor	Mechanism of action	Risk	Benefit
Phenylephrine	Pure α_1-receptor agonist	Peripheral and splanchnic vasoconstriction, reflex bradycardia	Augment venous return and increase central systemic vascular compartment volume No proven benefit in hemorrhagic shock
Norepinephrine	α_1-Receptor agonist with modest β_1-agonist activity	Increased oxygen consumption, decreased regional perfusion due to excessive vasoconstrictive effects, immunosuppression	Augment venous return and increase central systemic vascular compartment volume, increase coronary artery perfusion, support cardiac contractility through β_1 activity
Epinephrine	β_1, β_2 activity at doses <5 µg/min, additional α_1 activity with higher doses	Arrhythmia, increased lactate, cardiac ischemia	Improve cardiac contractility, augment venous return, and increase central systemic vascular compartment volume
Dopamine	D_1 and D_2 receptors at doses of 0.5-3 µg/kg/min, β_1-receptors at doses of 3-10 µg/kg/min, α_1-receptor at doses >10 µg/kg/min	Arrhythmia, cardiac ischemia, vasoconstriction, and increased LV afterload at high doses	Theoretical improved coronary and renal blood flow at low doses No proven benefit in hemorrhagic shock
Vasopressin	0.03-0.04 U/min	Increased visceral ischemia due to splanchnic vasoconstriction and translocation of intestinal bacteria, exacerbation of cerebral edema, coronary ischemia due to vasoconstriction	Activation of V_1 receptors and counteracting nitric oxide synthesis, thereby increasing vascular tone, immunomodulation, regulation of intravascular volume resorption via V_2 receptors in collecting tubules, decreased transfusion requirement (blood product and overall volume)

LV, left ventricular.

oxygenation should be determined with continuous pulse oximetry and the fraction of inspired concentration of gases. Ventilation is monitored with continuous end-tidal carbon dioxide measurements and exhaled tidal volume. Systemic blood pressure is determined either via a continuous invasive arterial catheter or noninvasive blood pressure cuff measured at least every 5 minutes. Heart rate and rhythm are monitored with continuous electrocardiographic telemetry. Last, all patients should have temperature measurements obtained when significant changes in body temperature are expected to occur. This is especially crucial for trauma patients who may experience prolonged exposure to the elements prior to hospital arrival, burn patients, or those who undergo sizable open operations with large insensible losses of fluid and heat. Furthermore, exposure to large volumes of resuscitative fluids may cause profound hypothermia and dilutional coagulopathy. In summary, every anesthetist must maintain constant and vigilant monitoring of the previously mentioned essential vital functions.

The basic anesthesia machine is designed to safely and efficiently deliver a mixture of oxygen, air, and inhalational anesthetic. Principles of redundancy, both in machine function and monitors/alarms, are incorporated to aid in early detection, and user alerts indicate particular risks (eg, delivery of a hypoxic gas mixture or the loss of tidal volume resulting from a breathing circuit disconnection). Despite the many safety systems inherent to the modern operating room anesthesia machine, there remain circumstances when anesthetics must be administered in austere environments or outside of a designated operating room setting, without access to the usual anesthetic apparatus and its safety features. In these clinical situations, the ASA standards of anesthetic monitoring must still be considered, but in dire emergencies, the anesthesiologist may initially rely on tools such as clinical observation, palpation of pulse, and auscultation of heart and lung sounds before there is time for application of routine monitors. Capnography can provide timely insight into states of hypoperfusion because end-tidal carbon dioxide falls with profound decreases in cardiac output. Portable monitors that display electrocardiographic telemetry, pulse oximetry, invasive and/or noninvasive blood pressure, and end-tidal carbon dioxide are routinely used for transport of critically injured trauma patients and may substitute for the anesthetic machine monitor when providing remote anesthesia service. In addition, backup safety equipment, such as manual ventilation bag-valve mask and circuit, airway and intubating devices, vasoactive medications, and intravenous sedation medications, must be readily available in all anesthetic locations.

There is no consensus guideline for intraoperative hemodynamic monitoring and resuscitation in trauma patients. Although continuous cardiac output monitors appear attractive, there is little comparative data to demonstrate improved clinical outcomes in the trauma setting. As previously described, serum markers of resuscitation, such as lactate, base deficit, and venous oxygenation, are valuable tools to guide resuscitation.[14,26] However, each has certain limitations, as discussed in other chapters of this text. Last, the anesthesiologist may be specially trained and certified to

perform transesophageal echocardiography (TEE). Although this modality has not been formally validated for intraoperative care of trauma patients, TEE appears to be gaining prominence as a valuable tool to aid in hemodynamic resuscitation.[27]

Anesthetic Types

Anesthetics can be categorized into three types: general, regional, and local anesthesia. Each one can be administered independently or in combination with the others. When regional or local anesthesia is provided in the absence of general anesthesia, the patient may require supplemental light or deep sedation. The decision as to which anesthetic to provide the trauma patient is dependent upon numerous variables. Most critically is the urgency of the operation, potential likelihood of clinical deterioration due to severity of injury, and underlying patient factors, such as risk of aspiration and patient mental status. Severe traumatic brain injury (TBI), intoxication, and the stress of a traumatic incident often render patients unable to cooperate such that they pose a danger to themselves and surrounding providers. Rapid induction and intubation followed by general anesthesia with an inhalational or intravenous anesthetic is often the most effective and safe option in these patients with careful consideration of hemodynamics, oxygenation, and ventilation to minimize secondary brain injury. Finally, in the severely injured patient, definitive airway control and general anesthesia allow for a smooth transition to the ICU or further surgical interventions if required.

General anesthesia is not without certain side effects and disadvantages. Nearly all sedative medications and inhalational anesthetic agents are sympatholytic and directly produce vasodilation and hypotension (Table 20-3), further exacerbated by hypovolemia. Therefore, continued and aggressive resuscitation prior to induction and maintenance of a general anesthetic is critical to intraoperative stability and tissue oxygen delivery. In addition, the use of vasopressors to counteract anesthetic vasoplegia may be used, as described previously.

Trauma patients are also at increased risk of intraoperative awareness (recall) when general anesthetics are used sparingly due to hypotensive instability. Recognition of this risk is crucial to minimizing potential adverse neuropsychological effects. Appropriate supplementation of a general anesthetic with a benzodiazepine (ie, midazolam 0.02 mg/kg) to prevent memory formation may assist in limiting intraoperative recall. Furthermore, a high index of suspicion and close postoperative evaluation with appropriate neuropsychological follow-up are also recommended.[28]

In the absence of an indication for general anesthesia with a definitive airway, regional anesthesia techniques, combined with minimal or no additional sedation, may be a valuable approach, especially for patients whose injuries are primarily localized to the extremities. This can be particularly useful for fracture reduction and splinting, application of traction, pain relief before or after surgical repair, and occasionally to facilitate definitive repair of injuries. The profound analgesia that can be provided by peripheral nerve blockade can greatly reduce the need for systemic opioids and their side effects and alleviates some of the patient distress that might otherwise be addressed with sedative-hypnotic drugs.[29] Caution must still be exercised when formulating plans for any sedation accompanying regional anesthetic techniques, recognizing that offering concurrent sedation may impair airway reflexes and could warrant airway securement and conversion to a general anesthetic.

Anesthetic Considerations

In addition to the focus on maintaining safe physiology and resuscitative medicine, anesthesiologists consider a number of other factors, including the importance of anxiolysis, analgesia, hypnosis and amnesia, and immobility to facilitate safe and comfortable care. An overview of these anesthetic goals is presented in Table 20-4 and discussed in the following four sections. The accompanying Table 20-3 summarizes properties of several classes of anesthetic medications commonly used in trauma that are referenced across this chapter.

ANXIOLYSIS

In the setting of traumatic injury, patients often experience increased anxiety due to the psychological impact of circumstances that led to the injury, acute trauma pain, fear from impaired situational awareness, and simultaneous stimulation by multiple providers and procedures involved in their care. Unfortunately, for trauma patients who require prolonged stays in the hospital or ICU, increased anxiety is prevalent.[30]

Before resorting to anxiolytic drugs, the side effects of which may be undesirable in early resuscitation, basic principles of bedside manner go a long way in easing patient fear. Reducing anxiety by speaking in a calm voice, listening, providing clear explanations and reassurance about the care being rendered, providing positive imagery, having respectful interactions with other members of the care team, and attending to comfort can reduce drug administration.[31] When necessary, various medications are also used to aid in anxiolysis, with the benzodiazepine class most commonly prescribed.

Benzodiazepines stimulate inhibitory γ-aminobutyric acid (GABA) receptors in the central nervous system. Clinically, they produce a dose-dependent effect of anxiolysis, hypnosis, and antegrade amnesia.[32] Commonly prescribed benzodiazepine medications and their properties in the acute care and ICU setting are listed in Table 20-3. Midazolam is the most frequently used intravenous benzodiazepine for preoperative anxiolysis due to its short onset of action (1–2 minutes), relatively short duration of action, and minimal adverse cardiovascular effects when administered at a premedication anxiolytic dose. Of considerable importance in the trauma patient with hemorrhagic shock and hypovolemia is that rather modest doses of benzodiazepines may result in marked cardiovascular depression. Therefore, appropriate dose adjustment and reduction are often necessary when administering these medications to under-resuscitated patients.[33]

Other medications used to minimize anxiety and agitation include α_2-adrenergic agonists (eg, dexmedetomidine

TABLE 20-3: Anesthetic Medications in Trauma

Intravenous benzodiazepines

Drug	Onset (min)	Duration of action (min)	Common clinical uses in trauma patients	Drug-specific side effects and considerations	Drug class side effects and considerations
Midazolam	0.5–1.5	10–30	Anxiolysis, antegrade amnesia, sedation, component of induction, seizure cessation, infusion for ICU sedation	↓MAP and ↓CBF when used at induction doses	All benzodiazepines can cause respiratory depression (hypoventilation, hypoxia, apnea) and potentiate other CNS and respiratory depressants; recommend avoidance in early pregnancy
Lorazepam	1–2	60–120	Anxiolysis	Pain on injection, disorientation, abuse and addictive potential	
Diazepam	1–1.5	15–30	Anxiolysis, skeletal muscle relaxant, part of multimodal analgesia	↓MAP, pain on injection	

Intravenous opioids

Drug	Onset (min)	Duration of action	Common clinical uses in trauma patients	Drug-specific side effects and considerations	Drug class side effects and considerations
Morphine	5–10	3–5 h	Analgesia, sedation	Asthma exacerbation, histamine release, drug accumulation in renal dysfunction	All opioids can cause respiratory depression (hypoventilation, hypoxia, apnea), potentiate other CNS and respiratory depressants, and result in ↓MAP, ileus, nausea and vomiting, abuse and addictive behavior, and pruritus
Fentanyl	3–5	30–60 min	Analgesia, sedation, infusion	Long context-sensitive half-time; primarily metabolized by liver so useful in renal failure; can cause chest wall rigidity	
Hydromorphone	5–15	1–3 h	Analgesia (often postoperative)		
Remifentanil	1–1.5	5–10 min	Analgesia, sedation; usually given by infusion	Very short context-sensitive half-time	
Sufentanil	1–3	60–90 min	Analgesia	Greater respiratory depression than fentanyl at equianalgesic levels	
Alfentanil	0.5–2	15–45 min	Analgesia, especially for briefly painful procedures (eg, fracture reduction, dressing change)		
Methadone	3–5	24–36 h	Analgesia	Histamine release, prolonged QTc; also acts via NMDA receptor antagonism	

(*continued*)

TABLE 20-3: Anesthetic Medications in Trauma (*Continued*)

Local anesthetics

Drug	Duration of action (h)	Maximum safe dose	Common clinical uses in trauma patients	Drug-specific side effects and considerations	General side effects and considerations
Lidocaine	3–4	5 mg/kg plain 7 mg/kg with epinephrine	Single injection, intravenous infusions for multimodal analgesia, part of anesthetic induction	Least cardiotoxic; used for intravenous regional anesthesia (Bier block)	All local anesthetics can cause local anesthetic systemic toxicity: can lead to mental status changes, arrhythmias, and cardiac arrest; reversed with intralipid
Mepivacaine	3–4	4.5 mg/kg plain 7 mg/kg with epinephrine	Single injection		
Ropivacaine	6–10	3 mg/kg	Single injection, continuous neuraxial or PNB infusion		
Bupivacaine	8–12	2.5 mg/kg	Single injection, continuous neuraxial or PNB infusion	Most cardiotoxic	
Levobupivacaine	8–12	2.5 mg/kg	Single injection, continuous neuraxial or PNB infusion		

Intravenous hypnotics/sedatives

Drug	Onset (min)	Duration of action (min)	Common clinical uses in trauma patients	Drug-specific side effects and considerations
Propofol	<0.5	5–10	Anesthetic induction and maintenance, procedural and ICU sedation	Pain on injection; respiratory depression; ↓SVR, ↓CVP with induction doses causes hypotension; ↓ICP; risk of propofol infusion syndrome with prolonged ICU infusion
Etomidate	<0.5	3–12	Anesthetic induction	Pain on injection; respiratory depression; 11β-hydroxylase inhibition may result in cortisol insufficiency
Ketamine	0.5–1	10–20	Anesthetic induction (alone or in combination with another agent), procedural sedation, analgesia	Increases sympathetic nervous system output; increases oral and tracheobronchial secretions; bronchodilator; analgesic properties via NMDA receptor antagonism; direct myocardial depressant effects may become evident in catecholamine-depleted patients; disturbing hallucinogenic effects
Dexmedetomidine	5–15	Dose dependent; usually given by infusion	Sedation for awake intubation, controlled emergence, ICU sedation	No respiratory depression; no increase in ICP; biphasic BP response (possible brief hypertension followed by hypotension); bradycardia; risk for sinus arrest in patients with high vagal tone

(*continued*)

TABLE 20-3: Anesthetic Medications in Trauma (*Continued*)

Inhaled anesthetics

Drug	Used for inhalation induction?	Potency[a]	Cardiovascular effects	Bronchodilatory effect	General side effects and considerations
Isoflurane	No	Greatest	Decrease BP, prolong QTc, increase HR	Yes	No analgesic properties; all promote immobility; all can cause hypotension, nausea and vomiting, hyperkalemia, and malignant hyperthermia and potentiate nondepolarizing muscle relaxants
Sevoflurane	Yes	Intermediate	Decrease BP, prolong QTc	Yes	
Desflurane	No	Low to intermediate	Decrease BP, prolong QTc, increase HR	No	
Nitrous oxide	Yes, but only in combination with other inhaled agents	Least	Decrease BP, increase HR	No	Analgesia even at subanesthetic doses; increases CBF and ICP; causes nausea and vomiting; does not trigger malignant hyperthermia; lowest potency—must be combined with other agents to achieve appropriate anesthetic depth

Neuromuscular blocking drugs

Drug	Class	Onset (s)	Duration of action (min)	Drug-specific side effects and considerations
Succinylcholine	Depolarizing	30–60	4–6	Risk of hyperkalemia, malignant hyperthermia
Rocuronium	Nondepolarizing, aminosteroid	60–120	30–60	Suitable for rapid sequence intubation with doses of 1.2 mg/kg; reversible with acetylcholinesterase inhibitors or sugammadex; can induce allergic reaction
Vecuronium	Nondepolarizing, aminosteroid	120–180	25–40	Reversible with acetylcholinesterase inhibitors or sugammadex
Cisatracurium	Nondepolarizing, benzylisoquinolinium	120–180	30–60	Elimination independent of renal or hepatic function; reversible with acetylcholinesterase inhibitors, but not with sugammadex

[a]Potency is a function of blood solubility of inhaled anesthetics and is inversely related to onset and elimination time.

BP, blood pressure; CBF, cerebral blood flow; CNS, central nervous system; CVP, central venous pressure; HR, heart rate; ICP, intracranial pressure; ICU, intensive care unit; MAP, mean arterial pressure; NMDA, *N*-methyl-D-aspartate; PNB, peripheral nerve block; QTc, corrected QT interval; SVR, systemic vascular resistance.

and clonidine), antihistamines (eg, diphenhydramine), and antidopaminergic medications (eg, haloperidol). However, their pharmacokinetic and pharmacodynamic properties differ from benzodiazepines and are less commonly used as anxiolytics in the preoperative setting.

ANALGESIA

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[34] Naturally, trauma patients often present with significant pain from tissue injury and inflammation, which is accompanied by increased sympathetic nervous system activity, reflexive movement, and emotional distress. Additional discomfort may result from comprehensive physical examination and invasive procedures (eg, supine positioning on hard backboard, vascular access, tube thoracostomy, injury assessment, fracture reduction, traction pin

TABLE 20-4: Overview of Anesthetic Goals

Goal	Nonpharmacologic tools or coexisting conditions affecting goal	Pharmacotherapy
Anxiolysis	• Calm demeanor • Empathetic listening • Explanations • Set expectations • Reassurance • Distraction, positive imagery • Attend to comfort (warm blankets, positioning, cover exposed areas)	• Benzodiazepines: midazolam, diazepam, lorazepam (and antagonism with flumazenil) • α_2-Agonists: dexmedetomidine, clonidine • Antihistamines: diphenhydramine • Antidopaminergics: droperidol, haloperidol • Anesthetic induction agents at low dose (eg, low-dose propofol infusion, low-dose ketamine) • Nitrous oxide
Analgesia	• Attend to comfort (especially positioning) • Set expectations; acknowledge expected degree of pain from injury or planned intervention • Homeopathic techniques • Ice • Distracting stimulus • Coexisting nerve injury or spinal cord injury may alter patient's perception of tissue injury	*Systemically administered drugs* • Acetaminophen • Nonsteroidal anti-inflammatory drugs (NSAIDs) • Steroids • Mu-opioid agonists (morphine, hydromorphone, fentanyl, alfentanil, sufentanil, remifentanil, meperidine, methadone, oxycodone, hydrocodone) (and antagonism with naloxone) • NMDA antagonists (ketamine, methadone) • Nitrous oxide *Local anesthetics* • Ester class (eg, procaine, chloroprocaine, tetracaine, benzocaine) • Amide class (eg, lidocaine, bupivacaine, mepivacaine, ropivacaine, levobupivacaine) *Location of local anesthetic deposition:* • Topical (mucosa or skin) • Infiltration/field block • Regional block (particular nerve or plexus) • Neuraxial block (epidural or spinal [subarachnoid])
Amnesia/ hypnosis	• Distraction • Traumatic brain injury may affect doses of agents needed to attain amnesia/hypnosis	Amnesia, potentially without hypnosis: benzodiazepines (especially midazolam), propofol (especially low dose) Sedation, potentially without amnesia: α_2-agonists (eg, dexmedetomidine) Hypnosis (impairment/loss of consciousness, generally accompanied by amnesia at anesthetic doses): • IV anesthetic agents: propofol, thiopental, methohexital, etomidate, ketamine, benzodiazepines (high dose) • Inhaled anesthetics: nitrous oxide, halothane, isoflurane, sevoflurane, desflurane

Immobility	• Verbal cues: "hold still"
	• Physical restraint
	• Attend to comfort (see above)
	• Coexisting nerve injury or spinal cord injury may impair neuromuscular function distal to injury
		• Deep anesthesia from any agent or combination (intravenous or inhaled anesthetics)
		• Opioids: sufficient doses suppress movement in response to noxious stimulus
		• Regional anesthesia with motor block
		• Neuromuscular blocking drugs
		  • Depolarizing class: succinylcholine
		  • Nondepolarizing class: vecuronium, rocuronium, atracurium, cisatracurium, pancuronium
		  • Reversal agents:
		  • For depolarizing class: none
		  • For nondepolarizing class: acetylcholinesterase inhibitors (neostigmine, edrophonium)
		  • For rocuronium and vecuronium: sugammadex

(*continued*)

TABLE 20-4: Overview of Anesthetic Goals (*Continued*)

Goal	Nonpharmacologic tools or coexisting conditions affecting goal	Pharmacotherapy
Resuscitation: monitor and maintain safe physiology and mitigate drug side effects	*Monitors* Noninvasive: visual inspection, palpation of pulse, auscultation of heart/lung sounds, blood pressure cuff, pulse oximetry, electrocardiogram, temperature, airway pressure, end-tidal gas (oxygen, carbon dioxide, anesthetic vapor), muscle paralysis, bispectral depth of anesthesia monitoring, point-of-care ultrasound (eg, color flow Doppler, lung scanning, transthoracic echocardiography), estimated blood loss Invasive: oral/nasal airways, tracheal intubation, arterial blood pressure, central venous pressure, cardiac output monitoring, transesophageal echocardiography, intracranial pressure, cerebrospinal fluid drains, urinary catheters *Therapies* Suction, active warming devices (air and fluid based), position changes (eg, reverse Trendelenburg for high intracranial pressure), DC cardioversion or pacing, pump oxygenators, vascular occlusion balloons, one-lung ventilation	*Resuscitation and optimization of oxygen delivery to end organs* • Oxygen • Fluid therapy: crystalloids, colloids, blood components • Vasoactive and inotropic drugs: direct- and indirect-acting agonists and antagonists of α_1, α_2, β_1, β_2, vasopressin receptors • Bronchodilators: antimuscarinics, β_2-agonists, steroids, epinephrine, inhaled anesthetics (except nitrous oxide) • Pulmonary vascular resistance: inhaled nitric oxide, prostaglandins *Optimization of cerebral oxygen delivery (especially with presence of intracranial hypertension)* • Hemodynamic regulation as above • Osmotic agents, loop diuretics (controversial; see Chapter 22) (in addition to nonpharmacologic approaches) • Anticonvulsants *Infection prophylaxis* • Euglycemia (insulin and dextrose) • Prophylactic and therapeutic antibiotics *Side effect treatment and prophylaxis* • Allergy: antihistamines (H_1 and H_2), epinephrine, steroids • Nausea: antidopaminergics, 5-HT_3 antagonists, antimuscarinic (transdermal scopolamine), steroids • Antiarrhythmics *Management of physiology with resuscitative endovascular balloon occlusion of the aorta (REBOA)* *Advanced Cardiac Life Support management* *Participation in emergency preservation and resuscitation (EPR) protocols*

DC, direct current; NMDA, *N*-methyl-D-aspartate.

applications, endotracheal intubation, surgery). Beyond the obvious benefits of improving patient comfort and distress, early treatment of pain may facilitate physical examination and therapeutic interventions and diminish the need for levels of sedation that could further impair physiology.

However, not all pain is physiologic. Complex psychological and behavioral factors, as well as past experiences and tolerances of prescribed or illicit analgesics, will alter a patient's reaction to painful stimuli, thereby requiring strategic assessment and treatment plans. Analgesic approaches should not only interrupt the transmission of noxious stimuli to the central nervous system, but also address the patient's physiologic and emotional experience of that nociception. Similar to anxiolysis, nonpharmacologic means of addressing pain are paramount, especially in the pediatric trauma population.[35] Allowing parents or other close allies of young children at the bedside can reduce stress and decrease painful experiences. Distraction techniques including cognitive interventions (eg, non–procedure-related conversation, music listening, video watching or playing, meditation) and behavioral techniques (eg, breathing exercises, squeezing an object) have all shown benefit.[36-38]

Outside of the operating room and postanesthesia care unit, pain management is generally provided by the surgical service or intensivist, while anesthesiologists manage all intraoperative and immediate postoperative pain needs. To provide continuity of care, information about patient analgesic needs should be shared among providers, and unusual tolerance or sensitivity to traditional medications and doses must be communicated.

Pharmacologically, opioids remain the cornerstone of analgesic treatment for acute trauma patients. They bind to mu, kappa, and delta opioid receptors in the peripheral and central nervous systems, resulting in a decreased response to noxious stimuli. Analgesic efficacy is often rapid and profound. Morphine, fentanyl, remifentanil, alfentanil, sufentanil, hydromorphone, and methadone are among the most common of the opioid class to be administered, and their specific properties, common uses, and considerations for trauma patients are listed in Table 20-3. When prescribing opioids, patients who are chronically dependent on opioids should be provided their prehospital daily doses with additional short- and long-acting analgesics required to treat the added acute pain burden. For acute trauma and surgical pain, a reverse

analgesic ladder, whereby diminishing doses of strong analgesics are prescribed as recovery occurs, is recommended.[39]

However, opioids alone are inadequate to treat pain and are relatively inefficient at managing neuropathic symptoms. They are associated with a long list of common deleterious side effects (eg, nausea, ileus, itching, sedation, dysphoria, respiratory depression), have a ceiling effect, and ironically can lead to the development of hyperalgesia. In the hypovolemic bleeding patient or a patient at high risk of respiratory failure (eg, rib fractures, pulmonary contusion, hemo- or pneumothorax), even small doses can lead to cardiovascular collapse or severe respiratory compromise.

Naloxone produces reliable antagonism of the narcosis and respiratory depression produced by opiate agonists. However, its short duration of action dictates close monitoring should re-narcotization occur due to longer-acting opioids. Furthermore, opioid antagonism requires slow dilute boluses of naloxone because rapid and full reversal of the opioid-induced analgesia can lead to extreme pain and massive sympathetic discharge sufficient to produce cardiac arrest.

More concerning perhaps is the large percentage of patients who survive their injuries but misuse or develop long-term dependence on opioid medications. Attempts to diminish side effects and curb the global opioid epidemic has led to innovative methods to treat pain. Multimodal analgesia by combining differing analgesic drugs and techniques to target a variety of pain receptors is encouraged to synergistically diminish pain scores and side effects at lower drug doses. Nonopioid analgesics, such as acetaminophen, nonsteroidal anti-inflammatory drugs, gabapentinoids, anticonvulsants, serotonin-norepinephrine reuptake inhibitors, ketamine infusions, and local anesthetics for neuraxial or peripheral nerve blockade, for intravenous infusion, or in transdermal patches (lidocaine), are increasingly being used to complement or, at times, replace opioid analgesics. Commonly used local anesthetics are summarized in Table 20-3. Although emerging data demonstrate superior pain relief, decreased opioid consumption, and shorter hospital stays when multimodal analgesia is implemented, more research is needed to determine improvement in long-term functional outcomes and differences in chronic opioid dependence and addiction.[40,41]

HYPNOSIS AND AMNESIA

Primary objectives of sedation or general anesthesia are to provide psychological comfort for the patient via hypnosis (depressed consciousness or sleep) and amnesia. It is physiologically possible to have amnesia without hypnosis (as is observed with the antegrade amnesia midazolam produces in conscious patients) and, conversely, to have hypnosis without amnesia (as can unfortunately happen with light anesthesia resulting in patient awareness). Patients may also present under the impairment of various substances that alter normal neurologic and psychologic function, and these factors are considered when selecting, dosing, and monitoring the effects of hypnotic drugs. Sedation may be achieved via multiple possible agents. The previously discussed classes of benzodiazepines and opioids produce sedative effects at higher than amnestic and analgesic doses, respectively, but are rarely used in isolation for these purposes in the operating room.

The most commonly used intravenous agents for sedation or induction of general anesthesia in trauma patients are propofol, etomidate, and ketamine (Table 20-3). Propofol is a lipid-soluble compound that, when administered as a bolus dose, is short lived. Significant dose reduction is critical when propofol is administered to patients with hypovolemia or shock or in patients of advanced age or frailty.[33] Etomidate is an imidazole-containing intravenous anesthetic that, unlike propofol, will induce sedation with relatively minimal hemodynamic side effects. Due to the favorable hemodynamic profile, etomidate would appear to be the ideal drug to provide safe and effective sedation in critically ill trauma patients. However, etomidate possesses intrinsic activity that inhibits 11β-hydroxylase in the synthesis of cortisol and therefore results in cortisol insufficiency. Previous retrospective investigations have noted that administration of etomidate to critically injured trauma patients is associated with acute respiratory distress syndrome.[42] A small, single-center, prospective study also demonstrated that etomidate caused an immediate decrease in cortisol levels in trauma patients and that patients who received etomidate required longer ICU and hospital lengths of stay.[43] Ketamine is a water-soluble compound with a mechanism of action that is related to its antagonism of the *N*-methyl-D-aspartate (NMDA) receptor and, as such, can also provide analgesia. Due to its neuropsychological stimulant property, ketamine was historically contraindicated in patients with TBI. However, evidence suggests that ketamine may be safely used with propofol as a total intravenous anesthetic in patients with TBI.[44] Although ketamine possesses direct negative inotropic effects, these are usually superseded by its sympathomimetic activity, often resulting in tachycardia and hypertension. This property of ketamine makes it an attractive option for administration in the hypovolemic, hypotensive trauma patient who requires immediate sedation and control of cardiorespiratory function. However, caution is advised not to ignore ongoing hemorrhage and hypovolemia in the setting of a pharmacologically induced elevation in blood pressure. In addition to the generally favorable hemodynamic profile, ketamine is a potent bronchodilator and is useful in patients with reactive airway disease.

Most trauma patients are anesthetically induced with intravenous medications, as described earlier. However, in pediatric trauma patients or patients with difficult airways, anesthetic gases may be administered to anesthetize a spontaneously breathing patient prior to advanced airway management techniques. Following induction, maintenance of general anesthesia is often sustained with inhaled gases, administration of intravenous drugs, or a combination thereof. Modern inhaled anesthetic agents, summarized in Table 20-3, exert a dose-dependent suppression of consciousness, memory formation, and movement. Apart from nitrous oxide (N_2O), this class consists of nonflammable halogenated ethers delivered by agent-specific vaporizers. Despite decades of research and over 150 years of clinical use,

the exact mechanism of inhaled anesthetics' action remains unknown.[45] Advantages of this drug class include a long history of safety, familiarity with the pharmacodynamics, and the convenience of rapid titration and monitoring of inspired and expired gas concentrations. The primary disadvantage is the degree of vasodilation that accompanies clinical doses of inhaled anesthetics. Hypotension and end-organ hypoperfusion are significant risks and can exacerbate shock in hypovolemic trauma patients. Dosing should be adjusted to promote optimal organ perfusion and oxygen delivery and often requires concurrent administration of vasoactive infusions, intravenous fluids, blood products, and supplemental intravenous anesthetic and analgesic agents.

IMMOBILITY

Most tracheal intubations and surgical operations require a patient to be immobile, both for safety and to facilitate operative progress. Multiple methods prevent movement, with neuromuscular blocking drugs being the most frequent drug class employed. Movement is also suppressed by deep anesthesia with any anesthetic agent and by use of systemic analgesics and local anesthetics to blunt the physiologic response to noxious stimuli. Regional anesthesia techniques that block motor nerves can also be of utility in preventing movement in particular muscle groups.

Neuromuscular blocking agents are classified into two broad categories: depolarizing (eg, succinylcholine) and nondepolarizing (eg, rocuronium). These are summarized in Table 20-3. Neither class produces any analgesic or sedative effects. Succinylcholine structurally consists of two linked acetylcholine molecules and binds to nicotinic acetylcholine receptors to cause rapid muscle depolarization. Generalized muscle fasciculations manifest within 30 to 60 seconds after an intubating dose, with subsequent flaccid paralysis lasting about 5 minutes. Succinylcholine transiently increases intraocular pressure and is contraindicated in patients with an open globe injury. Similarly, because succinylcholine may briefly increase ICP, questions can be raised about its safety in acute TBI. However, inadequately paralyzed patients may cough or be difficult to intubate, potentially leading to hypoxia, with either condition causing significant increases in ICP. Given these considerations, succinylcholine remains a reasonable option in rapid sequence intubation induction for TBI patients.

Nondepolarizing agents, such as rocuronium, vecuronium, and cisatracurium, competitively bind the acetylcholine receptors at the motor endplate and inhibit depolarization. Thus, no muscle fasciculations occur. Rocuronium achieves rapid and effective intubating conditions within 60 to 90 seconds, but given its slow metabolism, intubating doses may last as long as 1 hour. Vecuronium and cisatracurium have a slower onset, not suitable for rapid intubation. Cisatracurium, due to its elimination being independent of renal or hepatic dysfunction, is most commonly selected in patients with renal failure or as a continuous infusion in the ICU to achieve chemical paralysis in some patients with acute respiratory distress syndrome.[46]

Prior to extubation, patients must demonstrate appropriate neuromuscular function for adequate ventilation and airway protection. Whereas succinylcholine is rapidly metabolized and diaphragm strength returns within minutes, nondepolarizing neuromuscular blockers often require pharmacologic antagonism with acetylcholinesterase inhibitors (eg, neostigmine) or selective relaxant binding agents (eg, sugammadex) to hasten their spontaneous reversal. Acetylcholinesterase inhibitors increase the amount of acetylcholine available at the motor endplate to overcome the nondepolarizing neuromuscular blockers' competitive inhibition of the acetylcholine receptor. Adverse effects relate to parasympathetic activity of acetylcholine at muscarinic receptors, with potential for bradycardia, diarrhea, and bronchorrhea, typically counteracted by coadministration of a muscarinic anticholinergic drug (eg, glycopyrrolate or atropine).

Sugammadex is the first drug in a new class of selective relaxant binding agents; it binds to and irreversibly encapsulates rocuronium and, to a lesser extent, vecuronium, preventing their action at the neuromuscular junction. Sugammadex does not reverse cisatracurium. Sugammadex is especially useful in clinical scenarios where a deep neuromuscular blockade has been induced by rocuronium and rapid antagonism is necessary for prompt recovery of neuromuscular function.[47]

SPECIAL CONSIDERATIONS

Aside from resuscitation and standard anesthesia provisions, there are several unique considerations that may demand added attention and anesthetic modifications in the acute trauma patient. Detailed management of these concerns is found in other chapters of this text; however, given the anesthesiologist's role in leading the critical care efforts in the operating room, the surgical practitioner should be aware of several circumstances that may impact surgical planning and care.

Acute trauma patients are considered "full stomach," and therefore, rapid sequence induction and intubation is necessary when definitive control of the airway is indicated.[48] In the event of a traumatic or difficult airway or cervical spine injury with developing prevertebral edema, anesthesiology should request for surgical airway standby at the bedside and have the appropriate equipment and resources to secure the airway quickly and safely. Brief discussion should ensue between the anesthesiologist and surgeon to review the expected roles and action necessary should an immediate surgical airway be needed. Thoracic injuries that require a thoracotomy for hemothorax or repair of lung injury or intercostal vessels may benefit from one-lung ventilation to improve surgical exposure and definitive hemorrhage control. Decision to insert a large double-lumen endotracheal tube (ETT), to insert a single-lumen ETT and place a bronchial blocker, or to advance a single-lumen ETT to a particular bronchus will depend on the patient's airway assessment, the skill set and experience of the anesthesiologist, and the ability of the patient to tolerate one-lung ventilation. With various factors increasing ventilation-perfusion mismatch in these patients, modifications of one-lung ventilation may be intermittently required to avoid significant hypoxia and hypoventilation. Modifications include increasing the fraction of inspired

oxygen, endotracheal suctioning, confirmation of tube position with fiberoptic bronchoscopy, increasing positive end-expiratory pressure to the ventilated lung, adding continuous positive airway pressure to the nonventilated lung, and occasionally reinstitution of double-lung ventilation. Communication between the operative surgeon and anesthesiologist is critical to balance the need to visualize and address bleeding and injury with the requirement to maintain adequate oxygen saturation and carbon dioxide levels.

In patients who incur TBI, intraoperative management of elevated ICP may necessitate elevation of the head of the bed, hyperosmotic infusions, coagulopathy treatment, and a targeted cerebral perfusion pressure between 60 and 70 mm Hg. Indications of clinically intractable increases in ICP should be communicated to the surgeon with consideration of additional measures (eg, craniectomy, decompressive laparotomy) and termination of non–life-threatening procedures.[49] Primary brain surgery or other head and neck surgery may be best performed with the patient's head and airway positioned away from the anesthesiologist and anesthesia machine. Taking the necessary time to organize and secure connections of an extended breathing circuit, ensure access to intravenous lines, and be able to administer vasoactive and blood products is critical and can be lifesaving. Similarly, prone positioning for spinal surgery requires a coordinated effort for securing the airway (suturing the ETT to the teeth or lip) and intravascular lines, flipping the patient without dislodging or malpositioning life support devices, reapplying monitors quickly, and having the ability throughout the operation to rapidly flip back supine onto a nearby bed in situations of a lost airway or significant cardiovascular instability or arrest. Prone position is also associated with postoperative visual loss, and the anesthesiologist must be vigilant of factors that are associated with increased risk, such as large blood loss, hypotension, large-volume crystalloid resuscitation, and prolonged anesthetic time.[50]

Spinal surgeries that call for particular neurologic monitoring may indicate specific anesthetics. Motor evoked potentials require that a patient not receive intermediate- or long-acting neuromuscular blockade to evaluate central nervous system motor function intraoperatively. The maintenance anesthetic should rely primarily on an intravenous technique that does not alter the amplitude and latency of neurologic monitoring signals. Somatosensory evoked potentials that measure activity in the cerebral cortex will afford the administration of full neuromuscular blockade and volatile anesthetics.

Pediatric and geriatric trauma patients possess substantial deviations from what is considered "normal adult" cardiovascular, pulmonary, hepatic, and renal physiology. They may respond to volume depletion with precipitate hypotension, apnea is poorly tolerated, and drug clearance may be unpredictable (it is generally reduced) in the presence of immature or senescent hepatorenal function. They share an inability to maintain normal body temperature under conditions of stress, and an impressive coagulopathy may develop in the presence of hypothermia and bleeding. With profound differences in physiology, anesthetic tolerance, and equipment needed for pediatric trauma patients, anesthesiologists who routinely care for adults should seek assistance from their pediatric anesthesiology–trained colleagues when caring for injured children.

POSTOPERATIVE MANAGEMENT

The acute postoperative management of the trauma patient is extremely variable due to many factors. Analogous to successful discharge planning beginning on admission, anticipating postoperative needs should begin in the preoperative and intraoperative phases. In fact, consideration of postoperative care may dictate modifications to preoperative and intraoperative management. For example, intraoperative management of spinal injuries may necessitate placement of arterial and central venous catheters to ensure adequate MAPs during surgery and postoperatively.[24] Multiple rib fractures or limb salvage surgery should suggest consideration of a regional anesthesia technique to potentially favor early extubation and decrease opioid requirements. In austere environments, valuable resource utilization both intra- and postoperatively may champion nerve blocks as the surgical anesthetic of choice.

When transitioning out of the operating room, the evolutionary nature of traumatic injury and changing patient needs warrant frequent discussion between trauma and anesthesia providers. Dynamic modifications are required to enable unimpeded flow and optimized management for the next phase of care.[51] Factors considered include the severity of injury, expected resources needed for continued fluid/blood management and pharmacotherapy to meet target resuscitative end points, the nature of the surgery performed, monitoring needs for early detection and immediate treatment of potential complications or decompensation, cardiovascular and pulmonary support, plan for repeat surgical procedure, ability to protect airway, postoperative pain management, and, at times, availability of beds.

Planning disposition from the operating room requires differentiating patients who are suitable for a controlled extubation and emergence with transfer to the postanesthesia care unit from those who need further intervention in an angiography suite, and still others who need to complete the formal trauma evaluation and receive ongoing aggressive resuscitation in a multitrauma ICU or transfer to a higher care facility. Maintaining resuscitative activities during transport to the next point of care is a key responsibility. In addition, as for any postanesthesia patient, the anesthesiologist manages any immediate postoperative complications and leads the formulation of pain management plans. Strong coordination and protocol-driven hand-off communication during transfer of care are essential to ensure the safe and effective transition from the intraoperative to postoperative phase.[52]

Acute Pain Management

Postinjury and postsurgical pain management can vary significantly from no analgesic requirements to indications for a complex multimodal pain management regimen with

continuous neuraxial or peripheral nerve blockade. Adequate pain management following trauma is an important component of healing and recovery. Undertreated pain is a source of unnecessary human suffering and anxiety and can cause acute alterations in the immune response, coagulation cascade, and patient vital signs with potentially damaging consequences in an already compromised trauma patient.[53] If left untreated, acute trauma pain can lead to the development of debilitating posttraumatic pain syndromes.[54] While opioids remain a large component of acute pain management, there has been a concerted effort to decrease reliance on these drugs due to the global opioid epidemic and its deleterious side effects.[55] Moreover, many of these drugs have limited effectiveness due to preinjury substance dependence and tolerance even at high doses. Multimodal analgesic plans with limited opioids are favored especially in high-dose opioid-tolerant patients and in those who experience profound clinical side effects from narcotics. Intravenous ketamine and lidocaine infusions often infused intraoperatively can be continued in analgesic doses postoperatively. Combining acetaminophen, nonsteroidal anti-inflammatories, gabapentinoids, muscle relaxants, antidepressants, anxiolytics, and regional anesthesia techniques, when appropriate, provides the best pain relief and decreases the risk of side effects and addictive-forming behavior.[41] Enhanced recovery after surgery (ERAS) protocols have assisted in standardizing these multimodal methodologies.[56]

Over the past few decades, dedicated regional anesthesia and acute pain medicine (RAAPM) services have proliferated and should be sought to provide an increasing array of analgesic options. Whereas most anesthesiologists are trained in spinal and epidural blocks, RAAPM physicians are skilled in many additional single-shot and continuous catheter techniques that allow for significantly improved pain scores and possibly improved functional outcomes. Mild analgesia to dense anesthesia can be accomplished with the administration of local anesthetics (Table 20-3) on spinal, epidural, and peripheral nerves. Amino amides such as lidocaine, mepivacaine, ropivacaine, levobupivacaine, and bupivacaine all provide sodium channel blockade and inhibit action potentials of afferent nerves with varied clinical results due to their different physiochemical and pharmacodynamic properties. Caution must be taken to limit cumulative local anesthetic administration to below toxic doses because local anesthetic systemic toxicity (LAST) can lead to profound neurologic symptoms and fatal cardiovascular collapse. In fact, expert opinion advocates for incorporating the maximum allowed dose of local anesthetic during the surgical time-out to prevent overdose by multiple provider administration.[57] Accessibility to intravenous intralipid to treat LAST is necessary wherever local anesthetics are routinely used.

The implementation of safe and effective regional anesthesia techniques in trauma patients has gained momentum due to the growing knowledge and training of ultrasound-guided techniques.[29] For various approaches to the brachial plexus for upper extremity blocks, blockade of branches of the lumbosacral plexus (most notably the femoral and sciatic nerves) for the lower extremity, and many recently described interfascial plane blocks (pectoralis I, pectoralis II, serratus anterior muscle plane, erector spinae, rectus abdominis, transversus abdominis plane, quadratus lumborum) that target thoracic, abdominal, and pelvic pain, several reports of these procedures show significant benefits in the trauma population.[58,59] Aside from superior analgesia and improved patient satisfaction scores, regional techniques in the acute trauma patient have shown benefits in reducing the incidence and severity of chronic pain syndromes, decreasing side effects from other modalities, and possibly improving surgical outcomes in vascular injuries and repair via sympathetic blockade, and earlier discharge and facilitation of transport.[60-62] Although a full discussion of the risks, benefits, indications, and contraindications of regional anesthesia procedures is beyond the scope of this chapter, there are some unique conditions in trauma patients worth mentioning.

Multiple Rib Fractures

Multiple rib fractures can induce significant pain and impair pulmonary function with resultant risks of pneumonia, acute respiratory failure, chronic pain, and disability. Thoracic epidural analgesia, once considered the gold standard, has not demonstrated definitive mortality benefit, decreased length of stay in the ICU or hospital, or a decrease in ventilator days in large meta-analyses.[63] Nonetheless, it remains commonly practiced to decrease pain scores and provide improved patient satisfaction. Treatment plans for patients with epidurals require attention to hypotension from the sympathectomy-induced vasodilation and modification in thromboprophylaxis schedules to decrease the risk of an iatrogenic epidural hematoma. Alternative techniques include thoracic paravertebral, intrapleural, or intercostal blocks as well as novel fascial plane blocks (serratus anterior plane and erector spinae plane blocks), which may offer comparable benefits with fewer side effects. However, large prospective studies are still lacking. For best results, multidisciplinary protocols with strategical clinical pathways and a multimodal approach are strongly advised to improve outcomes and limit complications.[64]

Compartment Syndrome

Some injury patterns (high-energy musculoskeletal or vascular injuries) and orthopedic repairs (eg, tibial plateau or radial fracture repairs) can cause immense pain but also risk development of an acute compartment syndrome (ACS) with potentially devastating loss of function or limb if not detected early and treated emergently. Management of pain in these patients can be challenging as dense analgesia via peripheral or neuraxial blocks or via intravenous opioids carries the potential to mask the first signs of ACS—disproportionate pain and changes in neurologic function. With conflicting arguments as to the value of a comfortable patient with an impaired motor and sensory exam versus a more uncomfortable patient who can rapidly report an increase in pain and/or diminished function, direct communication between

surgeons and anesthesiology should occur with attention to vigilant serial neurologic exams, dilute and short-acting local anesthetic infusions that when paused allow for rapid return of nerve function, and the ability to perform emergent fasciotomies for high-risk patients.

Other reasons to consult the RAAPM service include their expertise with difficult-to-manage pain patients, high-dose opioid titration, transition to oral doses, discharge planning, and weaning schedules. RAAPM specialists can help achieve decreased pain scores and set reasonable functional expectations. Consideration of alternative therapies such as acupressure, acupuncture, music and art therapy, mirror therapy for acute amputees, and relaxation techniques is advisable and can decrease pharmacologic requirements. Unfortunately, posttraumatic and postsurgical pain can continue and sometimes worsen upon discharge. Appropriate counseling and short-interval follow-up will allow for serial evaluation of a patient's pain management needs. If patients require more than 90 mg of oral morphine equivalents a day upon discharge, follow-up with an outpatient pain specialist or perioperative surgical home clinic is recommended and should be scheduled prior to discharge.[65,66]

SUMMARY

The role of the anesthesiologist in trauma care has evolved significantly to function as a resuscitationist with the expertise to tailor a safe anesthetic and analgesic plan in the setting of an altered physiology due to trauma. Comprehensive and often rapid pre-, intra-, and postoperative planning and adaptive care are true hallmarks of trauma anesthesia practice and are paving the way for subspecialty training in trauma and acute care anesthesiology.[67] Direct and ongoing collaborative efforts between anesthesiologists, trauma surgeons, emergency medicine physicians, critical care physicians, and allied members of the trauma team remain the optimal mechanism to provide best practice and improve patient outcomes.

Infections

Heather L. Evans • Eileen Bulger

KEY POINTS

- *Staphylococcus aureus*, the most common pathogen associated with surgical site infections, has numerous virulence factors that facilitate invasion and thwart host defenses.
- Bacterial counts in the proximal gastrointestinal tract are in the range of 10^4 to 10^5 colony-forming units (CFU)/mL, whereas numbers in the terminal ileum (10^8–10^{10} CFU/mL) approach those in the colon (10^{11}–10^{12} CFU/mL).
- When childhood immunizations have not been given and there is a tetanus-prone wound, tetanus toxoid as well as tetanus immune globulin at a separate site should be administered.
- Approximately 25% of soft tissue infections from *Vibrio vulnificus* are caused by direct exposure of an open wound to warm seawater containing the organism.
- Class IV wounds are characterized by pus or extensive and prolonged contamination and had a historic infection rate of 30% if closed primarily.
- When using alcohol-based skin disinfectants in the operating room, it is imperative that the solution be dry prior to incision to lower the risk of an intraoperative fire.
- Acute infections in soft tissue still present with calor (heat), dolor (pain), rubor (redness), tumor (swelling), and loss of function (functio laesa).
- Intra-abdominal infections identified later in the hospital course (>4 days after injury) are more likely to be caused by hospital-associated rather than community-associated organisms.

INTRODUCTION

Death after traumatic injury has been described in terms of a bimodal distribution. Immediate and acute (<24 hours) deaths usually result from uncontrolled hemorrhage, but infections and multiple organ dysfunction syndrome, which often arise from infection, are responsible for a significant proportion of late deaths. Indeed, infection is responsible for most deaths in patients who survive longer than 48 hours after trauma.[1] Trauma-related infections can be divided into those that result directly from the injury (eg, due to contamination that occurs in conjunction with the traumatic injury) and nosocomial infections that arise in the health care setting in conjunction with treatment of the injury. The pathogens involved can be exogenous or endogenous bacteria, depending on the mechanism of injury and/or the iatrogenic cause.

Most posttraumatic infections are polymicrobial, involving a mixture of aerobic and anaerobic organisms.[2] In one series, 37% to 45% of all trauma patients experienced infectious complications during their initial hospitalization.[3] In that same study, 80% of trauma patients who were in the intensive care unit (ICU) at least 7 days met the criteria for the systemic inflammatory response syndrome (SIRS). All caregivers need to understand the principles of surgical infections in the context of traumatic injury. This chapter will review the following: factors that normally prevent infection, how trauma disrupts or overwhelms normal host defenses, recognition and treatment of the most common infectious complications after traumatic injury, principles of infection prevention, and how prophylaxis and prevention principles can be applied chronologically during the treatment of trauma patients.

PATHOGENESIS OF INFECTION

Humans have evolved mechanisms to avoid infection despite the ubiquitous presence of bacteria in our environment and throughout our bodies. A recent review documented the magnitude and diversity of the human microbiota.[4] Under normal circumstances, there is a balance between our microbiota,

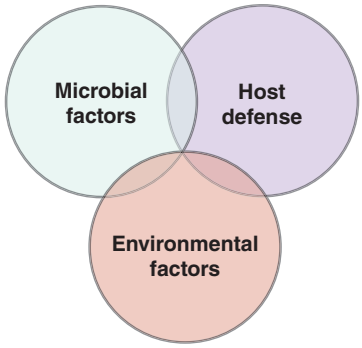

FIGURE 21-1 Under normal circumstances, the determinants of infection, microbial factors, environmental factors, and host defenses interact such that there is no infection. (Adapted with permission from Meakins JL, et al. Host defenses. In: Howard RJ, Simmons RL, eds. *Surgical Infectious Diseases.* 2nd ed. Norwalk, CT: Appleton & Lange; 1988. Copyright © The McGraw-Hill Companies, Inc.)

intact environmental barriers, and host defenses (Fig. 21-1). Invasive surgical procedures or traumatic injury disrupt this balance and significantly increase the probability of developing an infection (Fig. 21-2). Microbes are abundant on the surface of the skin and within the oral cavity and increase in number down the length of the gastrointestinal tract. Bacterial numbers differ at various locations, and the pathogenic species and their respective numbers at different anatomic sites are summarized in Table 21-1. Once inoculation of bacteria into normally sterile sites occurs, infection will ensue if bacteria proliferate faster than the host defense mechanisms eradicate them. Trauma generally results in a much greater disruption of normal barriers than occurs with elective surgery. Trauma may also have concomitant hypoperfusion (shock), devitalized tissue, and retained foreign bodies.

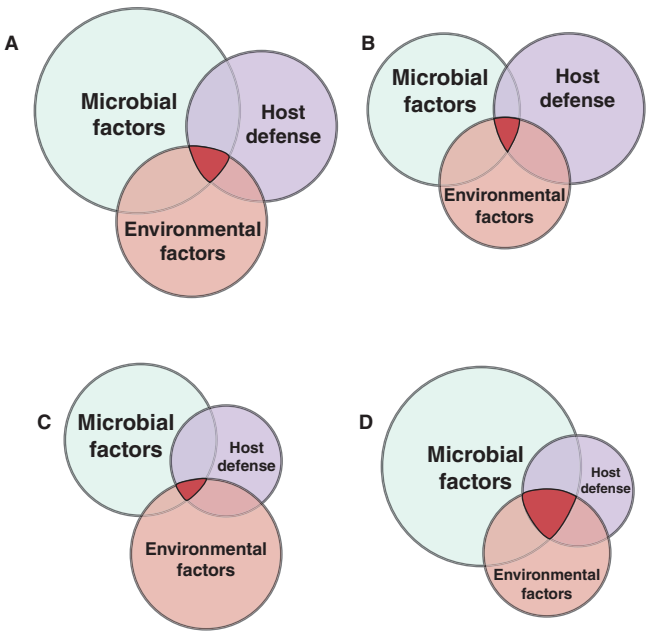

FIGURE 21-2 (**A**) Under circumstances in which there is excessive microbial contamination, (**B**) serious disruption of environmental barrier, (**C**) impaired host defenses, or (**D**) all factors that ensure there will be an increased likelihood of developing infection (shaded intersection of determinants of infection).

TABLE 21-1: Pathogenic Microorganisms Present at Various Anatomic Sites

Region	Microbes	Quantity
Skin (all areas)	*Staphylococcus aureus* and epidermidis *Streptococcus* (nonenterococcal)	10^{2-3}
Skin (infraumbilical)	*Streptococcus faecalis* and *S faecium* *Escherichia coli* *S aureus* and *S epidermidis* *Streptococcus* (nonenterococcal)	10^{2-5}
Oropharynx	*Bacteroides* (nonfragilis) *Fusobacterium* *Haemophilus* *Peptostreptococcus* *S aureus* and *S epidermidis* *Streptococcus* (nonenterococcal)	10^{9-11}
Stomach	*Streptococcus* (nonenterococcal) *Candida*	10^{2-3}
Proximal small intestine	*Bacteroides fragilis* and other *Escherichia coli* and other Enterobacteriaceae	10^{3-7}
Distal ileum and Colon	*Bacteroides fragilis* and other spp. *E coli* and other Enterobacteriaceae *Streptococcus faecalis* and *S faecium*	10^{5-10}

Environmental Barriers

Entry of microbes is normally limited by the integrity of environmental barriers, such as intact skin and the mucosa of the respiratory, gastrointestinal, and genitourinary tracts. The importance of intact skin is clearly evident when one considers the potential for microbial infection seen in burn patients or in patients with toxic epidermal necrolysis.[2] Many traumatic injuries are associated with an alteration in the integrity of the skin. Even minor lacerations and abrasions have the potential to disrupt crucial environmental barriers. Interventions made in the process of caring for trauma patients, such as insertion of intravenous or urinary catheters or tube thoracostomy, likewise disrupt the integument and may permit skin bacteria to access sterile sites. The quantitative number of microbes required to produce clinical infection is significantly decreased in the presence of foreign bodies, blood, or devitalized tissue, which are often present with traumatic wounds.[2]

Microbial Factors

The bacteria species responsible for clinical infections in surgical or trauma patients constitute a minority of the skin or gastrointestinal flora. These pathogenic bacterial species generally possess one or more virulence factors that facilitate infection and increase their pathogenicity. In contrast, the vast majority of endogenous and environmental bacteria are relatively nonpathogenic. For example, more than 99% of the colonic microbiota are nonpathogenic anaerobes that never cause clinical infections. Lactobacilli, which do not cause clinical infection, are the most abundant skin bacteria. In contrast, the most common pathogen associated with surgical site infections (SSI), *Staphylococcus aureus*, has numerous virulence factors that facilitate invasion and thwart host defenses. In the abdominal cavity, *Escherichia coli* and *Bacteroides fragilis* are the prototypical organisms associated with intra-abdominal infection, yet they account for only 0.01% and 1% of colonic bacteria, respectively. Under normal circumstances, the overwhelming numbers of nonpathogenic bacteria constitute a robust "defense" against infection, because infection is proportionately less likely if more than 99% of the inoculum is incapable of producing infection. This concept of adherent resident bacteria preventing invasion has been termed *colonization resistance*.[5] This is an important point because the skin and gastrointestinal microbial flora change considerably when trauma patients are hospitalized, both in terms of number and proportion of virulent bacteria and in terms of susceptibility to antibiotics, should an infection develop.

The skin microflora is relatively homogeneous, although bacterial numbers are higher in the axilla and groin areas. The endogenous skin bacteria are predominately gram-positive aerobic *Staphylococcus* and *Streptococcus* species, along with *Corynebacterium* and *Propionibacterium*.[5] As noted earlier, *S aureus* is the most common pathogen present on the skin, but increasingly isolates from trauma patients and those with community-acquired infections are methicillin-resistant *S aureus* (MRSA).[6,7] This fact needs to be taken into account in terms of appropriate empiric or prophylactic antibiotic selection for these patients.

The mouth and nasopharynx harbor large numbers of bacteria, most frequently streptococcal species. Much smaller numbers of bacteria, typically 10^2 to 10^3 colony-forming units (CFU)/mL, are present in the normal stomach because the normal acid pH of the stomach inhibits bacterial growth. Gastric bacterial numbers increase in the absence of gastric acid, as in patients receiving proton pump inhibitors. Bacterial numbers are much higher in the small intestine, and the density of bacteria increases from the duodenum to the terminal ileum. Bacterial counts in the proximal gastrointestinal tract are in the range of 10^4 to 10^5 CFU/mL, whereas numbers in the terminal ileum are close to colonic densities (10^8–10^{10} CFU/mL). Bacterial numbers in the colon are even higher (10^{11}–10^{12} CFU/mL), although most colonic bacteria are nonpathogenic. The presence of such large numbers is associated with very low oxygen tension, and 99.9% of bacteria present are anaerobes. The urogenital, biliary, pancreatic ductal, and distal respiratory tracts are "sterile" in healthy individuals.

Host Defense Mechanisms

Host defense refers to endogenous factors that counteract microbial invasion. In addition to the environmental factors and colonization resistance described earlier, crucial humoral and cellular host defense mechanisms exist that eliminate bacteria within sterile spaces. Initially, several primitive and relatively nonspecific host defenses, including proteins such as lactoferrin, fibrinogen, and complement, begin to act against invading microbes. Lactoferrin sequesters the critical microbial growth factor iron, thereby limiting microbial growth. Fibrinogen within the inflammatory fluid has the ability to trap large numbers of microbes during polymerization into fibrin.[5] Complement is activated on contact with bacteria and viruses, from tissue damage, or when IgG/IgM antibodies recognize microbial agents. Activation of complement releases C3a and C5a, which are potent chemotaxins that recruit neutrophils and macrophages. These components enhance endothelial adhesiveness and increase vascular permeability. Complement activation can directly destroy microbial agents via formation of a membrane attack complex (composed of complement proteins C5–C9) and enhance microbial phagocytosis by way of C1q and C3bi subunits. In vitro studies have shown that 50% to 70% of a moderate inoculum is eliminated *prior to* the influx of phagocytic host cells.

Many different tissues also contain resident innate immune cells. These include macrophages, dendritic cells, Kupffer cells, glial cells, mesangial cells, and alveolar macrophages.[8] These innate immune cells express a wide variety of pathogen-associated molecular pattern (PAMP) receptors on their surface.[9-11] The best known examples of PAMPs are the toll-like receptors (TLRs), of which there are now many well-described receptor molecules.[11] TLRs bind to ligands on bacteria (or damaged host tissue), and TLR binding results in activation of these cells. Activated macrophages secrete an array of substances in response, leading to amplification and regulation of the acute proinflammatory response (Fig. 21-3). Sequential release of protein cytokines, including tumor necrosis factor-α (TNF-α), interleukin (IL)-1, IL-6, IL-8, and interferon-γ (INF-γ), follows. These mediators produce the signs and symptoms that are associated with infection (eg, fever, tachycardia, tachypnea, leukocytosis). IL-8 is a very potent chemoattractant for neutrophils, the innate immune cells primarily responsible for ongoing microbial phagocytosis and intracellular microbial killing. Unfortunately, the same process that recruits neutrophils and stimulates phagocytosis and oxidative killing may also contribute to damage of host tissues. Simultaneous with this proinflammatory response, there is also production of anti-inflammatory mediators, such as IL-10 and transforming growth factor-β (TGFβ).[12] Some of these mediators may contribute to the immune "hyporesponsiveness of trauma" over the ensuing days (Table 21-2).[13]

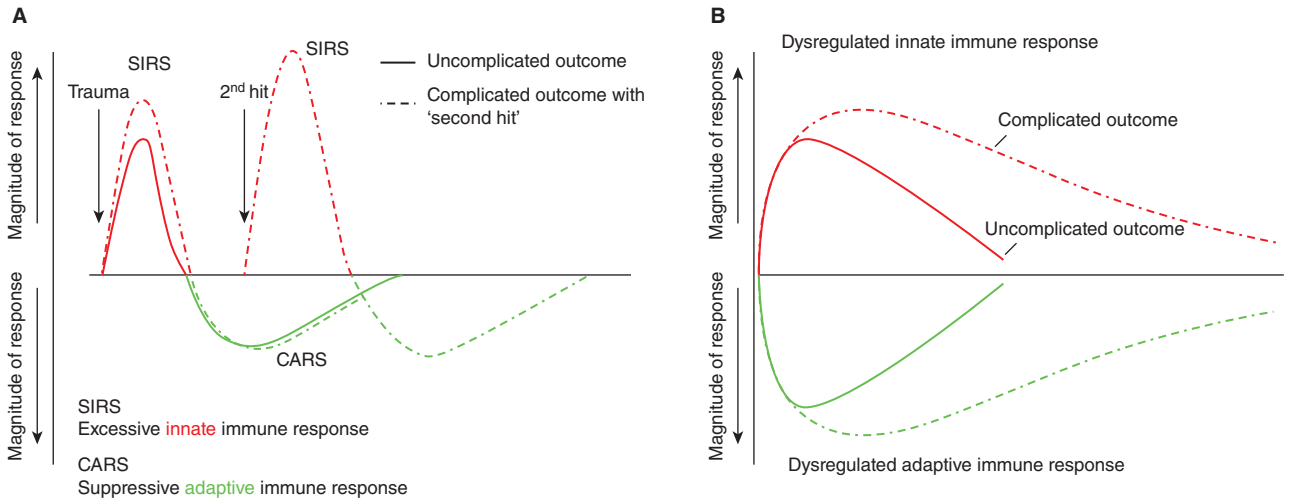

FIGURE 21-3 Schematic depiction of a refined paradigm for pro- and anti-inflammatory responses after trauma or inflammation based on empirically observed alterations in gene expression after injury. (**A**) The previous paradigm had invoked an initial proinflammatory response followed by an anti-inflammatory response. (**B**) The updated paradigm demonstrates that both pro- and anti-inflammatory responses take place simultaneously, beginning at the time of the initial injury or insult. Patients who go on to develop complications and multiple organ dysfunction syndrome (MODS) have a different temporal response, with prolongation of both responses, but they do not have qualitative or fundamental differences in the nature of the inflammatory responses. CARS, compensatory anti-inflammatory response syndrome; SIRS, systemic inflammatory response syndrome. (Reproduced, with permission, from Xiao W, Mindrinos MN, Seok J, et al. Genomic storm. *J Exp Med.* 2011;208(13):2581-2590.)

TABLE 21-2: Immunologic Defects Associated with Traumatic Injuries

Type of cell and action	Change from normal
T and B lymphocytes	
CD4+/CD8+ ratio	Decreased
TGF-β production	Increased
Th17 phenotype	Increased
Immunosuppressive T_{reg} phenotype	Increased
Monocytes/macrophages	
Immunocompetent activation	Decreased
HLA-DR expression	Decreased
Antigen-presenting capability	Decreased
PGE_2 production	Increased
IL-12 production	Decreased
IFN-γ release	Decreased
Common characteristics of T cells and monocytes	
Proportion of Th2 phenotype	Increased
Trauma-induced apoptosis	Increased
Polymorphonuclear neutrophils (PMN)	
Chemotaxis	Decreased
Phagocytic capacity	Decreased
Release of elastase	Increased
O_2 radical release	Increased
β-Integrin expression	Decreased
Leukotriene B_4 production	Decreased
Apoptosis	Delayed

IFN, interferon; IL, interleukin; TGF, transforming growth factor.

Specific anatomic locations have additional unique factors that defend against infection.[14] For example, the peritoneal cavity has lymphatic channels on the undersurface of the diaphragm that facilitate removal of bacteria.[15] The subdiaphragmatic surface is a lower-pressure area due to the effect of respiratory excursion, and this serves to move free fluid within the peritoneal cavity to this location. Movement of the diaphragm "pumps" this fluid into the thoracic duct, and from there, it gains rapid access to the systemic circulation. Experimental studies show that labeled bacteria inoculated into the peritoneal cavity appear in the thoracic duct within 6 minutes and in the bloodstream within 12 minutes.[14] The respiratory tract has unique host defenses that help to ensure the sterility of the lung parenchyma, as well. Goblet cells within the respiratory mucosa secrete mucin that helps to trap bacteria. Ciliated respiratory epithelial cells move the mucus centrally, where it, and the bacteria trapped within it, can be expectorated by coughing. The presence of endotracheal tubes, smoking, inhaled toxins, and some anesthetic agents interfere with mucociliary clearance mechanisms, and this may predispose to pneumonia. Bacteria or other microbes that gain access to the alveoli are normally phagocytized by alveolar macrophages, although the macrophage activation that may accompany this process has been proposed as one possible pathogenic mechanism for acute lung injury or adult respiratory distress syndrome (ARDS).[16-18]

MICROBIOLOGY

To a very large extent, the microbial agents responsible for infections or infectious complications after trauma are the same agents that cause most other surgical or ICU-associated

TABLE 21-3: Intensive Care Unit Pathogens Isolated from Patients with Ventilator-Associated Pneumonia

Organism/Class	% Total
Lactose-fermenting gram-negative bacillus	
Escherichia coli	8.1%
Klebsiella spp.	11.1%
Enterobacter spp.	7.6%
Morganella spp.	0.5%
Citrobacter spp.	1.0%
Serratia spp.	1.5%
Lactose-non-fermenting gram-negative bacillus	
Stenotrophomonas spp.	2.0%
Acinetobacter spp.	8.6%
Pseudomonas spp.	13.6%
Staphylococcus aureus	31.8% total
Methicillin-sensitive	22.2%
Methicillin-resistant	9.6%
Community pathogens	
Streptococcus pneumoniae	2.0%
Haemophilus spp.	3.0%
Other pathogens	
Polymicrobial species	3.0%
Fungus	1.5%

infections. Table 21-1 shows the most common infectious agents that cause trauma-associated infections at various anatomic sites. Generally, *Staphylococcus* spp. and *Streptococcus* spp. are the most common pathogens responsible for infections in which the traumatic injury or operative intervention needed to treat the injury did not transgress a mucosal surface. For traumatic injuries that involve the aerodigestive tract, the most common isolates are *E coli* (43.4%), *S aureus* (18.9%), *Klebsiella pneumoniae* (14.4%), and *Enterococcus faecalis* (5.6%).[1] Hospitalized trauma patients develop nosocomial bacterial infections from the usual ICU-associated pathogens (Table 21-3). A few infectious agents that can be associated with trauma are seldom encountered in other settings including rabies virus, *Clostridium tetani*, and *Vibrio*.

Rabies

Rabies is a rare, potentially fatal, clinical disease caused by the rabies virus. Rabies is an RNA virus present in the saliva of mammals, and transmission to humans generally occurs following a bite from a rabid animal. Prior to the development of a vaccine by Louis Pasteur, bites from a rabid animal were uniformly fatal. In North America, raccoons, skunks, bats, foxes, coyotes, and bobcats are the primary reservoirs. Most patients with rabies have no documented exposure to a rabid animal, and the majority of these are associated with bat bites. Many victims underestimate the importance of a bat bite, and a substantial portion do not even recall being bitten. Bats (Carnivora and Chiroptera) represent the ultimate zoonotic reservoir for the virus. The rabies virus is highly labile and can be inactivated readily by ultraviolet radiation, heat, desiccation, and other environmental factors.

The word *rabies* derives from the Latin *rabere*, meaning "to rage," and refers to the clinical manifestations of the disease that include hyperactivity, disorientation, hallucinations, and bizarre behavior. The rabies virus is neurotropic and causes an acute encephalitis. Other hallmarks of the disease include an intense fear of suffocation (eg, hydrophobia and aerophobia) secondary to intense laryngeal and pharyngeal spasm. Once the patient begins manifesting symptoms, death is nearly certain. With increased vaccination and postexposure prophylaxis (PEP) over the past 50 years, the clinical disease is becoming increasingly uncommon. According to the Centers for Disease Control and Prevention (CDC), 49 cases of human rabies were reported in the United States between 1995 and 2011, with only 3 survivors. That said, it is important for the practitioner of emergency medicine/surgery to be knowledgeable about rabies since animal bites are encountered frequently in clinical practice.

Humans are not routinely vaccinated against rabies, while domestic animals receive routine rabies vaccinations. If a human is bitten by a rabid animal, rabies can be *prevented* by PEP before the virus enters the central nervous system during the incubation period. The diagnosis of rabies can be made rapidly by identification of rabies virus in the brain of a potentially infected animal. This procedure can be performed most expeditiously by euthanizing the suspected animal. If the rabies test is negative, then no postexposure vaccination or prophylaxis is needed. The incidence of positive rabies tests ranges from as high as 6% to 10% in wild animals down to levels of approximately 1% in domestic pets. An acceptable alternative approach, if the suspected source is a domestic pet (eg, dog, cat, ferret), is for the offending animal to be quarantined and observed for 10 days. If the animal exhibits signs of rabies, the exposed person should begin PEP immediately and the animal should be euthanized and its brain tissue tested for rabies. If the animal is confirmed to have rabies, PEP must be completed; however, if the test results are negative, PEP can cease.

Immediate measures that should be taken to decrease the risk of rabies transmission include thorough washing of bite and scratch wounds with soap and water, followed by application of povidone–iodine or alcohol. Human rabies immune globulin (HRIG) and rabies vaccine should be given in all cases except in persons who have been immunized previously.[19] Immune globulin should never be delivered in the same syringe as the vaccine, as this will cause precipitation. The Advisory Committee on Immunization Practices (ACIP) of the CDC and the American Academy of Pediatrics recommend a single dose (20 IU/kg) of HRIG be given to provide protection for the first 2 weeks until the vaccine elicits an antibody response. Detailed and up-to-date information for rabies exposure is available on the CDC's website

(http://www.cdc.gov/rabies/index.html), and this site should be consulted for the latest information. The ACIP recommends a regimen of human diploid cell vaccine (Imovax) for PEP on days 0, 3, 7, 14, and 28, along with a single dose of HRIG on day 0. Once initiated, rabies prophylaxis should not be interrupted or discontinued because of local or mild systemic reactions to the vaccine.

Tetanus

Tetanus is a rare, life-threatening condition that is caused by toxins produced by *Clostridium tetani*, a spore-forming, gram-positive bacillus.[20] Clostridial spores can survive indefinitely, and they are ubiquitous in soil and feces. Under anaerobic conditions, the spores can germinate into mature bacilli that elaborate the neurotoxins tetanospasmin and tetanolysin. Tetanospasmin produces most prominent clinical symptoms by interfering with motor neuron release of the inhibitory neurotransmitters γ-aminobutyric acid (GABA) and glycine. The resulting loss of inhibition produces muscle spasm (usually spasm of the masseter muscle) and severe autonomic overactivity manifested by high fever, tachycardia, and hypertension. Historically, tetanus was highly fatal, but intensive medical therapy with neuromuscular blockade, mechanical ventilation, and ICU monitoring has lowered the case fatality rate to 11% to 28%. According to the CDC, there were a total of 233 tetanus cases reported in the United States between 2001 and 2008, with 71.7% arising from acute trauma. Clinicians and trauma surgeons must remain alert for the potential of clostridial contamination and provide appropriate, timely tetanus prophylaxis.[20]

The diagnosis of tetanus is made on clinical grounds alone, as there are no laboratory tests that can diagnose the condition or rule it out. Tetanus immunization is accomplished as a component of standard early childhood immunizations (diphtheria–pertussis–tetanus), with administration of tetanus toxoid (TT) every 5 to 10 years to maintain immune memory (see http://www.cdc.gov/tetanus/vaccination.html). No deaths have been reported in individuals who have been fully immunized. The CDC recommendations for tetanus prophylaxis depend on the wound characteristics and the prior immunization status of the patient. A wound with extensive contamination, one that is poorly vascularized, or one with extensive soft tissue trauma is considered to be a "tetanus-prone wound." A tetanus booster should be administered to patients who have received primary immunization but who have not received TT during the past 10 years, or the past 5 years for tetanus-prone wounds.[19] In patients who have never undergone primary immunization, human tetanus immune globulin (TIG) should be administered along with TT at a different site. Antitetanus antibody binds to exotoxins and neutralizes their toxicity. High-risk groups such as the elderly, individuals with HIV, and intravenous drug users who had received primary vaccination may not have tetanus antibodies, and more liberal use of TIG should be considered in these groups.[19] If TIG is not available, intravenous immune globulin (IVIG) may be substituted.

Infections Associated with Marine Trauma

Vibrio vulnificus is a gram-negative rod present in seawater that can result in atypical, necrotizing soft tissue infections when traumatic injuries occur in the ocean.[21-23] *V vulnificus* is common in warm seawater and thrives in water temperatures greater than 68°F (20°C). The organism is not associated with pollution or fecal waste. Approximately 25% of *V vulnificus* infections are caused by direct exposure of an open wound to warm seawater containing the organism. Exposure typically occurs when the patient is participating in water activities such as boating, fishing, or swimming. Infections are occasionally attributed to contact with raw seafood or marine wildlife. The risk of developing *Vibrio* infection is much higher in immunocompromised patients or patients with preexisting hepatic disease or diabetes mellitus.[22] Established infection with *V vulnificus* can be highly invasive, with mortality rates of 30% to 40% and a mortality of greater than 50% in immunocompromised patients. A published report from 2009 documented a 37% mortality rate even after implementation of a specific treatment guideline for necrotizing *Vibrio* infections.[21]

Patients with wound infections caused by *V vulnificus* develop painful cellulitis that progresses rapidly.[22-24] Physical examination will often reveal marked swelling and painful, hemorrhagic bullae surrounding traumatic wounds. In some cases, there can be rapid progression and associated systemic symptoms. Marked local tissue swelling with hemorrhagic bullae are characteristic. Systemic symptoms include fever and chills, and bacteria are present in the bloodstream in more than 50% of patients. Hypotension or septic shock may be an early symptom, and alterations in mental status occur in approximately one-third of patients. Table 21-4 summarizes clinical symptoms present in patients with *Vibrio* infection.[23]

TABLE 21-4: Clinical Characteristics Associated with *Vibrio vulnificus* Wound Infections

Characteristic	% of Patients
Cellulitis at wound site	88
Skin bullae	88
Fever (>37.8°C)	65
Chills	29
Ecchymosis	18
Obtundation, disorientation, or lethargy	18
Hypotension (<90 mm Hg)	12
Vomiting	6
Diarrhea	6

Source: Adapted from Klontz KC, Lieb S, Schreiber M, Janowski HT, Baldy LM, Gunn RA. Syndromes of *Vibrio vulnificus* infections. Clinical and epidemiologic features in Florida cases, 1981-1987. *Ann Intern Med.* 1988;109(4):318-323.

It is important for trauma surgeons to be aware of the potential for *Vibrio* infections in the appropriate clinical setting, because antibiotic treatment is distinctly different from the agents typically employed for trauma patients. Aggressive surgical debridement, incision and drainage of purulent collections, and even amputation may be crucial adjuncts for management of these often severe soft tissue infections.[22] Recent experience in 30 patients with documented *Vibrio* infection found that fasciotomy was needed in all patients, and 17% required amputation.[21] Recommended antibiotics include doxycycline (100 mg intravenously or orally twice a day), ceftazidime (2 g every 8 hours), cefotaxime (2 g every 8 hours), or ciprofloxacin (750 mg orally twice a day or 400 mg intravenously every 12 hours).[22,25]

Traumatic injuries that occur in freshwater conditions may develop infections from *Aeromonas hydrophila*.[24] *A hydrophila* is a gram-negative anaerobic rod that is a common pathogen of fish and amphibians. Cutaneous inoculation of the organism can result in cellulitis, abscesses, and, occasionally, necrotizing soft tissue infections. Like the situation with *Vibrio* infections, patients with hepatic disease and immunocompromise have a greater risk of developing generalized disease. *A hydrophila* can be recovered from the bloodstream in a significant proportion of patients, and this fact, along with a history of injury in fresh water, will aid in alerting clinicians to the correct diagnosis. Antibiotic agents active against *A hydrophila* include third-generation cephalosporins, fluoroquinolones, doxycycline, or trimethoprim-sulfamethoxazole.[24]

Ebola Virus Disease

On September 30, 2014, in the midst of the worst Ebola virus disease (EVD) outbreak on record, the CDC confirmed the first documented case of EVD in the United States in Dallas, Texas.[26] Within 2 weeks, a nurse who cared for that initial patient was also diagnosed with the disease. While EVD is not a surgical disease per se, knowledge and skills in resuscitation, critical care, and disaster management may be invaluable in the treatment of EVD. Therefore, all surgeons should be familiar with the fundamentals of EVD management.

TRANSMISSION

Ebola virus is a zoonosis belonging to the *Filoviridae* family. Five species have been identified as follows: *Zaire, Sudan, Ivory Coast, Bundibugyo*, and *Reston*.[27] Ebola is a single-stranded RNA virus that sporadically spreads to humans from a presumptive animal or bat reservoir in the wild. Human spread only occurs through *direct contact with infected bodily fluid*, and the most infectious sources are blood, feces, and vomit.[28] Ebola virus can remain viable on surfaces for 1 to 6 days, although the risk of transmission from a surface contact is considered very low.[29,30] Humans are only contagious while they are symptomatic. Blood from patients with untreated late EVD harbor 10^9 virus particles/mL, making it highly infectious. This value can be compared to the much lower viral loads in patients with untreated HIV (10^5/mL blood) or hepatitis C (5–20 × 10^6/mL blood), both of which are recognized as being highly transmissible.[31] EVD is not an airborne pathogen, but since it can be transmitted via large droplets, health care providers in close contact with symptomatic patients should take necessary droplet precautions (see Prevention).[28]

PATHOPHYSIOLOGY

Ebola virus enters the body through breaks in the skin, mucus membranes, or ingestion and then infiltrates cells, especially lymph tissues, liver, and spleen. The virus continues to replicate until cells become necrotic and lyse, spilling more viral particles into the circulation. Ebola virus elicits a profound proinflammatory cytokine and chemokine response, producing a vigorous SIRS reaction.[32,33] Significant endothelial injury ensues, with loss of vascular tone and increased vascular permeability leading to hypotension and shock.[34,35] At the end stages of disease, the virus is found in all body fluids and skin, making handling of bodies of EVD victims extremely hazardous. In contrast to prevailing biases, bleeding does not occur in all patients and only manifests late in the disease process as bleeding from skin, gums, and the gastrointestinal tract.[36] Mortality rate remains high at 50% to 90% overall, with a poorer prognosis seen in those with older age, diarrhea, hemorrhagic conjunctivitis, shortness of breath, confusion/coma, and hemorrhage.[37]

SYMPTOMS

Patients in early stages of the disease present with the acute onset of flu-like symptoms. Fever is the most common symptom (present in 87%), with fatigue (76%), abdominal pain (44%), and nausea and vomiting (65%) also frequently seen.[37,38] Late symptoms are representative of a fulminant infection and SIRS with symptoms of severe vomiting and diarrhea, both of which may be bloody. Other late signs include a coagulopathy identified by diffuse oozing from mucosal surfaces and sites of intravenous lines. Death is often the result of recalcitrant multiorgan system failure.[26]

TREATMENT

Currently, there is no vaccine against or pharmacologic treatment for EVD, and the mainstay of therapy is supportive care. Many patients will have severe diarrhea, losing up to 15 L/d, and require aggressive resuscitation efforts focused on replenishing circulatory volume. Significant electrolyte abnormalities are common, and correction of these must be done in order to prevent cardiac dysrhythmias. In the early stages of the disease, patients can often tolerate oral fluids, antiemetics, and antidiarrheals. Patients with protracted vomiting or in those later stages of the disease should have intravenous fluids administered. Blood transfusions may be necessary, especially for those with hemorrhagic symptoms, and should follow current recommendations for transfusion

triggers. Respiratory support in the form of mechanical ventilation may be necessary, but caution should be exercised with noninvasive support, as it may lead to aerosolization.[39] Some novel antivirals known to have in vitro or animal anti-Ebola activity were used during the 2014 outbreak, but data regarding their effectiveness are inconclusive at this time. Experimental therapies used during the 2014 EVD outbreak included plasma from convalescent or immune patients and experimental monoclonal antibodies, but it is not clear that either method provided a survival benefit.[40,41] Several vaccines are currently undergoing accelerated human trials, but none as yet are commercially available.[42]

PREVENTION

The 2014 EVD outbreak clearly demonstrated how globalization has enhanced the capacity for a previously isolated tropical disease to rapidly spread. Prevention relies on maintaining a level of preparedness of providers and facilities that can receive patients with EVD, provide quality critical care, protect the providers, and assuage the fears of the community. Preventing EVD transmission is divided into mitigating transmission of the primary disease and screening for early identification of the disease as part of planning for a disaster.

With a new outbreak in the Congo in 2018, the recommendations issued by the CDC for use in health care facilities are still relevant.[43] Strict adherence to protocols for use of personal protective equipment (PPE) and adoption of practices to limit exposure to body fluids constitute the mainstays of primary prevention, as well as environmental controls.[44] Practiced use of full PPE, as described by the CDC (http://www.cdc.gov/vhf/ebola/healthcare-us/ppe/guidance.html), that is donned and doffed in the presence of a trained observer is paramount when treating a patient with EVD.[45] All practitioners who will come into contact with a patient with EVD should be trained and certified in their ability to properly wear full PPE prior to their first encounter with the patient. The body should be covered from head to toe with single-use hood, gown (or coveralls), double gloves, impermeable boot covers, and a respirator or N95 mask. Ideally, extended cuff gloves, gowns with thumb hooks, and/or tape securing the gowns and gloves should be used. During contact with the patient, the practitioner should limit contact with surfaces with body fluid, keep their hands away from their face, and employ frequent alcohol-based scrubs on their gloved hands. There should be no rush or shortcuts taken while placing the PPE, so time consideration should be given if plans for procedures or intubation are required. Total time spent in the care of the patient while wearing PPE should be monitored because providers can become fatigued and dehydrated. Elective surgical procedures should be postponed in a patient with EVD, and nonoperative alternatives should be strongly considered for urgent conditions (eg, appendicitis, perforated ulcer). A risk-benefit analysis considering the risk of exposure to the operative team must be considered prior to operating for an emergent condition bearing in mind that, in late EVD disease, the patient is unlikely to survive.

DISASTER MANAGEMENT

Health care preparedness for a real or potential Ebola outbreak mandates the presence of an effective screening procedure that will capture any potential carrier of EVD. A robust program that contains multiple contingency plans and has been rehearsed by all the team members is essential, as disaster leaders should be prepared to operate without significant assistance for at least 72 hours. A simple screening method that can be used at any first encounter with a patient (including clerical areas) should focus on the following: (1) recent travel (last 21 days) to an affected area; and/or (2) recent (21 days) direct contact with a patient infected with Ebola.

Positive responses to these simple questions lead to an escalation of care with an immediate separation and isolation of the patient. After proper isolation, a more focused history identifying exposure risk can be performed. Once a diagnosis of EVD is confirmed, the CDC recommends that plans should be in place to ensure immediate isolation is available, which includes a private room with a door, a private bathroom, and separate areas for donning and doffing PPE. Other pragmatic plans for handling of lab specimens, environmental waste management, and restriction of nonessential personnel must be in place.[46] The institutional management of threatened or actual Ebola outbreak requires trained, professional emergency managers and disaster management experts to be involved in incident command. Incident control should designate a team of site managers who have a constant presence to oversee implementation of safety precautions, monitor adequacy of necessary supplies, and evaluate care in isolation areas.

The high infectious risk and mortality rate of EVD evoke strong emotions of fear, both in health care workers and the general public. The incident command should remain the voice of calm and reason during the disaster and encourage constant communication between the front-line providers, the incident commander, and the community.

PREVENTION OF INFECTIONS

General Principles

As in all other aspects of surgical care, it is preferable to try to prevent infections wherever possible. A number of interventions and practices have been demonstrated to be highly effective in preventing infections after elective operations, and many of those techniques have specific application in the care of injured patients. In this section, current evidence-based interventions that are applicable to trauma patients to prevent infection will be reviewed.

Prophylactic Antibiotics

Prophylactic antibiotics are intended to *prevent* development of infection. The concept of prophylaxis presupposes that infection is *not* present. The decision to use prophylactic antibiotics and the choice of agents are based on the risk of developing SSI. There are very good data regarding SSI

TABLE 21-5: Classification of Surgical Wounds

Wound class	Characteristics	Examples	SSI rate (%)
Clean (I)	Uninfected, no inflammation, no mucosal surface transected	Mastectomy Thyroidectomy Vascular bypass CABG	<2%
Clean-contaminated (II)	Uninfected, no inflammation, no mucosal surface transected	Colectomy Cholecystectomy Laryngectomy Urologic procedures Pulmonary lobectomy	5%–15%
Contaminated (III)	Open accidental wounds, break in sterile conditions, spillage, stomas	Appendicitis Diverticulitis Small bowel GSW	15%–30%
Dirty-infected (IV)[a]	Infection, perforation, devitalized tissue	Incise and drain abscess Peritonitis Enteric fistulas Remove infected implant	>30%

[a]Dirty wounds = infection antibiotics indicated as therapy.

CABG, coronary artery bypass graft; GSW, gunshot wound.

Source: Adapted from Nichols RL. Surgical infections: prevention and treatment—1965 to 1995. *Am J Surg*. 1996;172(1):68-74.

rates for elective surgery, and the incidence of SSI by wound class for elective operations is shown in Table 21-5.[47] Traditionally, class I, or clean wounds, are those that do not violate the respiratory, alimentary, or genitourinary tracts. The wound infection rate is approximately 2%. Class II, or clean-contaminated wounds, refers to elective operations on potentially contaminated organs, such as the gastrointestinal tract, biliary tract, genitourinary tract, and respiratory tree (the procedure will violate a mucosal surface, which can never be completely sterile). The usual incidence of infection for these types of wounds is 5% to 10%. Contaminated wounds (class III) differ from class II wounds by the degree of spillage, with an incidence of infection of 15% to 30%. Finally, class IV, or dirty-infected wounds, are characterized by frank pus or extensive and prolonged contamination. In one series of patients from the 1970s, these wounds were characterized by an infection rate of greater than 30% if primary closure is attempted.[48] A recent single-center, randomized controlled trial of primary versus delayed closure of wounds in complicated appendicitis reported nonsignificantly lower SSI rates in the primary closure group, with rates ranging from 7% to 10%.[49] Overall, it appears that hospitalized SSI rates were considerably lower in 2015 compared to 2011 in a National Healthcare Safety Network (NHSN) point prevalence study in 199 hospitals across 10 states, with the number of *Clostridium difficile* infections surpassing SSI for the first time.[50]

In trauma surgery, the majority of wounds encountered will be class III or IV, and the luxury of a preinoculation dose of antibiotics, as recommended by the Surgical Care Improvement Project, is usually unavailable.[7] These recommendations were reinforced in 2017 in updated guidelines for prevention of SSI from the CDC.[51] A single-center retrospective cohort study of laparotomy following mostly penetrating trauma demonstrated a very high rate of SSI (39%) and increased risk of SSI if intraoperative temperatures dipped below 35°C.[52] Interestingly, failure to administer preoperative antimicrobials was not an independent predictor of SSI, whereas hypothermia was. With this in mind, it is prudent to administer a single dose of an agent with activity against community-acquired aerobic and anaerobic pathogens as soon as possible for all patients requiring operation in the thorax or abdomen. Evidence-based guidelines for antibiotic prophylaxis of other surgical interventions or different anatomic sites are summarized in Table 21-6.

The issue of postoperative continuation of prophylactic antibiotics in penetrating abdominal trauma has been investigated extensively. The Eastern Association for the Surgery of Trauma (EAST) has published guidelines derived from an evidence-based review.[53] A single preoperative dose of a prophylactic antibiotic with broad-spectrum aerobic and anaerobic coverage is recommended for trauma patients sustaining penetrating abdominal wounds. Absence of an injury to a hollow viscus requires no further administration. Even in the presence of a hollow viscus injury, class I evidence supports limiting prophylactic antibiotics to only 24 hours.[54] Timely discontinuation of prophylactic antibiotics is important because the practice of prolonged administration has been linked to increased rates of subsequent nosocomial infections with resistant organisms.[55] To maintain adequate tissue and serum levels of antibiotics in the face of ongoing hemorrhage and vasoconstriction, the administered dose may be increased two- or threefold and repeated after every 10 units of transfusion of blood products, although there is no evidence to support this practice.

TABLE 21-6: Evidence-Based Recommendations for Antibiotic Prophylaxis for Specific Interventions or Injuries

Intervention/Injury	Agent/Route/Duration	Reference(s)
Chest tube	May use first-generation cephalosporin prior to chest tube insertion, ≤24-h duration, but not enough evidence to support this recommendation (EAST guidelines)	118
Mandibular fractures	Perioperative antibiotics only, 24-h duration at most	223
Open globe injuries	Ceftazidime and vancomycin IV for 48 h to reduce risk of endophthalmitis	224
Basilar skull fractures	Evidence does not support prophylactic antibiotics to decrease risk of meningitis in presence of rhinorrhea or otorrhea	225
Penetrating brain injury	First-generation cephalosporin for 5 days after injury	226
Intraventricular pressure monitor	Antimicrobial based on local antibiogram administered prior to insertion only; use antimicrobial-impregnated catheters	227
Burns	Prophylactic systemic parenteral antibiotics are strongly discouraged	228
Hand/tendon repairs	Single dose of first-generation cephalosporin may be beneficial; no evidence to support >24-h duration	229, 230
Closed fractures	Perioperative first-generation cephalosporin at time of ORIF; no longer than 24 h	231
Open fractures	First-generation cephalosporin for 48 or 24 h after wound closed Gram negative antimicrobial coverage for grade III fractures Add anaerobic coverage for soil, fecal, or standing water contamination No benefit to routine use of antibiotic beads	174, 232, 233
Chest trauma	Cephalosporin	116
Penetrating abdominal trauma	Agent(s) with activity against aerobic and anaerobic bacteria	54, 141
Combat injuries	Point of injury/delayed evacuation: moxifloxacin 400 mg PO × 1 dose; ertapenem 1 g IV or IM if penetrating abdominal injury, shock, or unable to tolerate PO medications Extremity injury: cefazolin 2 g IV q 6–8 h for 24–72 h Abdominal injury: cefazolin 2 g IV q 6–8 h plus metronidazole 500 mg IV q 8–12 h for 24 h after definitive washout	234

EAST, Eastern Association for the Surgery of Trauma; IM, intramuscular; IV, intravenous; ORIF, open reduction internal fixation; PO, oral; q, every.

Surgical Scrub

For many years, povidone–iodine scrub was the standard disinfectant used for preparation of surgical sites and preoperative scrubbing by the surgical team. This dominance was challenged by a randomized controlled trial performed in elective surgery showing significantly lower SSI rates with the use of chlorhexidine–alcohol compared with iodine (9.5% vs 16.1%).[56] On the contrary, a prospective cohort analysis of over 7500 patients across the state of Washington demonstrated no clear benefit to any one skin preparation agent,[57] and a randomized controlled trial of povidone–iodine versus chlorhexidine gluconate in clean-contaminated upper gastrointestinal and hepatobiliary operations detected no difference in SSI rates between the two arms.[58] There are no published trials of the use of skin preparations in trauma or other emergency surgery, however, but the fact that chlorhexidine–alcohol begins bacterial killing immediately on contact and does not require drying for antimicrobial effectiveness makes it potentially attractive for use in these cases. One caveat regarding use of alcohol-based disinfectants is that it is imperative that the solutions dry prior to incision to lower risk of intraoperative fires.

Double Gloving

Glove perforation is an underappreciated phenomenon that may adversely impact the sterility of an operative procedure. Microperforation rates as high as 16% have been reported.[59] When two pairs of gloves are used, inner glove perforation rate is substantially lower. In addition to patient outcome, the surgeon must also consider personal safety (see Occupational Exposure section).

Temperature Control

Hypothermia has been shown to be a strong independent predictor of poor outcome.[60] Hypothermia slows enzymatic activity needed for blood clotting and can induce an acquired coagulopathy. Hypothermia also modulates the inflammatory response, resulting in immune suppression associated with higher rates of all infectious complications, including SSI.

In elective colorectal surgery, a prospective, randomized study compared a group in whom intraoperative normothermia (36.6°C) was maintained to a control group with mild hypothermia (34.7°C). The normothermic group had a significantly lower rate of SSI (6% vs 19%) and a 20% shorter hospital stay.[61] The precise mechanism for the beneficial effects of normothermia remains unclear but may relate to tissue perfusion and improved host defense. Therefore, every reasonable effort should be made to maintain normothermia in all surgical patients.

Supplemental Oxygen

Perioperative supplemental oxygen is now strongly recommended for the reduction of SSI risk. In another prospective randomized study in patients undergoing elective colorectal operations, the authors observed a significantly lower SSI rate when 80% versus 30% inspired oxygen was delivered during the operation.[62] This was recently replicated in a study of emergency laparotomy for perforated peptic ulcer, demonstrating a 50% decrease in SSI with 80% fraction of inspired oxygen delivered during and for 6 hours following surgery.[63]

Suture Material

Sutures decrease the inoculum of bacteria needed to establish infection and can serve as a foreign body within potentially infected wounds, so there is a sound physiologic basis for a potential benefit in using antimicrobial impregnated suture material. There have now been several randomized controlled trials demonstrating a decreased incidence of SSI when antibiotic-coated sutures were employed for facial closure, and a 30% decrease in SSI was seen in a large meta-analysis.[64] Subsequent trials, however, have failed to demonstrate benefit.[65]

Blood Transfusion

Blood transfusion can be lifesaving for an exsanguinating patient, but numerous authors have reported worse infectious complications with increased blood utilization both in the immediate resuscitation[66-69] and when used in a delayed fashion.[70-72] Transfusion results in a multitude of immunosuppressive effects, including the following: (1) decreased CD3+, CD4+, and CD8+ cells; (2) overall reduced T-cell proliferation to mitogenic stimuli; (3) decreased natural killer cell activity; (4) defective antigen presentation; and (5) impaired cell-mediated immunity.[73] The increased risk of infection associated with blood transfusion appears to be dose dependent,[72,74] and logistic regression analyses report that the risk of infection in patients sustaining burn injury increases 13% per unit transfused.[75] Taylor et al[76] reported that for each unit of packed red blood cells (PRBCs) transfused, the odds of developing a nosocomial infection were increased by a factor of 1.5 in critically ill surgical patients. The age of the transfused blood is an additional risk factor for infectious complications.[77,78] As blood ages in the blood bank, it undergoes predictable changes that affect its ability to deliver oxygen. This "storage lesion" includes the following: (1) an increased affinity of hemoglobin for oxygen and reduced oxygen release to tissues; (2) depletion of 2,3-diphosphoglyerate (2,3-DPG) with resultant inadequacy of oxygen transport by red blood cells (RBCs); (3) reduction in deformability, altered adhesiveness, and aggregability; and (4) accumulation of bioactive compounds with proinflammatory effects. In trauma patients, Zallen et al[79] estimated that each transfused unit of RBCs older than 14 days increased the risk of organ failure by 13%.

To minimize infection risk, blood transfusion in nonbleeding patients should be avoided when at all possible. A large multicenter randomized study reported the safety of a restrictive transfusion strategy (trigger of 7.0 g/dL hemoglobin) compared to a liberal strategy (trigger of 10.0 g/dL). In fact, mortality rates in patients who were younger (age <55) and less sick (Acute Physiology and Chronic Health Evaluation [APACHE] score <20) were more than double with liberal transfusion.[80] When the subgroup of trauma patients (n = 203) was reviewed in a secondary analysis, McIntyre et al[81] confirmed the safety of the restrictive strategy. Additionally, practices to be avoided include using blood as a volume expander and transfusing blood preemptively in anticipation of future operative blood loss. Advanced age should not be used as a sole criterion to transfuse a patient. Further guidelines for the transfusion of RBCs in trauma patients in the postresuscitation period are available.[82,83]

Nutritional Support

The timing, adequacy, and route of administration of nutrition to trauma patients have definite implications for infectious complications. Adequate nutrition is essential for patient recovery, healing of traumatic wounds, and posttrauma rehabilitation. This is because trauma causes increased metabolism and protein turnover that results in a catabolic state characterized by breakdown of skeletal muscle, impaired healing, and immunosuppression. Once acute resuscitation is complete, nutritional support should be instituted, and the enteral route is preferred. Numerous trials have compared enteral nutrition (EN) with parenteral nutrition (PN). Advantages of the enteral route include lower cost, maintenance of function of the gut mucosal barrier, and more physiologic delivery of nutrients; PN may be administered as soon as intravenous access is available and in the setting of ileus or gastrointestinal tract discontinuity commonly seen in critically ill trauma patients. While past evidence strongly favors the use of EN over PN in trauma patients in regard to infectious complications,[84,85] newer studies support the use of early PN with decreased risk of infection, hyperglycemia, and overfeeding.[86,87]

An additional factor that has been implicated in infectious complications is poor glycemic control. Current recommendations relating to glycemic control are in flux, but it appears clear that results are improved when hyper- and hypoglycemia are avoided. Enthusiasm for "very tight" glucose control has waned after several studies showed no

benefit and increased complications with attempts to maintain blood glucose less than 110 mg/dL.[88-91] Newer consensus documents favor continuous glucose monitoring and dynamic insulin protocols to optimize glucose control, although one randomized controlled trial demonstrated that computerized decision support for tight glucose control was associated with more frequent severe hypoglycemic episodes.[92,93]

Tracheostomy

Although several studies comparing early and late tracheostomy have been performed, there is still no consensus regarding whether earlier tracheostomy impacts development of ventilator-associated pneumonia.[94-96] The decision to perform tracheostomy is often institution and surgeon specific, but increasing evidence is mounting that in acutely brain-injured patients, early tracheostomy is favorable to prolonged intubation. The most recent Cochrane Database meta-analysis showed that mortality was decreased slightly (relative risk [RR], 0.83) and that the likelihood of discharge from the ICU was higher at day 28 (RR, 1.29) with early versus late tracheostomy.[97] A systematic review of 10 randomized controlled trials of early versus late tracheostomy following acute brain injury demonstrated not only lower ICU and long-term mortality, but also decreased ICU ventilator days, suggesting that early tracheostomy (defined in this review as within the first 10 days of intubation) may improve access to intensive care beds by enabling earlier ICU discharge and transfer to long-term care facilities.[98,99]

TRAUMA-RELATED INFECTIONS

Diagnosis of Infection

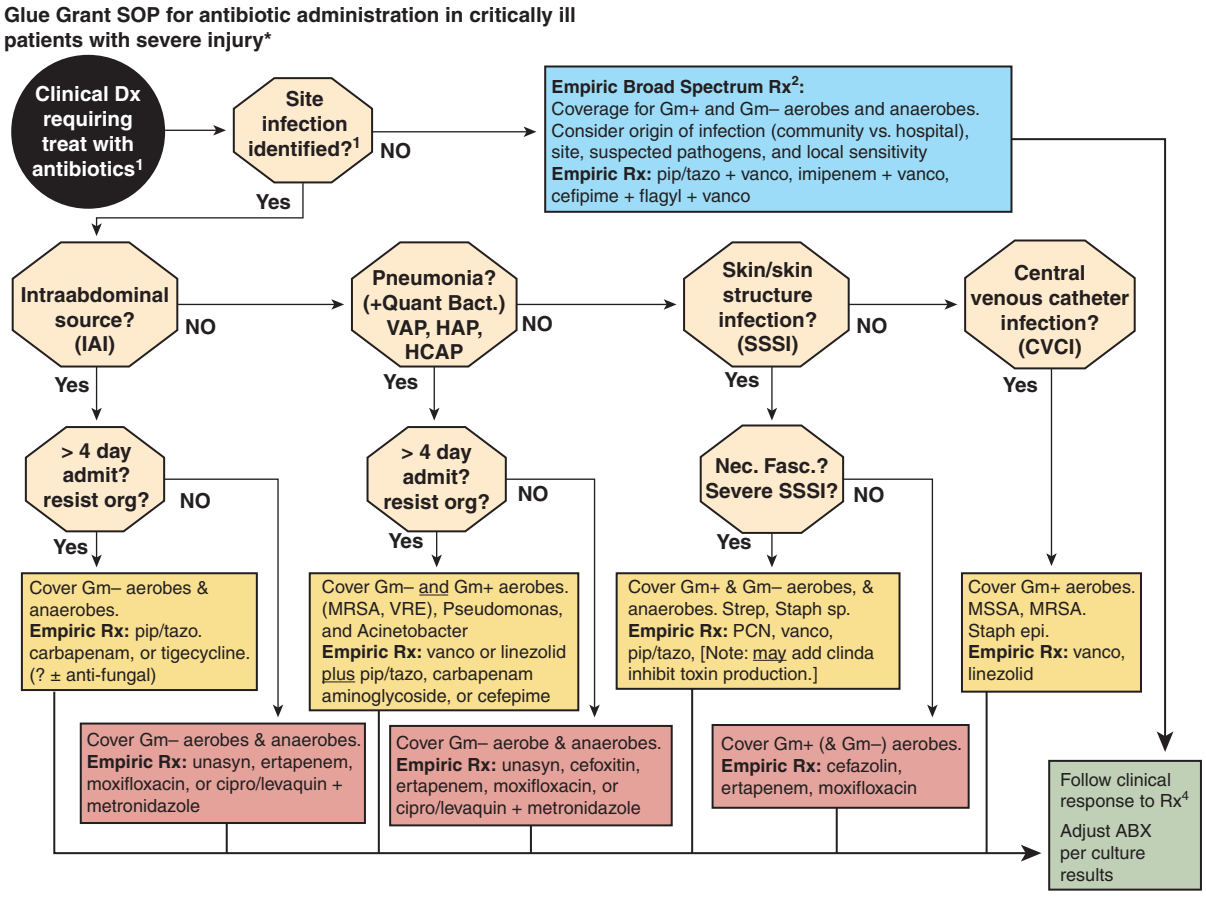
Almost by definition, infectious problems are rarely the presenting complaint of a patient who has sustained an acute traumatic injury. Recognition of an infection in a patient recovering from traumatic injuries, however, continues to be a common, sometimes challenging, clinical problem. Frequently, many of the signs and symptoms commonly associated with infections are also present in trauma patients. The immediate physiologic and immunologic response to tissue injury is initiation of the inflammatory response. Acute traumatic injuries cause the cardinal signs of inflammation including pain (*dolor*), edema (*turgor*), heat (*calor*), redness (*rubor*), and loss of function (*functio laesa*). Trauma victims will often manifest several of the SIRS criteria (eg, tachycardia, elevated temperature, elevated white blood cells [WBCs]) in a clinical context where they are at increased risk for infection.[100]

The diagnosis of infection requires a high clinical suspicion tempered by knowledge of the most likely infectious complications at various time points after injury and filtered by experience with caring for patients with similar injuries. When prevention measures have been ineffective, the diagnosis of infection is based on clinical, laboratory, and imaging methods. Most trauma patients, especially those requiring operative interventions, those with open fractures, or those who have sustained penetrating trauma, will be treated with a course of empiric antibiotics (Table 21-6). The choice of specific antimicrobial agents is determined by the endogenous pathogens or likely exogenous contamination at the anatomic site of injury (eg, exposure to *Vibrio* spp. with marine trauma, exposure to *Clostridium* spp. with farm injury).

Hospitalized patients are at risk for development of *nosocomial* infections, and the diagnosis is made based on a high suspicion coupled with laboratory and/or radiologic confirmation. In most cases, bacterial culture constitutes the gold standard for diagnosis of infection, although at times it can be impractical or impossible to obtain adequate samples. The most specific culture information, if available, is obtained with quantitative or semiquantitative methods (eg, burn wound biopsy, bronchoscopic alveolar lavage [BAL], or mini-BAL). In cases where cultures cannot be obtained, empiric treatment is initiated based on the most likely pathogenic organisms and adjusted based on clinical response. Evidence-based recommendations have been developed for diagnosis and antimicrobial treatment of most hospital-acquired infections,[51,101-104] albeit not specifically addressing trauma patients. The trauma Glue Grant (www.gluegrant.org) proposed a standard operating procedure (SOP) to identify the source of infection in critically ill trauma patients.[105] An updated adaptation of the SOP is reproduced in Fig. 21-4. This approach emphasizes and prioritizes the most likely infections and suggests acceptable antimicrobial agents that are otherwise consistent with evidence-based guidelines from infectious disease societies for a wide range of different infections. Diagnostic imaging, particularly cross-sectional imaging, and/or ultrasound can be helpful to identify and access potentially infected fluid collections in deep locations. Percutaneous aspiration and/or drainage has largely replaced the need for operative management of deep infections and abscesses.[106,107]

Intra-Abdominal Infections

Intra-abdominal infections may complicate both blunt and penetrating abdominal injury. The presence of very high numbers of bacteria within the gut, coupled with the impaired perfusion present in shock states and the immune alterations associated with trauma, result in a 10% to 25% incidence of intra-abdominal infection. Appropriate resuscitation and empiric antibiotics, along with sound intraoperative decision making, minimize the risk for infectious complications. Early source control is crucial to limit the likelihood for postoperative infections. Clinical examination may provide sufficient information to warrant abdominal exploration, and the presence of peritoneal signs or other signs of an acute abdomen should not be ignored in trauma patients. However, hollow viscous injury may be difficult to recognize upon initial presentation, especially if patients arrive after field intubation or if there are distracting injuries that belie a good examination of the abdomen. Peritonitis and acute abdominal signs may develop if bacterial contamination has been present for more than 12 hours. The presence of unexplained free fluid or free air on initial imaging studies is highly suspicious for



1 Important to try, whenever possible, to obtain cultures from suspected sites of infection prior to initiating antimicrobial therapy.

2 Empiric choice should include ≥ 1 antibiotic with activity directed against the likely pathogens.

3 Adjust antibiotics with eye toward appropriate "de-escalation" of therapy based on culture results, response to therapy and clinical condition.

4 Always reassess antimicrobials after 48–73 hr based on micro and clinical data. There is no evidence that combination Rx is more effective than mono Rx if microorganisms are sensitive to agent. Duration of Rx should typically be 7–10 days.

* Individual antibiotic choices will be heavily influenced by local ID restrictions and/or formulary choices. This guideline is intended to highlight parameters that need to be considered in choice of agents.

FIGURE 21-4 Diagnostic approach to identify and treat postinjury infections in critically ill trauma patients. Note that oral metronidazole is no longer recommended as first-line treatment for *Clostridium difficile* colitis (enteral vancomycin is first line, with intravenous [IV] Flagyl and vancomycin enemas added in the setting of septic shock). ABX, antibiotics; Dx, diagnosis; Gm, Gram stain; HAP, hospital-acquired pneumonia; HCAP, health care–associated pneumonia; IAI, intra-abdominal infection; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *S aureus*; PCN, penicillin; Rx, treatment; SOP, standard operating procedure; VAP, ventilator-associated pneumonia; VRE, vancomycin-resistant *Enterococcus*. Inflammation and the host response to injury, a large-scale collaborative project: patient-oriented research core–standard operating procedures for clinical care VII: guidelines for antibiotic administration in severely injured patients. *J Trauma.* 2008;65(6):1511-1519.)

injury to a hollow viscus, but other signs such as mesenteric hematoma or bowel thickening are also suggestive and may warrant exploration.[108]

Intra-abdominal infections identified later in the hospital course (>4 days after injury) are much more likely to be caused by hospital-associated, rather than community-associated, organisms, as most patients will have received one or several doses of relatively broad-spectrum antibiotics that alter the bacterial flora.[101] Late intra-abdominal infections may grow *Pseudomonas* spp., *Serratia* spp., or *Candida* spp. Percutaneous aspiration and/or drainage has become the mainstay for treatment of late intra-abdominal abscesses and fluid collections. Whenever possible, material from intra-abdominal collections should be sent for Gram stain, culture, and sensitivity determination to guide therapy. The Surgical Infection Society (SIS) and the Infectious Diseases Society of American (IDSA) published updated evidence-based guidelines to inform antibiotic choices for intra-abdominal infections.[109] These guidelines differentiate between community- and hospital-acquired infections (Tables 21-7 and 21-8). As a general rule, antimicrobial coverage directed against community abdominal pathogens may be given within the first 3 days after injury, whereas antibiotic choices 4 or more days after injury should anticipate hospital organisms. A recent multicenter, randomized controlled trial of intra-abdominal infection demonstrated that short duration (4 days) of antimicrobial therapy after definitive source control of infection is as effective as treatment extended twice as long.[110] To avoid antibiotic-associated complications, such as *C difficile* colitis and infection and/or colonization with antibiotic-resistant organisms, antibiotic exposure should be limited to the shortest duration possible.

Empyema

Under normal circumstances, the pleural cavity has a net negative pressure and a very small (<20 mL) volume of fluid.[111] Current understanding of fluid flux within the pleural cavity implicates parietal pleural lymphatics as the main route through which fluid is removed.[112] Pleural fluid normally turns over at a rate of approximately 0.15 mL/kg/h (10–12 mL/h for a 70-kg individual), and the maximum capacity for lymphatic drainage is estimated to be 700 mL/d (~30 mL/h). When there is increased production or decreased clearance of pleural fluid, a pleural effusion develops. Pleural effusions are frequently associated with fluid overload, but they may also arise in the setting of acute inflammatory processes of the lung including pneumonia (parapneumonic effusion), acute lung injury, or ARDS. Blunt and penetrating chest trauma can induce alterations within the pleural cavity, with loss of negative pressure (traumatic pneumothorax), accumulation of blood (hemothorax), or a combination of both (hemopneumothorax).

TABLE 21-7: SIS/IDSA Evidence-Based Guidelines for Antibiotic Choices for Community-Acquired Intra-Abdominal Infections

	Adults		Children
	Mild-moderate severity	**Severe or high-risk patients**	**Severe or high-risk patients**
Monotherapy (single agent)	Cefoxitin Ertapenem Moxifloxacin[a] Tigecycline Ticarcillin-clavulanate	Imipenem-cilastatin Meropenem Doripenem Piperacillin-tazobactam	Ertapenem Meropenem Imipenem-cilastatin Ticarcillin-clavulanate Piperacillin-tazobactam
Combination therapy[b]	Cefazolin Cefuroxime Ceftriaxone Cefotaxime, ciprofloxacin[a] Levofloxacin[a] **plus** Metronidazole	Cefepime Ceftazidime Ciprofloxacin[a] Levofloxacin[a] **plus** Metronidazole	Ceftriaxone Cefotaxime Cefepime Ceftazidime **plus** Metronidazole Gentamicin Tobramycin **plus** Metronidazole Or clindamycin ± Ampicillin

[a]*E coli* resistance to fluroquinolones is increasingly reported, so local sensitivity information should be consulted.
[b]With combination regimens, acceptable agents with activity against aerobic gram-negative bacteria are listed first, followed by agents directed against anaerobes. A single agent with aerobic activity should be paired (combined) with an antianaerobic drug.

TABLE 21-8: SIS/IDSA Evidence-Based Guidelines for Initial Adult Antibiotic Dosing in Intra-Abdominal Infections

Antibiotic	Adult dosage
β-Lactam/β-lactamase inhibitor combination	
Piperacillin-tazobactam	3.375 g q 6 h (Note: increase dose to 3.375 g q 4 h or 4.5 g q 6 h for *Pseudomonas* infections)
Ticarcillin-clavulanic acid	3.1 g q 6 h (FDA labeling indicates 200 mg/kg/d in divided doses q 6 h for moderate infection and 300 mg/kg/d in divided doses q 4 h for severe infection)
Carbapenems	
Doripenem	500 mg q 8 h
Ertapenem	1 g q 24 h
Imipenem-cilastatin	500 mg q 6 h or 1 g q 8 h
Meropenem	1 g q 8 h
Cephalosporins	
Cefazolin	1–2 g q 8 h
Cefepime	2 g q 8–12 h
Cefotaxime	1–2 g q 6–8 h
Cefoxitin	2 g q 6 h
Ceftazidime	2 g q 8 h
Ceftriaxone	1–2 g q 12–24 h
Cefuroxime	1.5 g q 8 h
Tigecycline	100 mg initial dose, then 50 mg q 12 h
Fluoroquinolones	
Ciprofloxacin	400 mg q 12 h
Levofloxacin	750 mg q 24 h
Moxifloxacin	400 mg q 24 h
Metronidazole	500 mg q 8–12 h or 1500 mg q 24 h
Aminoglycosides	
Gentamicin or tobramycin	5–7 mg/kg q 24 h (based on adjusted body weight)
Amikacin	15–20 mg/kg q 24 h (based on adjusted body weight)
Aztreonam	1–2 g q 6–8 h
Vancomycin	15–20 mg/kg q 8–12 h (based on total body weight)

Treatment of either condition generally requires insertion of a thoracostomy tube, and this can introduce bacterial contamination of the fluid or blood present within the pleural cavity, particularly when chest tubes are placed emergently under less than sterile conditions. Because lymphatic stomata of the parietal pleural are the means by which blood and/or fluid is normally reabsorbed, the presence of a fibrin clot can obstruct this route of egress and contribute to persistence of fluid within the chest cavity.

TABLE 21-9: Bacteriology of Posttraumatic Empyema (N = 37)

Organism	No. (%)
Staphylococcus aureus	20 (54%)
Methicillin-resistant *S aureus*	7 (19%)
Pseudomonas aeruginosa	2 (6%)
Streptococcus pneumoniae	1 (3%)

Diagnosis of empyema requires sampling of fluid or tissue from the pleural space.[113] In the setting of empyema, analysis of pleural fluid will demonstrate a pH of less than 7.20, glucose of less than 40, the presence of bacteria on Gram stain, or a positive culture.[114] Table 21-9 shows the most common bacterial isolates from posttraumatic empyema (although some purulent collections may not grow bacteria). It is now generally understood that posttraumatic empyema arises from exogenous contamination of the pleural cavity. Hoth and colleagues[115] obtained simultaneous BAL and pleural cultures and noted that there was minimal correlation between pleural cultures and BAL samples. Recognition that skin flora is associated with empyema underscores the importance of using sterile technique during insertion of a thoracostomy tube. A meta-analysis of five trials that included patients with blunt or penetrating thoracic trauma found a significant reduction in the risk of empyema (RR, 0.19; 95% confidence interval [CI], 0.04–0.70) and pneumonia (RR, 0.44; 95% CI, 0.15–0.87) for patients who received antibiotic prophylaxis compared with placebo.[116] However, because of conflicting accumulated evidence, in 2012, the EAST Practice Management Guidelines Work Group revised an earlier guideline[117] and declined to make a definitive recommendation for or against the routine use of presumptive antibiotics in trauma thoracostomy placement for traumatic hemopneumothorax to reduce the incidence of empyema and pneumonia.[118]

Complete evacuation of a hemothorax and reexpansion of the lung at the time of initial thoracostomy tube placement are important to prevent empyema. Retained hemothorax and empyema complicate about 4% of patients with a hemothorax treated with a thoracostomy tube.[119] In a prospective, multicenter, observational study of patients with posttraumatic retained hemothorax, the incidence of empyema was 26.8%.[120] Rib fractures, severe injury, and need for additional interventions beyond chest tube thoracostomy to evacuate hemothorax were found to be independent predictors of empyema. Instillation of fibrinolytic agents has been demonstrated to aid in the evacuation of a retained hemothorax; while presence of an intrathoracic injury would seem to increase risk of bleeding complications, this has not been borne out in several case series.[121] Video-assisted

thoracoscopy (VATS) is more widely employed for the treatment of retained hemothorax, but the ideal timing of VATS is unclear, and multiple procedures including conversion to thoracotomy may be required if the hemothorax is large or diaphragm injury is concurrent, or if empyema develops.[118] For patients with flail chest physiology, rib fixation is increasingly used for chest wall stabilization and may prevent the subsequent development of pneumonia or empyema.[122-124]

Osteomyelitis/Septic Arthritis

Trauma-related osteomyelitis and septic arthritis may complicate musculoskeletal injury.[125] Posttraumatic musculoskeletal infections generally arise from bacteria introduced exogenously, either at the time of injury or during operative repair. This is in contrast with hematogenous dissemination of bacteria with most nontraumatic bone and joint infections. Although a variety of bacterial species have been isolated from posttraumatic osteomyelitis and septic arthritis (Table 21-10), *Staphylococcus* species are far and away the most common isolates.[126,127] *S aureus* and *Staphylococcus epidermidis* have a number of virulence factors that provide a particular predilection to bone tissue.[127] These virulence factors, summarized in Table 21-11, include adhesive properties and exotoxins and enzymes that facilitate invasion. Another property important to the development and persistence of osteomyelitis is a small colony variant (SCV) phenotype that grows more slowly with increased resistance to aminoglycosides and decreased hemolytic activity.[126] Clinical use of aminoglycoside beads and broader-spectrum antibiotics may select for these more resilient SCV phenotypes in vivo.

TABLE 21-10: Bacteria Isolated from Septic Joints and Osteomyelitic Bone Infections

Bacteria isolated from joint infections

The presence of contaminating bacteria at the site of a bone or joint injury incites a vigorous local inflammatory response. The local source of the inflammatory cytokines TNF, IL-1, and IL-6 is not entirely clear, but osteoblasts may contribute. In any case, high local levels of proinflammatory cytokines have dramatic effects on bone turnover and new bone formation. TNF and IL-1 induce increased maturation of osteoclasts and enhance osteoclastic activity.[128] At the same time, these mediators inhibit mesenchymal cell differentiation into osteoblasts. Similar processes contribute to destruction of cartilage and bone in chronic arthritic conditions. In such settings, anti-TNF and anti–IL-1 therapies have been very successful in preventing inflammation.[129] The net impact of increased osteoclast and decreased osteoblast activity is either bone destruction or inhibition of bone healing. Furthermore, contact between osteoblasts and *S aureus* can induce TNF-related apoptosis-inducing ligand (TRAIL), which, in the presence of Fas-associated death domain (FADD), commits cells to apoptotic cell death.

Several unique factors associated with bone infection underscore the importance of evidence-based recommendations that emphasize early and continuing aggressive debridement of orthopedic injuries, particularly those associated with open or contaminated wounds.[130] During the initial evaluation of the patient in the emergency room, it is imperative to promptly begin antibiotic prophylaxis for open fractures, with antibiotic coverage increasing with degree of injury, tissue devitalization, and contamination with soil or standing water.[131,132] At sites of bone or joint injury, local blood supply to fragments may be interrupted, predisposing to bone necrosis. Lack of blood supply also precludes delivery of systemic antibiotics, host inflammatory cells, and the molecular oxygen needed for oxygen-dependent bactericidal activity of such cells. It is axiomatic that all dead bone must be removed to minimize the risk of bone infection. In addition, many

orthopedic injuries require the presence of foreign bodies, such as plates or rods, to stabilize fractures. Experimentally only very low levels of bacteria are needed to produce infection in the presence of foreign material. In the presence of extensive local bony destruction and/or contamination, many orthopedic surgeons use external fixation devices to minimize, but not eliminate, the risk of infection and nonunion.

Occupational Exposure to Environmental Pathogens

It is an unfortunate reality that health care workers in general, and surgeons in particular, are exposed to bloodborne occupational hazards, including hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV. Body fluids considered potentially infectious include blood, cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, and amniotic fluid. Conversely, exposures to feces, nasal secretions, saliva, sputum, sweat, tears, urine, and vomitus are not considered potentially infectious, as the risk for transmission of HBV, HCV, and HIV infection from these fluids is extremely low.[133] PPE demonstrated to be effective include double gloving, using blunt needles for fascial closure, protective eye shields, impervious surgical gowns, and routine implementation of universal precautions.

The CDC estimates that more than 2.7 million US citizens (~1%) have chronic HCV (http://www.cdc.gov/hepatitis/HCV/HCVfaq.htm) and that 1.2 million Americans are living with HIV (http://www.cdc.gov/hiv/basics/livingwithhiv/index.html). One epidemiologic study has reported the prevalence of HIV and HCV to be as high as 20% to 65% and 10% to 45%, respectively, in an urban university hospital population for patients undergoing lymph node biopsy or drainage of a soft tissue infection.[134] A 2-year prospective study of penetrating trauma patients at an urban trauma center reported a 9% rate of HIV, HBV, or HCV, with 75% of these patients unaware of their seropositive status prior to admission.[135] In addition to reducing the potential inoculum by sixfold, double gloving affords the benefit of detecting glove failure, if indicator gloves are used.[136]

While prevention is the best course of action, certain measures taken after an exposure can decrease the risk of seroconversion. The first step involves treatment of the exposure site. Wounds and skin sites should be washed with soap and water, and mucous membranes flushed with water. There is no evidence to support applying antiseptics to the wound or expressing fluid to reduce the risk of transmitting a bloodborne pathogen. The CDC strongly discourages the application of caustic agents (eg, bleach) or the injection of antiseptics or disinfectants into the wound. Second, the exposure source (ie, the patient) should be evaluated for their HBV, HCV, and HIV status. If the status is unknown, the patient should be informed of the incident. The health care practitioner must be aware of applicable state and local laws regarding informed consent for serologic testing. Testing of needles or other sharp instruments involved in the exposure is not acceptable as a replacement or complement to testing the source patient. Additional up-to-date resources and recommendations are available via the National Clinician's Postexposure Prophylaxis (PEP) Hotline (PEPline, 888-448-4911) or via http://nccc.ucsf.edu/clinical-resources/pep-resources/pep-guidelines/.

When an exposure to HBV occurs, the risk of seroconversion is dependent on the degree of contact (ie, size of the inoculum) and the hepatitis B e antigen (HBeAg) status of the source. For example, if the patient is HBeAg positive, the risk of developing HBV infection is about 50%, compared to 25% if the patient is HBeAg negative. PEP includes hepatitis B immune globulin (HBIG) and, possibly, the hepatitis B vaccination series, depending on the hepatitis B antigen status of the patient and the antibody status of the at-risk health care worker. If indicated, HBIG should be given as soon as possible, since early administration after exposure to hepatitis B surface antigen–positive blood can provide an estimated 75% protection from HBV infection.[133]

In contrast to HBV, HCV is not efficiently transmitted via occupational exposure. It is estimated that HCV seroconversion after accidental percutaneous exposure from an HCV-positive source occurs 1.8% of the time, and some have suggested that transmission occurs only from puncture by hollow-bore needles. Transmission has never been reported after intact or nonintact skin exposure to blood and only rarely occurs after exposure of mucous membranes to blood. Currently, IVIG is not recommended after occupational HCV exposure. The rationale is based on several clinical observations, including the following: (1) HCV infection does not incite a protective antibody response; (2) studies of IVIG use for PEP in virus and HBV cannot be extrapolated to HCV; and (3) HCV IVIG use in chimpanzees has failed to prevent HCV seroconversion after exposure.[133] There is no evidence that the administration of interferon-α or antiviral agents prevents HCV infection after occupational exposure, and their use is not currently recommended. The exposed health care worker should be tested for baseline HCV viral status and should have continued close follow-up for 12 months for the purpose of early identification should seroconversion occur. Transient suppression of viremia can occur with acute HCV infection, even among those who progress to chronic HCV, so a single negative test is not enough to rule out infection.[137] Additionally, the health care worker should contact the CDC Hepatitis Information Line (888-443-7232) or see http://www.cdc.gov/hepatitis/hcv/index.htm.

Like HCV, transmission of HIV occurs rarely after occupational exposure. The CDC estimates the risk of seroconversion at approximately 0.3% following a percutaneous exposure to HIV-infected blood and 0.09% after exposure of a mucous membrane. For exposure to fluids or tissues other than HIV-infected blood, the risk of transmission has not been quantified but is probably much lower. In 2013, the US Public Health Service updated the recommendations for HIV PEP to include three agents: raltegravir and Truvada (tenofovir plus emtricitabine).[138] To maximize the possibility of protection, the health care worker exposed to HIV should be evaluated within hours, and PEP should be initiated

as soon as possible. A baseline HIV test should be performed, and HIV antibody testing should be performed for at least 6 months after exposure (at 6 weeks, 12 weeks, and 6 months). A 4-week regimen is advised for most HIV exposures. If the source person's virus is known to be resistant to the routine PEP regimen, selection of an alternate regimen is highly recommended.

CHRONOLOGIC APPROACH TO PREVENTION, RECOGNITION, AND TREATMENT OF INFECTIONS IN TRAUMA PATIENTS

Resuscitation Bay

Efforts to minimize infection must be initiated as soon as the patient arrives in the trauma bay. Although the initial focus will appropriately center on control of hemorrhage and initiation of resuscitation, these efforts will reduce the risk of infection as well. Restoration of adequate blood flow and oxygen delivery is the first step in reducing the incidence of infection. It has been clearly shown that the incidence of infection from invasive procedures in the ICU, such as insertion of a central venous line, is dramatically decreased by employing handwashing, full-barrier precautions, and chlorhexidine skin preparation as part of an evidence-based procedural bundle to prevent infection.[139] Full-barrier precautions may not always be practical in severely injured victims, but suspension of proven infection control measures and sterile technique for invasive procedures should be the rare exception. Maintenance of normothermia likewise represents optimal treatment for the trauma patient and has the additional benefit that it will decrease the likelihood for development of infectious complications.[61] Contaminated wounds should be cleaned and/or formally debrided in an expeditious time frame, although more recent reviews of experience in high-energy orthopedic injuries have downplayed the importance of time to debridement as the most important factor to prevent osteomyelitis.[140]

Prophylactic or empiric antibiotics, if indicated, should be initiated in the trauma bay. Antibiotics should be started in patients with open fractures or penetrating abdominal injuries and in any patient in whom there is a high likelihood of injury to a hollow viscus.[131,141] Due to the hostile environment in which military injuries occur, current recommendations are that injured soldiers start oral or parenteral antibiotics as soon as possible if there is any break in the skin.[142] Patients with blunt mechanisms who require operative interventions should receive perioperative antibiotic prophylaxis according to established evidence-based guidelines. Antibiotic choices for different anatomic regions are compiled in Table 21-6.

Operating Room

The conduct of operative interventions can significantly impact the likelihood of postoperative infectious complications. The primary factors determining the risk for infection are the nature and magnitude of the traumatic injury requiring surgical intervention. The surgeon must remember that the highest initial priority during an exploratory laparotomy for hemorrhagic shock is bleeding control and not control of enteric content. After acute hemorrhage control, it is appropriate to stop ongoing leakage from the bowel and to evacuate gross contamination. In addition to the bacterial contamination arising from enteric leakage, disruption of gastrointestinal integrity also releases foreign bodies (eg, undigested food), mucin, and bile. These adjuvant substances significantly decrease the bacterial inoculum needed for clinical infection via two mechanisms. First, some adjuvant substances augment bacterial growth or stimulate bacteria to express virulence factors.[143] Second, they may interfere with host defense mechanisms such as the function of innate immune cells.[15] For example, the detergent activity of bile can lyse polymorphonuclear leukocytes and macrophages. Blood and devitalized tissue are two additional adjuvant factors frequently present. Blood (specifically hemoglobin) can be converted to a leukotoxin by some enteric bacteria.[144] Fibrin clots sequester bacteria and make them inaccessible to host phagocytes, and this may predispose to late development of intra-abdominal abscesses.[145,146] Devitalized, ischemic, or necrotic tissues are also potent sources of damage/danger signals that activate host immune cells and exacerbate acute inflammation. At the same time, these substances can interfere with phagocytosis and oxidative killing mechanisms of the host defense cells.[9,147] Thus, to the extent possible, blood and blood clots should be removed from the peritoneal cavity. This can be accomplished by irrigating the peritoneal cavity with a goal of removing the obvious contamination, foreign material, and blood. It is worth noting that a prospective randomized study showed no benefit to formal meticulous debridement to remove fibrinous debris from the peritoneal cavity in established peritonitis.[148] Additionally, neither a meta-analysis of a rather heterogeneous set of studies of intraoperative irrigation nor a recent single-center, randomized controlled trial of different volumes of intra-abdominal irrigation in emergency trauma laparotomy demonstrated benefit in preventing SSI.[149,150] Increased deep SSI in the large-volume (20 L) irrigation group compared to 5 L of irrigation suggests that the least amount of irrigation sufficient to remove gross contamination and adjuvant material should be used, avoiding leaving exogenous fluid in the abdominal cavity.

Evidence-based guidelines for antimicrobial prophylaxis of trauma recommend broad-spectrum agents with activity against the anticipated pathogens that are likely to be encountered at the anatomic area of injury.[141] With respect to the infectious risk after blunt or penetrating abdominal injury, this requires coverage against colonic bacterial flora. In the case of abdominal trauma, agents with activity against aerobic and anaerobic bacteria are recommended.[151-153] However, extended courses of antibiotics are not indicated, even in the setting of hollow viscus injury, and there is no current evidence to support continued antibiotic administration following damage control operations prior to abdominal fascial closure.[54,141] With injuries to the extremities, the most likely

pathogens will be aerobic gram-positive bacteria, particularly *Staphylococcus* species. Injury to maxillofacial structures requires antibiotic prophylaxis with activity against normal oral flora, and neurosurgical procedures most often employ agents similar to those used for the extremities.

Little is known about the pharmacology of antibiotics in the acute resuscitative phase of trauma. Most available pharmacologic data derive from healthy individuals and, therefore, cannot be applied directly to injured patients, but there are a few studies in critically ill patients. Buijk et al[154] described a cohort of 89 septic patients who received aminoglycosides. The volume of distribution was significantly higher than in those without septic shock, and the maximum antibiotic concentration achieved was significantly lower. In a study of patients who required significant resuscitation with fluids and blood during a laparotomy, the volume of distribution was expanded and correlated with the degree of fluid resuscitation.[155] Antibiotic elimination was also more rapid in these injured patients compared with normal controls.

With massive blood loss, antibiotic prophylaxis requires frequent redosing to maintain plasma and tissue levels above the mean inhibitory concentration (MIC). Animal models of experimental infection after hemorrhagic shock report better prophylaxis with increasing doses of appropriate intraoperative antibiotics.[156] Large-volume resuscitation and altered endothelial permeability with trauma or burns result in an expanded volume of distribution. Renal dysfunction from hypovolemia, myoglobinuria, or radiologic contrast often accompanies severe injury, but the potential risk of a nephropathy has no impact on acute antibiotic dosing. The greatest risk for subsequent infectious complications arises from underdosing rather than overdosing in acute trauma.

The conduct of the operation itself significantly impacts the risk of infection. Damage control resuscitation has the collateral benefit of positively impacting the incidence of postoperative infectious complications.[157,158] In most cases, vascular reconstruction and bowel anastomoses, if needed, should be delayed until the patient is warm, adequately resuscitated, and hemodynamically stable. If the patient is hemodynamically stable, euvolemic, and normothermic, then there is no adverse impact to definitively managing abdominal, vascular, neurosurgical, or orthopedic injuries during the first operation. In a grossly contaminated wound, primary closure is associated with an unacceptably high wound infection rate. Delayed primary closure (DPC), a practice dating back to Ambrose Pare, was advocated by surgical pioneer John Hunter in the 1700s and popularized during World War I.[159] It is based on development of fine granulations within the wound prior to definitive closure. Thus, DPC combines the infective resistance of healing by secondary intention with the cosmetic benefits of primary closure. Randomized prospective trials have reported significantly lower rates of wound infections compared to primary closure of grossly contaminated wounds.[160-162]

The management of penetrating wounds to the colon has evolved since World War II, when the diverting ostomy reduced mortality rates to about 30% in the preantibiotic era. With improvements in trauma resuscitation and accumulating experience with antibiotics, investigators began to question whether fecal diversion was necessary after colonic repair. Initially, Stone and Fabian[163] published the first prospective randomized trial of colostomy versus primary repair. They excluded patients with "high-risk" criteria such as shock, hemorrhage, greater than two organs injured, gross contamination, operative delay greater than 8 hours, injury requiring resection, and loss of the abdominal wall. Subsequent investigations have reported that primary colon repair, even in the face of "high-risk" criteria, is associated with a decreased incidence of infectious complications compared to diverting ostomy.[164-166] In a more recent American Association for the Surgery of Trauma multicenter cohort study of predominantly penetrating rectal injuries, for patients with intraperitoneal injury, diversion was not associated with better outcomes; distal rectal washout and presacral drainage at the time of the index operation for extraperitoneal injuries were independent risk factors for developing subsequent abdominal complications.[167]

Open pelvic fractures are associated with extremely high morbidity and mortality, including from septic complications. Diverting colostomies are often placed in such patients, but the evidence supporting this approach is weak and generally derived from small retrospective studies. One systematic review found no difference in the overall infection rate with or without colostomy, with the exception of a lower complication rate when colostomy was used for perineal/rectal wounds.[168] Subsequent single-center retrospective studies have demonstrated a higher rate of mortality with rectal laceration in the setting of shock and absence of diversion.[169,170] More studies are required to provide definitive recommendations, but diversion is still the preference for many surgeons in the setting of extraperitoneal rectal injury.[171]

Recommendations for management of extremity fractures continue to evolve. A large study found that the most important factor in outcome was early transfer to a trauma center for definitive management.[140] Specifically, this study called into question the benefit of early operative debridement of open fractures, inasmuch as time to operative debridement did not confer a statistically significant benefit. The concept of damage control has also been applied to orthopedic injuries.[172] The military experience in Iraq and Afghanistan also underscores the utility of this concept, coupled with more liberal use of external fixation devices to minimize infectious complications in this hostile environment.[173] With proper debridement and acute management of the fracture, bacteria inoculated into fractures at the time of injury are rarely isolated from postoperative infections. Rather, hospital-acquired flora are almost universally responsible for infections in fractures.[174]

Intensive Care Unit and Early Postoperative Period

Infectious complications are commonly encountered in the early postoperative period and are even more likely to be seen

TABLE 21-12: Health Care–Associated Infections (HAI) in the Surgical/Trauma Intensive Care Unit

Pneumonia

Sinusitis

in patients who require ongoing critical care (Table 21-12). Clinicians should have a high index of suspicion and consider potential sources of infection in the context of the injuries, characteristics of the patient, likely offending organisms, and length of hospital stay. The immediate postoperative course of a severely injured patient typically involves a vigorous systemic inflammatory response.[100] Clinical signs such as mild to moderate fever and tachycardia are almost universal. Furthermore, it is now known that danger signals released from injured tissue activate innate immune responses via the same TLR pathways stimulated by bacterial infection. Leukocytosis is a common manifestation, so monitoring the WBC count immediately after injury has little utility. It is useful to keep the overall trajectory of the patient in mind before automatically initiating a series of expensive and low-yield investigations (eg, blood cultures, urinalysis, x-rays). Identifying infection is particularly difficult in the ICU setting.[175] Injured patients are at increased risk for development of nosocomial infections such as pneumonia, central line–associated bloodstream infections (CLABSIs), catheter-associated urinary tract infections (CAUTIs), *C difficile* infection (CDI), and SSI; however, critically ill trauma victims are susceptible to severe sepsis and septic shock as well.

The most recent update of the Surviving Sepsis Campaign guidelines restates the fundamental definition of sepsis as a "life-threatening organ dysfunction caused by a dysregulated host response to infection." Specifically, the diagnosis of sepsis now requires an increase in the Sequential Organ Dysfunction Score (SOFA) from baseline by 2 points or greater in the setting of suspected or confirmed infection. This change was initiated in order to provide more objective clinical criteria that were demonstrated to be more predictive than the SIRS criteria intensivists have relied on to date.[176] The 2018 update of the Surviving Sepsis Campaign includes a directed guideline for the first hour of care after sepsis is recognized

TABLE 21-13: Hour 1 Surviving Sepsis Campaign Bundle of Care

Measure lactate level. Remeasure if initial lactate is >2 mmol/L.
Obtain blood cultures prior to the administration of antibiotics.
Administer broad spectrum antibiotics.
Begin rapid administration of 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L.
Apply vasopressors if patient is hypotensive during or after fluid resuscitation to maintain MAP ≥65 mm Hg.
Time of presentation is defined as the earliest time of triage or from the earliest chart annotation consistent with all elements of sepsis (formerly called severe sepsis) or septic shock ascertained through chart review.

Source: Adapted, with permission, from Levy MM, Evans LE, Rhodes A. The Surviving Sepsis Campaign Bundle: 2018 update. *Crit Care Med.* 2018;46(6): 997-1000.

(Table 21-13). It is unclear how the Sepsis 3 definitions will differently affect the care of the critically injured trauma patient with suspected infection, as clinicians adjust to applying the new evaluative strategy. While the intent behind these changes is to allow for more prompt recognition and discrimination of sepsis from other physiologic responses, prospective evaluation of this new strategy and the impact on timely, appropriate resuscitation and early institution of broad-spectrum antimicrobial agents is essential.

HEALTH CARE–ASSOCIATED INFECTIONS

Pneumonia

As in sepsis, the definition of pneumonia has undergone reevaluation and the result is controversial. Currently, pneumonia can still be divided into community-acquired pneumonia (CAP) and hospital- or health care–associated pneumonia (HCAP), with the former being present on admission and the latter manifesting later in the hospital course. HCAP can further be divided into early (<4 days) and late (≥4 days). These distinctions are more than merely pedantic, as pneumonia that develops later is more likely caused by multidrug-resistant organisms. Patients with CAP or early HCAP who have no known risk factors should be treated with ceftriaxone or levofloxacin (or equivalent), ampicillin/sulbactam, or ertapenem in accordance with local prevalence patterns.[177]

Within the broader category of HCAP, an important subgroup are patients on mechanical ventilation who develop pneumonia. Ventilator-associated pneumonia (VAP) is a leading cause of morbidity and mortality in the injured population and remains a daunting diagnostic challenge. The definition of VAP is very nonspecific, does not correlate well with histopathologic findings of pneumonia, and is a poor-quality measure in the ICU. In 2013, in an effort to improve the surveillance of noninfectious etiologies of pulmonary dysfunction in mechanically ventilated patients, the NHSN

released the guidelines for detecting ventilator-associated events (VAEs).[178] This new guideline replaces the older definition of VAP; it is intentionally broad in order to encompass all pulmonary complications affecting critically patients, including ARDS, atelectasis, and cardiogenic sources of pulmonary edema. The new definition consists of a three-tiered progression from ventilator-associated condition (VAC) to infection-related ventilator-associated condition (IVAC) to probable ventilator-associated pneumonia (PrVAP). This is a shift away from reporting only on the infectious complications that affect mechanically ventilated patients and is thought to improve comparability, facilitate automation, and minimize gaming in the reporting of pulmonary dysfunction in ICU patients.

The first tier of VAE is a VAC. This occurs when a patient (ventilated for at least 2 days) has more than 2 days of worsening oxygenation (defined by >0.2 increase in the minimum daily fraction of inspired oxygen or positive end-expiratory pressure increase of >3 cm H_2O). The second-tier VAE is the IVAC that occurs when the criteria for VAC have been met in the presence of (1) fever, (2) abnormal WBC (>12 or <4 × $10^3/mm^3$), and (3) the initiation of antibiotics for >4 days. The third VAC tier consists of possible VAP (PoVAP) and PrVAP. PoVAP is considered when there is the presence of purulent secretions and/or positive cultures. PrVAP must meet the specific diagnostic requirements for culture growth based on the method in which the samples were obtained. The first two VAE tiers of VAE are intended as quality metrics, whereas the third tier is meant to be used for internal quality improvement only.

Despite the intentions of the improved surveillance and reporting structure of VAEs, there have been little data to support its effectiveness in improving diagnostic discrimination. In a retrospective analysis of over 1300 patients from 11 North American ICUs, Muscedere et al[178] found a 10.5% VAC rate and 4.9% IVAC rate, but an 11.2% VAP rate (based on traditional definitions). Further, interrater reliability was very low (VAP and VAC $\kappa = 0.18$ and VAP and IVAC $\kappa = 0.19$), and the VAC rates did not change with the increase in preventative measures. However, VAC and IVAC were both associated with a significantly higher morbidity and mortality than VAP. Additional studies have demonstrated that the new criteria are identifying a fundamentally different group of patients, in some cases failing to detect up to 75% of VAP.[179]

While the criteria for VAE were designed to be objective and reproducible by electronic medical record review, the clinical diagnostic criteria for VAP are more subjective. Diagnosing pneumonia in critically ill trauma patients is particularly difficult because physical examination is often limited in the obtunded or sedated patient. In addition, lung trauma, including contusions and lacerations, as well as hemopneumothorax particularly complicate the interpretation of chest x-rays in trauma patients. Bacterial colonization of the endotracheal tube and trachea is universal after a few days of mechanical ventilation, so distinguishing between this and a clinically significant lung infection becomes challenging as well. The clinical pulmonary infection score (CPIS) initially described by Pugin to compare invasive and noninvasive pulmonary sampling techniques for VAP has been used to assist in the diagnosis of VAP, but subsequent trials have shown that CPIS alone is not sufficiently accurate to diagnose or rule out VAP.[180,181] It is difficult to make the diagnosis, as a gold standard really does not exist.

Diagnostic sampling of the respiratory tract can assist in differentiating tracheal colonization from true infection and in guiding antibiotic therapy. Three modalities of diagnostic sampling of the lower respiratory tree—BAL, bronchoscopic protected specimen brushing, and blind mini-BAL—are currently employed, and the specimens are sent for quantitative or semiquantitative microbiologic culture. A positive confirmatory culture is defined as a BAL or mini-BAL culture greater than 10^4 CFU/mL or protected specimen brush greater than 10^3 CFU/mL. Some controversy remains as to the optimal mode for sampling, and the quantitative criteria differ depending on the diagnostic method of diagnosis. To make matters more confusing, in 2016, the American Thoracic Society guidelines advise that noninvasive sampling with semiquantitative cultures should be used to diagnose VAP, rather than invasive (BAL or mini-BAL) sampling with quantitative cultures or noninvasive sampling with quantitative cultures.[182]

The impact of all of these diagnostic criteria changes on VAP rates and outcomes are not yet clear. However, like all other infections in the critically ill, when pneumonia is identified, it is important to institute therapy as soon as possible. Current recommendations for antimicrobial coverage for pneumonia, and especially VAP, emphasize beginning with broad-spectrum coverage and then de-escalating or narrowing the coverage once culture results are obtained. Inadequate initial antibiotic therapy has repeatedly been shown to be associated with worse outcomes and increased mortality.[183-185] Again, knowledge of local antibiograms should be used when choosing initial therapy. Patients with late HCAP or VAP are at risk of having multidrug-resistant bacteria including *Pseudomonas*, *Acinetobacter*, and extended-spectrum β-lactamase producers such as *Klebsiella* and *E coli*, especially if previously exposed to antibiotics. Gram-negative coverage should include antipseudomonal agents such as piperacillin/tazobactam, cefepime, imipenem, or meropenem. The addition of an aminoglycoside for "synergistic effect" against *Pseudomonas* is not supported by current guidelines. With the increasing prevalence of MRSA, vancomycin should always be included as initial empiric coverage. Once pneumonia has been diagnosed and therapy initiated, the next question is the appropriate duration of therapy. A study by Chastre and colleagues[186] reported that an 8-day antibiotic course was equivalent to 15-day therapy for VAP. The foremost consideration should be the clinical status of the patient, with a good response consisting of resolution of elevated temperature, resolving leukocytosis, decreased respiratory secretions, and improved oxygenation. Radiographic resolution often lags behind clinical improvement.

In the ICU, there are abundant data focusing on the utility of process measures designed to prevent VAP.[187] All

postoperative patients are at risk for pulmonary complications, and, therefore, aggressive mobilization and pulmonary toilet should be employed when possible. Unfortunately, injuries such as rib fractures that interfere with coughing and deep breathing, orthopedic injuries that limit mobility, and traumatic brain injuries resulting in an altered mental status may complicate therapies employed to combat altered mucociliary clearance and pulmonary physiology. Measures such as routine hand hygiene and elevation (30–45°) of the head of bed to decrease the likelihood of reflux have resulted in dramatic decreases in VAP rates as part of care bundles. Reverse Trendelenburg positioning is an acceptable alternative in patients who must remain supine due to spinal precautions or other restrictions. The duration of mechanical ventilation is the greatest risk factor for development of VAP, with an estimated risk of developing pneumonia of 1.2% to 3.5% per day of mechanical ventilation.[188] Every effort should be made to achieve liberation from the ventilator as soon as possible. Patients should be assessed daily for a trial of spontaneous breathing, and extubation should occur if the patient successfully passes the trial.[189-191]

Catheter-Associated Urinary Tract Infection

CAUTI is the most common hospital-acquired infection and is almost universally associated with an indwelling urinary catheter.[192-194] Most injured patients in the ICU require urinary drainage, and differentiation between urinary colonization (asymptomatic bacteriuria) and infection can be difficult. The diagnosis of CAUTI requires a quantitative urine culture with greater than 10^5 CFU/mL along with at least one of the following clinical criteria: (1) temperature greater than 38.5°C; (2) WBC greater than 10,000 or less than 3000; and (3) urinary urgency, dysuria, or suprapubic tenderness.[195] Diagnosis can be made with greater than 10^3 CFU/mL if there is also pyuria (>3 WBC per high-power field) or a positive leukocyte esterase. Clinically significant CAUTI usually occurs in the setting of urinary trauma and/or repair. Responsible organisms in hospitalized patients include *E coli*, *Pseudomonas*, *Proteus*, *Enterobacter*, *Serratia*, and *Citrobacter*.[196] Gram-negative coverage is indicated, but local resistance patterns should be taken into consideration when empiric antimicrobials are selected prior to confirmatory culture results. Fortunately, many systemic antibiotics are excreted via the kidney and will achieve urinary levels that far exceed the MICs for most of these pathogens.

Central Line–Associated Bloodstream Infection

CLABSIs have decreased in incidence in recent years, but they remain a source of serious morbidity, increased hospital and ICU stay, increased costs, and potential death.[197] The decision to insert a central line should not be taken lightly. Indications for central access include poor peripheral access, administration of total PN, and administration of high-dose vasoactive medications. Large-bore introducers are also commonly inserted to assist in the acute resuscitation of unstable patients. Often, the clinician is faced with the difficult decision to remove necessary central access or maintain the catheter in the face of potential line sepsis.

In trauma patients in whom catheters were placed emergently using nonsterile technique, the lines should be removed and replaced, if needed, with aseptically inserted catheter(s) at a new site(s). Femoral venous catheters are associated with unacceptably high rates of both infection and deep vein thrombosis, and catheters at these sites should always be removed as soon as possible. The use of peripherally inserted central catheters (PICCs) is associated with a lower incidence of CLABSI. Routine guidewire exchange at predefined intervals does not decrease the rate of CLABSI and may even increase the incidence. Using an evidence-based approach, Pronovost et al[198] reported a 66% sustained reduction in the incidence of CLABSI by removing unnecessary catheters, avoiding the femoral site, using full-barrier precautions during insertion, hand washing, and cleaning the skin with chlorhexidine. The data regarding routine antibiotic-impregnated catheter use is not clear; however, if the local CLABSI rate exceeds the NHSN surveillance data, then consideration should be given to using these types of catheters.[199]

The diagnosis of CLABSI is one of exclusion and requires the presence of bacteremia or fungemia in a patient in whom there is no alternate source of infection. Unless there are local signs of infection (ie, redness and purulence), a search for other infectious etiologies should always be performed first. Infected catheters are frequently thrombogenic, and the first sign of infection may be an inability to aspirate blood through the port. It is important to acknowledge that CLABSI is a surveillance definition instituted by the CDC for ease in identification and tracking of bacteremia, and there is a significant risk of overestimation of bacteremia in surgical patients in particular, due to the likelihood of bacterial translocation from the gut as a source.[200] The older clinical definition of catheter-related bloodstream infection (CRBSI) favored by infectious disease societies includes more specified criteria: (1) positive semiquantitative culture (>15 CFU/cm catheter segment); (2) quantitative (>10^3 CFU/cm catheter segment) culture with the same organism isolated from blood cultures; and (3) simultaneous quantitative blood cultures with greater than 3:1 central venous catheter to blood ratio of the same bacterial species.

Surgical Site Infections

Surgical site infections (SSIs) arise at the site of a previous surgical procedure, defined as a location in which an incision had been made or a procedure performed.[201,202] Classification of SSI is based on the anatomic depth of the infection and whether the infection is present in the wound or within an organ space. Superficial and deep incisional SSIs are differentiated based on whether the infection extends below the fascial layers (deep SSI). By convention, SSIs are infections identified within 30 days of the initial surgical procedure.

Superficial SSIs are not infrequent in trauma patients based on the wound classification, disruption of environmental barriers, bacterial inoculation at the time of injury, and dysfunction of host defenses seen with injury. Diagnosis of a superficial SSI is determined by the presence of at least one of the following clinical criteria at the site of a surgical procedure: (1) purulent drainage from the surgical incision; (2) culture of organisms from an aseptically obtained fluid or tissue sample from the incision; (3) clinical signs or symptoms of infection; or (4) clinical diagnosis of infection by the surgeon (eg, the need to open wound). Conditions such as stitch abscesses and erythema or serous drainage at external fixator pin sites do not constitute superficial SSI. In contrast to superficial SSI, a deep SSI involves the deeper soft tissues (eg, fascial and muscle layers) at the site of the surgical incision and at least one of the following: (1) purulent drainage deep to the fascia or muscle layers; (2) spontaneous fascial dehiscence; or (3) identification of a deep abscess on direct examination, during reoperation, or on radiologic examination. Finally, an organ space SSI involves anatomic structures (eg, organs or spaces) that were manipulated during the surgical procedure. In addition, diagnosis of an organ space SSI is based on at least one of the following: (1) purulent drainage from a drain placed into the organ or space (either incisional or percutaneously drained); (2) culture-positive fluid or tissue; or (3) the presence of an abscess during reoperation or radiologic evaluation.

Treatment of SSI depends on the location and depth of infection.[203,204] Superficial SSIs are treated by opening of the surgical incision followed by local wound care. There is no demonstrated benefit to systemic antibiotic treatment for superficial SSIs in the absence of systemic symptoms. For deep SSIs and organ space infections, it is advisable to try to obtain cultures of any purulent drainage, since prior antibiotic selection pressure and the increasing incidence of resistant strains within hospitals make it difficult to predict antimicrobial responses.[105] In the face of negative cultures, clinicians should base antibiotic choices on the anticipated pathogens at the anatomic site. It is well to keep in mind that infections that arise after treatment with a longer course of antibiotics will likely be resistant to, or perhaps only partially sensitive to, the prior agent used. Thus, while awaiting culture and sensitivity results, it is wise to employ a different antibiotic agent from a different class of antibiotics.

Clostridium difficile Infection

C difficile is a gram-positive anaerobic bacterium that is a frequent cause of infectious colitis.[205] It is a part of the normal colonic flora in 2% to 5% of the healthy population and is normally nonpathogenic. The incidence in the trauma population has been reported to be 3%.[206] Disruption of the colonic microbiota by antibiotics causes relative overgrowth of this organism. Although the occurrence has been reported with all antibiotics, the association is highest with clindamycin and third-generation cephalosporins. The organism reproduces via spore formation and should be considered highly contagious, as the spores are heat and stomach acid resistant. Additionally, alcohol-based hand sanitizers are ineffective in eradicating the spores. Soap-and-water hand washing is mandatory after contact with a contagious patient. Since 2001, there has been a significant increase in the incidence of CDI to approximately 84 per 100,000, and this has coincided with an increased number of serious or fatal infections.

Increasing failure rates with metronidazole therapy have led to the issuance of new guidelines that no longer recommend metronidazole as first-line therapy in adults.[207] Oral vancomycin (125 mg four times a day) or fidaxomicin (200 mg twice daily) should be administered for 10 days in both nonsevere and severe CDI. This new recommendation was made based on evidence that use of vancomycin or fidaxomicin provides patients with the highest likelihood of sustained symptom resolution 1 month after treatment. In patients with nonsevere cases of CDI, metronidazole may still be administered when patients are unable to obtain or be treated with vancomycin or fidaxomicin. In patients with severe, complicated CDI with shock, hypotension, ileus, or megacolon, vancomycin 500 mg four times a day is recommended in combination with parenteral metronidazole. Patients with ileus can be administered vancomycin via retention enema.

Surgical therapy for CDIs was historically limited to performing a subtotal colectomy in patients who developed severe complicated infection unresponsive to medical therapy. The result was often associated with a high mortality. More recently, there has been considerable interest in a different surgical approach using laparoscopic placement of a loop ileostomy for antegrade flushing of the colon. Intraoperatively, the colon is lavaged with warm polyethylene glycol, and postoperatively, vancomycin is instilled via the ileostomy antegrade through the colon. In a small trial, the mortality of this approach was 19% versus 50% in historic controls of subtotal colectomy. Furthermore, in the loop ileostomy group, 83% of the operations were done laparoscopically, and there was a greater than 90% salvage rate of the colon.[208] There are still no clear indications for determining which patients should undergo this type of surgical intervention; however, contraindications include colonic necrosis or perforation as well as the presence of abdominal compartment syndrome.[205]

Another therapeutic modality for recurrent CDI that is gaining popularity is fecal microbiota transplantation (FMT) to repopulate the normal colonic flora. While the first report of administration of a fecal enema for severe sepsis associated with CDI was in 1958,[209] the first prospective clinical trial of FMT via nasoenteric feeding tube did not occur until 2013.[210] The investigators in this trial compared three groups as follows: (1) vancomycin followed by colonic lavage and then FMT delivered via a nasoduodenal tube; (2) vancomycin followed by colonic lavage; and (3) vancomycin alone. The trial was stopped early because almost all of the patients in the control groups had CDI recurrence, whereas the success rate in the FMT group was 81%. Although FMT is still considered an investigational therapy by the US Food and Drug Administration, current guidelines strongly recommend FMT as therapy for multiply recurrent CDI (at least

two prior episodes).[207] The dramatic growth in microbiome science and supportive laboratories for the screening, processing, and banking of stool specimens and the increasing acceptance of oral encapsulation of processed donor fecal material suggest that this therapy will only continue to expand in indication.

LATE INFECTIOUS COMPLICATIONS

Overwhelming Postsplenectomy Infection

Historically, the spleen was considered expendable and the prevailing opinion was that it could be removed with relative impunity. Our current understanding is that the spleen plays an important role in the production of immune mediators that aid in the clearance of bacteria and viruses. Splenic mediators (opsonins) coat circulating bacteria and viruses and convert them into immune complexes, facilitating clearance.[211,212] *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae* type b, and influenza virus are important vaccination targets. It is difficult to estimate the current incidence of overwhelming postsplenectomy infection, as most of the published data on OPSI antedate the widespread availability of the pneumococcal and *H influenzae* vaccines. The time since splenectomy is an important risk factor because 50% to 70% of admissions to the hospital for serious infections occur within the first 2 years. A recent retrospective cohort study of 20,132 Swedish patients who underwent splenectomy for a variety of indications between 1979 and 2009 found an overall incidence of hospital admission for sepsis of 5.7% (95% CI, 5.6%–6.0%).[213] These investigators found that the incidence of sepsis and mortality was lower if splenectomy occurred secondary to trauma versus a hematologic malignancy. Interestingly, they did not observe a major impact following initiation of routine vaccination, except in the subjects undergoing splenectomy for hematologic conditions. In a more recent series from 173 ICUs across Germany, pneumococcal infections accounted for the majority of cases likely due to the lower overall vaccination rate than in the Swedish study.[214]

Postsplenectomy Vaccinations

The optimal timing of administration of vaccines after traumatic splenectomy is unknown, but data suggest an increasing trend for elevated functional antibody activity with a delay in vaccination and improved immune antibody response to vaccination at 14 days after surgery.[215] Most trauma patients will be discharged from the hospital within this interval; given that the population of trauma patients is characterized by poor follow-up, it is generally advised to vaccinate the patient prior to discharge (Table 21-14). ACIP recommends the use of the 23-valent polysaccharide pneumococcal vaccine for persons age 2 to 64 years who have functional or anatomic asplenia. The CDC suggests a single booster dose for those older than 2 years of age who are at high risk for serious pneumococcal infection and those most likely to have a rapid decline in antibody titers. A single revaccination should be given at least 5 years after the first dose, with further dosing not recommended routinely. *H influenzae* vaccination with ActHIB conjugate vaccine is recommended. There currently is no recommendation to revaccinate for *H influenzae* type b (Table 21-14). There are two types of meningococcal vaccinations recommended for patients with impaired splenic function in the United States: a quadrivalent meningococcal conjugate vaccine that protects against meningococcal

TABLE 21-14: Recommendations for Postsplenectomy Vaccinations in Adults Undergoing Emergent Splenectomy*

Vaccine	Primary series	Revaccination (booster)
Pneumococcal vaccine • PCV13 (Prevnar) plus PPSV23 (Pneumovax)	1 dose of PCV13 followed by 1 dose of PPSV23 ≥8 weeks later¶	PPSV23 every 5 years[Δ◊]
***Haemophilus influenzae* type b vaccine** • Hib	1 dose§	Not applicable
Meningococcal serotype ACWY vaccine • MenACWY (Menactra or Menveo)	2 doses at least 8 weeks apart¥	Every 5 years
Meningococcal serotype B • MenB-FHbp (Trumemba) or MenB-4C (Bexsero)	2 doses of MenB-4C at least 1 month apart or 3 doses of MenB-FHbp at 0, 1 to 2, and 6 months‡	Not applicable
Seasonal influenza virus	1 dose annually at the start of influenza season	Repeat annually at start of influenza season

*Available vaccine formulations and recommendations may differ outside of the United States.
¶If primary series already received (eg, due to concurrent immunocompromising condition or age >65 years), revaccinate with PPSV23 every five years. If only a single vaccine in the series has been received, refer to the UpToDate topic on prevention of sepsis in patients with impaired splenic function.
ΔSome experts prefer to give the second dose of PPSV23 three years after the first dose of PPSV in patients with sickle cell disease.
◊This recommendation differs from the Advisory Committee on Immunization Practices, which recommends a single revaccination dose of PPSV23 five years after the first PPSV23 dose.
§Hib vaccination is recommended for all adults who have not been previously vaccinated or if vaccination status is unknown.
¥If primary series already received, continue revaccinating every five years.
‡If not already received.

serotypes A, C, W, and Y (MenACWY [Menactra or Menveo]) and a univalent serogroup B vaccine (MenB-4C [Bexsero] or MenB-FHbp [Trumenba]). Both vaccines are given as a primary series. Only the quadrivalent vaccines require revaccination.

Surgical Site Infection After Discharge

In the modern health care environment, there is increased pressure for earlier hospital discharge. However, it must be recognized that with shorter hospital stays, the relative rates of postdischarge SSI have increased substantially, and the ability to detect postdischarge SSIs is limited by resources available to prospectively collect these data.[216] In a prospective study of 268 trauma patients, 33% of all patients with SSI were diagnosed after hospital discharge.[217] Trauma caregivers should educate patients about signs and symptoms of SSI at the time of discharge and request that they be notified if infections are identified. However, even with these systematic measures in place, patients describe feeling unprepared for the challenges of self-monitoring postoperative wounds and tend to overtriage.[218,219] Telehealth platforms, and mobile health apps in particular, provide an innovative solution for ongoing education and communication with patients at their most vulnerable time; evidence is growing to support the feasibility of user adoption and substitution of virtual care for in-person follow-up visits, even for wound assessment.[220-222] Smart-enabled devices for vital sign, wound temperature, and activity monitoring are increasingly available and used by consumers, but widespread integration of patient-centered mobile health apps within health system–based telemedicine platforms awaits reimbursement for such encounters and better interoperability for documentation and reporting.

KEY SUMMARY POINTS

1. Trauma patients are susceptible to infection because of their unique exposure to tissue trauma and common need for surgical interventions with breach of host defenses and subsequent inflammatory response.
2. Trauma surgeons require training in infection control and prevention including knowledge of vaccinations and antimicrobial prophylaxis, as well as management of relatively rare infectious disease exposures in the context of disaster management and critical care support.
3. Comprehensive care of patients who sustain traumatic injury requires a commitment to health care–associated infection triage and prompt treatment of infectious complications to ensure optimal outcomes.

KEY POINTS

- Of the approximately 1.4 million individuals who are evaluated for traumatic brain injuries in emergency departments in the United States each year, 1.1 million are treated and released, 240,000 are hospitalized, and 50,000 die.
- In patients with gunshot wounds to the head, the mortality rate is greater than 50% among those who are alive upon presentation to a hospital.
- When calculating a Glasgow Coma Scale score, confounding factors include alcohol and other drugs, hypotension, hypoxia, sepsis, hypothermia, and other systemic factors.
- Magnetic resonance imaging (MRI) scans provide higher resolution images of the brain, spinal cord, and other soft tissues than computed tomography scans.
- In patients with diffuse axonal injury, T2-weighted MRI scans may show multifocal hyperintense lesions at gray matter/white matter interfaces.
- As many as 90% of patients with a concussion do not exhibit loss of consciousness; however, when this does occur, it is usually brief.
- The modified Monro-Kellie hypothesis states that an increase in the volume of one component inside the skull (brain, intravascular blood, cerebrospinal fluid) or addition of a new component (hemorrhage, tumor) mandates a compensatory decrease in other components to maintain constant intracranial pressure.
- Relative indications for surgical elevation of a depressed skull fracture include depression of greater than 8 to 10 mm or greater than the thickness of the adjacent skull, a focal neurologic deficit due to compression of underlying brain, significant inward intrusion of bone fragments, and persistence of cosmetic deformity after overlying scalp swelling has subsided.
- An acute subdural hematoma with a thickness of greater than 1 cm or a midline shift of greater than 5 mm should usually be evacuated regardless of Glasgow Coma Scale score.
- When intracranial hypertension cannot be controlled by routine measures, hypothermia, barbiturate coma, and unilateral hemispheric decompressive craniectomy should be considered.

INTRODUCTION

Traumatic brain injury (TBI) remains frustratingly resistant to treatment. Several decades ago, progress in resuscitation, hemostasis, imaging, noninvasive management, critical care, rehabilitation, and emergency medical services organization brought about a decrease in mortality rates, but the failure to develop interventions targeted specifically to the injured brain has inhibited further improvements in outcome. New and developing insights into our classification and approach to TBI may soon pave the way for meaningful advances. Until then, clinicians who care for these patients must rely upon therapies that still await validation in appropriately constructed clinical trials.

TBI has been defined in many different ways. A good working definition is that it is a disruption or alteration of brain structure or function caused by external mechanical forces. The disruption may be variable in severity and may be transient or permanent. The causative external forces are diverse and include rapid acceleration or deceleration, direct compression, penetration and physical disruption of brain tissue, blast and other complex mechanisms, and various combinations of these and other etiologies. Mild TBI may be present despite absence of abnormalities on imaging studies. At the other end of the spectrum, severe injuries may be associated with large contusions, traumatic hematomas, or other immediately life-threatening structural lesions.

EPIDEMIOLOGY

The exact number of people who sustain TBI is unknown since some patients with severe systemic injuries do not survive long enough to undergo a thorough evaluation that would uncover the presence of brain injury. At the other end of the spectrum, many individuals suffering mild or moderate TBI choose not to seek medical care.

Many epidemiologic studies include only TBI patients who receive medical care in an emergency department. By this criterion, approximately 1.4 million people per year suffer TBI in the United States. Approximately 1.1 million are treated and released, 240,000 are hospitalized, and 50,000 die.[1]

Common causes of TBI include falls, motor vehicle collisions (MVCs), pedestrian impact, and assault. TBI has a bimodal age distribution, with the greatest risk in 0- to 4-year-olds and 15- to 19-year-olds. Falls predominate at the extremes of age, whereas MVCs are most common in teenagers and young adults. The incidence in males is 1.5-fold higher than in females. The youngest patients are often victims of abuse. Military personnel compose a statistically small number of the overall volume of TBI patients, but combat operations cause them to have a higher incidence of penetrating and blast injuries.

TYPES OF INJURY

Classification and Management

PRIMARY VERSUS SECONDARY INJURY

TBI is a dynamic process. Knowledge of the natural history of the various types of TBI is essential for optimal care because management priorities for a given patient may change rapidly as his or her underlying pathophysiology changes.

Primary injuries result directly from the forces imparted at the time of the accident, or primary insult. These may include both focal disruption of tissue, such as contusions and hematomas, and diffusely distributed damage.

Secondary insults are defined as those occurring subsequent to the initial impact. These injuries may include hypoxemia, ischemia, seizures, fever, hypoglycemia, and other systemic (nonneurologic) events that can directly impact the brain's ability to respond to a primary insult. Thus, secondary insults may lead to secondary injuries. A brief period of mild hypotension or hypoxia may be tolerated quite well by an uninjured brain, but the same minimal secondary insult can be devastating if it occurs soon after a brain injury. A neurosurgeon may spend several hours operating on an acutely injured patient, but the biggest determinant of outcome may be the management that the patient receives in the intensive care unit (ICU) in the days and weeks after admission.

CLOSED VERSUS PENETRATING INJURY

Closed injuries are those in which the overlying scalp remains intact.

Penetrating Nonmissile Injury. Penetrating injuries to the central nervous system are generally considered to be of low velocity when caused by such objects as knives, arrows, lawn darts, or ice picks. High-velocity injuries are caused by missile-type projectiles. Physical examination should describe any visible wounds, but labeling these as "entry" or "exit" wounds is best avoided until all information is available, including results of detailed imaging studies. Clipping or shaving hair may be required for a complete assessment. Control of vigorous scalp hemorrhage may require suturing or tight wrapping of scalp wounds, which can bleed profusely.

Assessment and resuscitation proceed as in other types of TBI. Computed tomography (CT) scanning should be performed to localize any intracranial projectiles or indriven bone fragments and to characterize the extent of injury. If a foreign body has passed near the location of any major vessels, catheter angiography should be considered once more urgent evaluation and stabilization have been performed. Antibiotics and prophylactic anticonvulsants are usually administered.

If an object is still embedded and protruding from the skull, great care should be taken to stabilize it during transport and evaluation. Evaluation, planning, and operative setup should be undertaken with the foreign body still in place, and removal should proceed only in the operating room (Fig. 22-1). To help plan the removal, a similar or identical object may be useful to have on hand as a reference.

Penetrating Missile Injury. Gunshot wounds to the head (GSWHs) make up the majority of penetrating cranial injuries. In some parts of the United States, GSWHs are the most

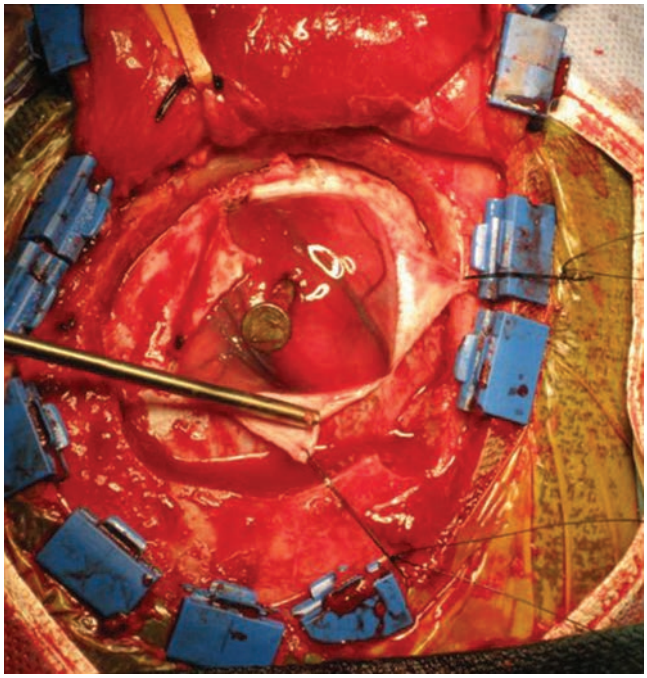

FIGURE 22-1 Intraoperative photograph of a penetrating intracerebral nail gun injury. The bone flap has been removed and the dura has been opened, showing the nail entering the brain parenchyma.

common form of TBI. Some studies report an overall mortality rate of greater than 90% if on-scene deaths are included, with a mortality rate exceeding 50% among those who are alive upon presentation to a hospital.

Traditionally, GSWHs have been divided into those from high-muzzle-velocity rounds (approximately 750–1000 m/s, such as hunting rifles and military weapons) and those from low-muzzle-velocity rounds (approximately 200–500 m/s, as seen in most handguns). With escalating civilian firepower, however, these distinctions are becoming blurred.

Primary injuries from gunshot wounds include direct injuries to face and scalp, pressure waves of gaseous combustion from the weapon if it is touching the target or fired at close range, coup and contrecoup injuries from missile impact, and destruction of brain or bone along the primary path of the original bullet or secondary paths created by fragments of bullets and bone. High-velocity projectiles also create secondary cavitation that pushes tissue away from the bullet in a cone of injury many times wider than the projectile itself. The vacuum that follows the cavitation may pull surface debris into the wound, potentially creating a nidus for infection. Some specially designed bullets mushroom, fragment, or tumble in order to increase the width of the destructive path. Projectiles can also ricochet off the inner table of the skull.

Secondary injuries from GSWHs mimic those seen in other types of TBI and include edema, growth of contusions, disseminated intravascular coagulation (DIC), hemorrhage from vessel disruption, ischemia, infarction, and herniation. Late complications can include abscess or traumatic aneurysm formation, seizures, and migration of fragments of bone, bullet, or other debris.

The decision about whether to take a GSWH patient to the operating room may be difficult since many of these patients have devastating and irrecoverable injuries that will not benefit from surgery. The Glasgow Coma Scale (GCS) score is the most useful piece of information for triaging a GSWH patient.[2] Patients with GCS scores of 3 to 4 generally have a poor outcome regardless of CT findings, and for that reason some clinicians do not even obtain CT scans on these patients. Limited treatment is a reasonable course in such cases. Those with a GCS score of 5 are in an indeterminate category. If the GCS score is 6 or higher, most experts would opt for aggressive treatment in the absence of additional significant findings to suggest that a less aggressive course would be preferable. Poor prognostic factors include self-infliction of injuries, the presence of bilaterally fixed and dilated pupils, and the development of coagulopathy. Poor prognosis and high mortality have also been associated with bullet passage across the midline, through the geographic center of the brain, through the ventricles, or across more than one lobe of the brain.[3]

Basic principles of surgery for GSWH include evacuation of hematomas causing mass effect, meticulous hemostasis, thorough debridement of devitalized tissue and foreign debris, and watertight layered closure to prevent cerebrospinal fluid (CSF) leaks. A "chain of evidence" for forensic purpose should be preserved when bullet fragments are removed.

Diffuse Injury

DIFFUSE AXONAL INJURY

Diffuse axonal injury (DAI) refers to axonal damage that is caused largely by rotational and other mechanical forces. Mild cases result in axonal stretching and transient neuronal dysfunction. More severe cases may set into motion a complex series of cellular events that cause focal impairment of axoplasmic transport, culminating in axonal disconnection at the site of impairment. In humans, this sequence of events may occur over the course of roughly 6 to 12 hours, suggesting that a yet-to-be-developed therapeutic intervention might be administered within this time frame. More severe traumatic forces may cause direct mechanical disruption of tissue and immediate disconnection of axons. Subsequent axonal sprouting and attempts to reestablish connectivity may result in the creation of aberrant neural pathways, potentially contributing to the morbidity of severe brain injury. The development of DAI does not require direct impact to the head. It may result from rapid noncontact acceleration or deceleration in a linear or rotational fashion.[4]

Histologically, DAI-associated lesions are usually microscopic in size and nonhemorrhagic in composition. CT scans may be normal or may show hyperdense petechial hemorrhages. T2-weighted magnetic resonance imaging (MRI) scans may show multifocal hyperintense lesions at gray matter/white matter interfaces, especially in the frontal lobes, corpus callosum, and brainstem. When hemorrhagic DAI is visible on CT or MRI scanning, one must assume that the radiologically visible lesions are just the tip of the iceberg and that more widespread DAI exists.

Injury severity parallels the amount of force required to cause DAI. Prognosis worsens with increasing number of lesions or as lesion depth progresses from the cortex to corpus callosum to brainstem.

BLAST INJURY

Military personnel are at much higher risk than civilians for blast TBI (bTBI). Brain injury accounts for approximately 20% of all combat-related injuries in modern wars,[5,6] including Operation Enduring Freedom in Afghanistan and Operation Iraqi Freedom. In these two conflicts, bTBI was frequently caused by improvised explosive devices (IEDs). Modern helmets, body armor, rapid transport of injured personnel, and forward-based field hospitals have brought about unprecedented rates of warfighter survival and have allowed for a better understanding of the effects of bTBI.

bTBI may be composed of four distinct types of injuries that often overlap. Primary blast injury occurs from overpressure. This has long been known to contribute to injuries in air-filled organs, such as the lungs, bowel, and middle ear. The potential contribution of overpressure to brain injury is currently the focus of much study. Secondary blast injury results from penetration of objects that are set into motion by the explosion. Tertiary blast injury results from a patient being thrown and striking the ground or other object. Quaternary

blast injury refers to additional factors not included earlier, such as heat, toxic fumes, and inhalational injury, or hypoxia. Blast injuries in an enclosed space produce an enhanced and complex pattern of forces as energy reflects off walls and objects to impact the head and body at multiple angles and to multiple degrees.

bTBI often includes closed and penetrating TBI components, and many of these patients also have additional serious injuries, such as traumatic limb amputations or hemorrhagic shock. This combination of factors makes it difficult to assess the true contribution of primary or quaternary blast effects on patients who present with TBI after an explosion. In milder cases, combatants may not recognize that they suffer delayed effects of bTBI, or they may knowingly hide their deficits in hopes of remaining with their combat unit.

bTBI can cause headache, confusion, amnesia, altered mental status, and other symptoms associated with concussions. Postconcussive symptoms may be difficult to differentiate from posttraumatic stress disorder, which often coexists with TBI.

Severe bTBI may cause hyperemia and severe cerebral edema early after injury, often requiring decompressive craniotomy. Higher rates of traumatic pseudoaneurysm formation and vasospasm are seen in comparison to civilian closed and penetrating TBI. These vascular pathologies may require more frequent endovascular or open vascular repair.[7]

CONCUSSION

Concussion is the mildest form of TBI. It may be defined as a usually transient alteration of neurologic function caused by nonpenetrating injury to the brain and characterized by normal imaging studies. Classic symptoms of concussion include headache, irritability, confusion, amnesia, nausea, vomiting, memory problems, difficulty concentrating, vertigo, alterations of balance, anorexia, insomnia, hypersomnolence, impaired coordination, anxiety, and depression. As many as 90% of concussed patients exhibit no loss of consciousness, and when this does occur, it is usually brief. Grading the severity of concussion is currently not recommended because the grading systems that have been described to date have not been shown to correlate with outcome, treatment recommendations, or duration of symptoms.

By definition, CT scanning is unremarkable in these patients. MRI may reveal abnormalities in up to 25% of cases in which CT scans are normal.[8] Pathologic specimens generally show no gross or microscopic parenchymal abnormalities in patients who have suffered a single concussion.

Second impact syndrome is a rare but potentially catastrophic sequela of concussion. It is seen most commonly in children and teenagers. These patients are still recovering from the effects of a concussion when they suffer a second one. Within minutes, the patient develops cerebral vascular engorgement, possibly from impairment of cerebral autoregulation caused by the first concussion. Neurologic deterioration quickly follows, usually culminating in cerebral herniation and death.

Most important for the treatment of concussion is the recognition of injury. Signs of concussion might be so subtle that they do not prompt the patient or family to seek medical attention. However, returning while still symptomatic to an activity that carries a risk of another concussion, such as contact sports, can be disastrous. All experts agree that a symptomatic player should not return to play until he or she has fully recovered.

ABUSIVE HEAD TRAUMA

Nonaccidental trauma (NAT) is traumatic injury that is deliberately inflicted on infants and children. The concept was first described in infants as an injury triad consisting of long bone metaphyseal fractures, subdural hematomas (SDHs), and retinal hemorrhages[9] and has become known in common parlance as "whiplash shaken infant syndrome" or "shaken baby syndrome."[10] Despite the fact that it is almost certainly underreported, it is nevertheless recognized as the primary etiology of brain injury–associated death in children less than 2 years of age.

Some medical professionals find management of these cases to be difficult due to awkwardness of discussions with the child's parents, emotional attachment to the children, frequent lack of accurate information, rarity of admissions of guilt from perpetrators, and the medicolegal implications of child abuse accusations. However, a heightened level of suspicion must be maintained since missed recognition of NAT returns the child to a harmful environment, almost always results in continuation or escalation of the abuse, and may result in the patient's death.

The two most commonly provided histories are trivial blunt trauma, such as a short-height fall from bed or low surface, or complete denial of any history of trauma. Except for the rare epidural hematoma (EDH) with middle meningeal arterial bleeding, low-height falls (head-to-impact distance <3 ft) do not result in life-threatening brain injuries.[11,12] In the absence of a history of trauma, the existence of NAT may be indicated by feeding difficulty, emesis, lethargy, irritability, abnormal movements, seizures, unresponsiveness, or apnea.

On imaging studies, NAT may appear as multiple brain injuries that are more severe than expected given the reported history. Injuries may appear to vary in age (some recent, some remote). Impact injuries include skull fractures and superficial scalp lacerations or swelling in addition to injuries to the underlying brain. There is a high association with other organ injuries. Historically, some fracture patterns have been incorrectly considered suspicious for child abuse. Fractures that are multiple, compound, diastatic, midline, or nonparietal or that cross suture lines may denote a greater degree of imparted force, but they are not pathognomonic for NAT.

A shaking mechanism can result in diffusely distributed SDH. The most frequent hemorrhagic finding is a combination of convexity and interhemispheric SDH, often located posteriorly. Some experts believe interhemispheric SDH has the highest degree of specificity for abuse of any intracranial injury. SDH, subarachnoid hemorrhage (SAH), and retinal

hemorrhages are far more commonly seen in abused than nonabused children. EDHs can occur, but they are much more commonly associated with accidental injury. Retinal hemorrhages are seen in 65% to 95% of children with inflicted head injuries and may be unilateral or bilateral. However, severe bilateral retinal hemorrhages are occasionally seen in accidental trauma, usually after major application of force via a well-defined mechanism, such as MVC.

In the appropriate circumstances, practically any pattern of hemorrhage or fracture can result from either accidental or inflicted trauma. However, inflicted injury is the only known illness or condition associated with the combination of acute SDH, skeletal fractures, and severe bilateral retinal hemorrhages. The severity of injury is staggering, with 15% to 38% overall mortality and 60% mortality if the patient is comatose on presentation. Survivors face a 60% to 70% likelihood of significant neurologic handicap.

Focal Injuries and Their Management

TBI varies widely in both severity and subtype. During a single traumatic event, a patient may be subjected to multiple forces that differ in magnitude, direction, and duration. Although the following injuries are discussed individually, it must be remembered that multiple types of injury may, and often do, occur in the same patient. Furthermore, focal and diffuse injuries often coexist. For example, initial treatment efforts may focus on immediate evacuation of a patient's large SDH, but associated DAI may have an even greater influence on ultimate neurologic outcome.

SKULL FRACTURE

Skull fractures can be categorized by the state of the overlying scalp (closed or open), the number of bone fragments (simple or comminuted), the relationship of bone fragments to each other (depressed or nondepressed), the widening or entry of a fracture into an existing cranial suture (diastatic), and involvement of the cranial vault or skull base. In general, lower-force impacts like falls from standing will create fractures that tend to be linear, closed, and without dural laceration. Higher-force impacts like motor vehicle accidents, falls from heights, or penetrating trauma are more likely to produce comminuted, open fractures with a greater likelihood of underlying dural or cerebral injury. "Ping-pong" fractures are greenstick-type fractures usually seen in newborns due to the plasticity of the skull (Fig. 22-2). They show a local concavity of the skull, without sharp edges, and usually do not require intervention because the skull remodels significantly during growth, with gradual improvement or even resolution of the cosmetic deformity.[13]

Clinical signs suggestive of the presence of calvarial fractures include gross deformity and palpable step-offs. Basilar skull fractures may show postauricular or periorbital ecchymosis, hemotympanum or laceration of the external auditory canal, and CSF rhinorrhea or otorrhea. Cranial nerve (CN) injuries may be seen with fractures of the cribriform plate (CN I, anosmia), optic canal (CN II, visual deficit), and temporal bone (CN VII, facial weakness; or CN VIII, hearing loss). Severe basilar skull fractures may result in pituitary gland or stalk injury and resultant endocrinopathies. Direct injury to vasculature that penetrates the skull base may result in arterial dissection, traumatic aneurysm formation, or traumatic carotid-cavernous sinus fistula formation with resulting cranial neuropathies, chemosis, bruit, and stroke. Fractures of air sinuses or mastoid air cells may result in meningitis, even years after the initial event.

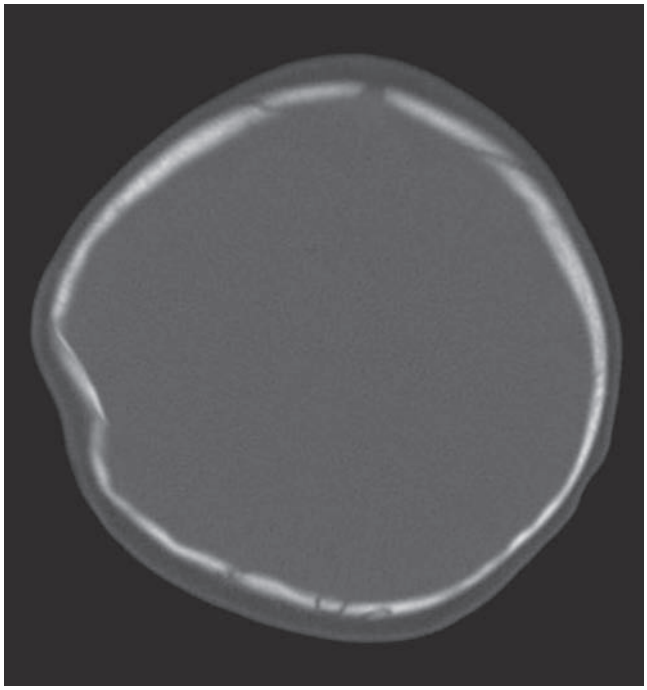

FIGURE 22-2 Computed tomography scan showing ping-pong skull fracture. The multiple nondisplaced linear lucencies are normal calvarial sutures.

Most skull fractures can be seen on CT scans. Plain films may be superior to CT for discovering linear calvarial fractures parallel to the skull base (in the plane of CT slice acquisition). They can be differentiated from vascular grooves or normal cranial sutures by the characteristics listed in Table 22-1.[14] CT scans provide better visualization of facial and orbital

TABLE 22-1: Differential Diagnosis of Fractures on Skull X-Rays

	Linear skull fracture	Vascular groove	Suture line
Density	Black	Gray	Gray
Course	Straight	Curving	Follows known suture course
Branches	Usually none	Often branching	Joins other suture lines
Width	Very thin	Thicker than fracture	Jagged, wide

fractures, temporal bone fractures, and pneumocephalus, as well as better detection of air-fluid levels and varying degrees of opacification that may indicate injury to air sinuses and mastoid air cells. Thin-cut bone windows can be reconstructed in coronal and sagittal planes and via three-dimensional surface modeling to aid in fracture characterization and surgical planning. CT angiograms and venograms are useful for assessing fractures involving skull base foramina containing important vasculature, such as the carotid canal and foramen magnum, or fractures that cross major venous sinuses.

Fractures must be assessed and treated in concert with management of any underlying brain injury. The following discussion of skull fracture treatment assumes that evaluation has been conducted and appropriate treatment instituted for SDHs or EDHs, parenchymal hemorrhages, contusions, and/or cerebral edema, and that clinical criteria do not mandate separate operative intervention for these lesions.

Closed, nondisplaced fractures do not normally require intervention. Open skull fractures may require debridement and careful exploration in addition to prophylactic antibiotics. Those with obvious underlying dural laceration or CSF leakage require layered surgical repair to reduce the risks of meningitis or brain herniation through a dural defect. In the pediatric population, laceration of the underlying dura may rarely lead to development of a growing skull fracture (or leptomeningeal cyst) in 0.05% to 0.6% of skull fractures.[15] Over time, pulsations of the underlying rapidly growing brain widen the dural laceration and fracture line (Fig. 22-3). These are most common in children under 1 year of age, and over 90% occur in children less than 3 years old. Surgical repair includes wide bony exposure to repair dural edges that often retract beyond the limits of the visible fracture.

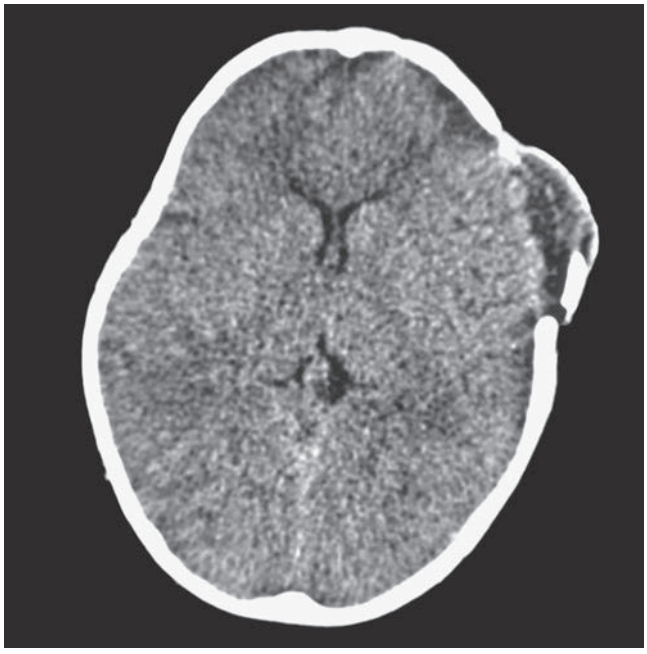

FIGURE 22-3 Computed tomography scan showing growing skull fracture from leptomeningeal cyst in child. Note displaced bone and expansion of cerebrospinal fluid–filled soft tissue.

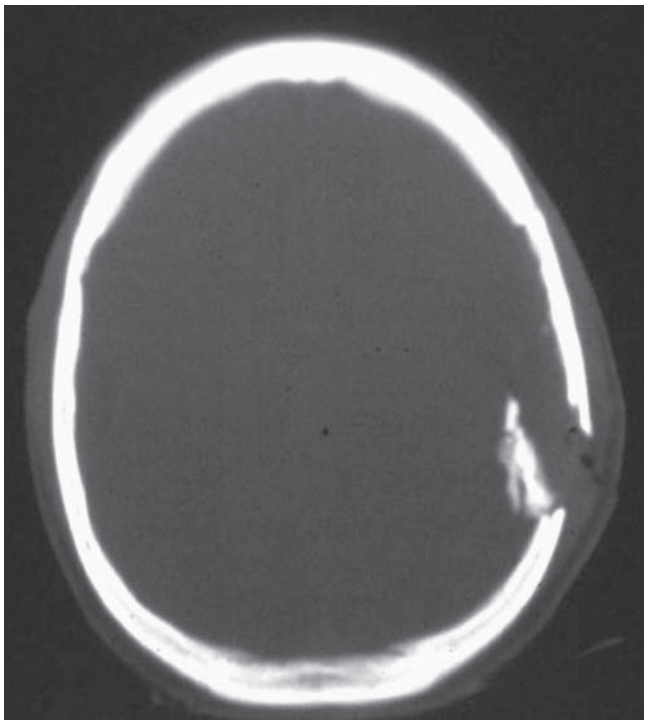

FIGURE 22-4 Computed tomography scan showing a depressed skull fracture that required surgical elevation and dural repair. The patient also had an underlying brain contusion and presented with a receptive aphasia.

Relative indications for surgical elevation of a depressed skull fracture include depression greater than 8 to 10 mm or greater than the thickness of the adjacent skull (Fig. 22-4), a focal neurologic deficit clearly attributable to compression of underlying brain, significant inward intrusion of bone fragments (implying possible dural laceration), and persistence of cosmetic deformity after overlying scalp swelling has subsided. For simple depressed fractures without dural violation, there is no evidence that posttraumatic seizure risk[16] or neurologic outcome[17] is improved by surgical elevation of the fracture. At least in very young patients, cosmesis may not be improved by surgery because, over time, the growth of the child's brain induces remodeling of the overlying skull.[17] Fractures that cross a major dural venous sinus may warrant a more conservative approach given the increased risks of bleeding and air embolism that may occur during surgical repair.

Current recommendations support surgical repair of open fractures depressed greater than the thickness of the cranium. Surgery is also supported in the presence of significant intracranial hematoma, depression greater than 1 cm, significant frontal sinus or nasofrontal duct involvement, gross cosmetic deformity, wound infection, pneumocephalus, or gross wound contamination. In the absence of gross contamination, primary bone fragments may be replaced without excessive risk of infection.[18] Nonoperative management may be preferred

for management of open depressed cranial fractures if there is no evidence of dural penetration.

EPIDURAL HEMATOMA

EDH occurs when blood collects in the potential space between the dura and inner table of the skull. Although classically described EDHs arise from arterial bleeding caused by a temporal bone fracture that lacerates the middle meningeal artery, the advent of CT scanning has revealed that many EDHs originate from bleeding of the bony edges of skull fractures. Another common cause is injury to a venous sinus.

On CT scanning, an EDH usually appears as a hyperdense, biconvex (lenticular) mass adjacent to the inner table of the skull (Fig. 22-5). Unless sutural diastasis is present, the EDH is often externally bounded by cranial sutures. Additional associated findings may include SDHs and cerebral contusions. A significant percentage of EDHs managed nonsurgically will demonstrate an increase in size, usually in the first few hours after injury. Some of these lesions may appear in a delayed manner after an initial CT scan failed to reveal their presence.

The classic clinical presentation of an EDH describes a brief posttraumatic loss of consciousness (LOC) followed by a lucid interval of varying duration, which progresses to obtundation, contralateral hemiparesis, and ipsilateral pupillary dilatation. In reality, however, this sequence of events occurs only rarely. LOC is seen in a small minority of cases. Overall mortality from a unilateral EDH has been reported as 5% to 12%,[19] with rates increasing in cases of bilateral EDHs, posterior fossa location (25% mortality), and concurrent acute SDH.

FIGURE 22-5 Computed tomography scan of acute epidural hematoma. Note the biconvex- or lenticular-shaped hemorrhage. This hematoma was subjacent to a diastatic left lambdoid suture.

Rapid diagnosis and timely intervention are essential for optimal outcome (see Atlas Figures 2 and 3). Surgical guidelines suggest that an EDH greater than 30 cm^3 in volume should be evacuated regardless of GCS score. An EDH less than 30 cm^3 in volume and less than 15 mm of thickness and less than 5-mm midline shift may be treated conservatively at a neurosurgical center with frequent neurologic examinations and serial CT scanning.[18] Relative indications for evacuation of EDHs include the presence of neurologic symptoms or maximal hematoma thickness greater than 1 cm. Acute EDH patients in a coma (GCS score ≤8) and with anisocoria should undergo surgical evacuation as soon as possible.[18]

Posterior fossa injury is rare, composing less than 3% of head injuries. However, a disproportionately large proportion of these lesions are EDHs. The limited volume of the posterior fossa and the potential compromise of the brainstem and CSF pathways underscore the importance of rapid evacuation via suboccipital craniectomy.[18] Patients without signs of mass effect or neurologic deterioration may be watched conservatively, with serial neurologic examinations, CT scans, and a low threshold for surgical intervention.

SUBDURAL HEMATOMA

SDH occurs when blood collects between the arachnoid and inner dural layers of the meninges. Thus, from a strict anatomic point of view, these are really intradural hematomas. A common cause is traumatic stretching and tearing of cortical bridging veins that cross the subdural space and drain into the dura or into a dural sinus. The force may be applied by direct impact or by indirect linear or rotational motion. Less common etiologies include coagulopathy, subdural dissection of parenchymal hematomas, and rupture of a vascular anomaly into the subdural space. Patients with cerebral atrophy, cranial CSF shunts, and large middle fossa arachnoid cysts are predisposed to SDH because of increased traction on cortical veins. Many patients with acute SDHs also have other significant intracranial lesions.

SDHs are commonly located over the cerebral convexities and may cover part or all of a hemisphere. Classically, they are crescent shaped, may cross calvarial suture lines, and layer along the falx or tentorium (Fig. 22-6). Patients may present with symptoms of mass effect or of underlying diffuse brain injury. Chronic SDH may present more insidiously, with progressively worsening headaches and/or focal deficits.

The appearance of SDHs evolves over time. On CT scanning, acute SDHs are usually hyperdense, but some may show areas of mixed density if ongoing active bleeding causes

FIGURE 22-6 Computed tomography scan of acute subdural hematoma. Note that the crescentic hemorrhage crosses under the right coronal suture.

the not-yet-clotted blood to continue to accumulate in the subdural space. Some acute SDHs may be isodense in the presence of coagulopathy, significant anemia, or admixing of blood and CSF. Subacute SDHs are isodense to brain, and chronic SDHs become hypodense. Inward displacement of the gray/white cortical ribbon and cortical vessels may be evident on contrast-enhanced CT scanning. The subdural membranes that often exist with chronic SDHs may appear within 4 days and enhance with contrast administration.[20] MRI may show evolving signal intensities that vary with the age of the SDH as blood breakdown products are converted to oxyhemoglobin, deoxyhemoglobin, methemoglobin, and hemosiderin (Table 22-2).

SDHs often have worse outcomes than EDHs of similar size. EDHs are frequently of arterial origin and thus present with symptoms quickly, facilitating prompt diagnosis and treatment. In contrast to EDHs, it has been postulated that many SDHs result from higher-magnitude forces, which cause greater damage to the brain and cortical vessels. Because of the venous origins of the bleeding, an SDH may require more time to grow and become symptomatic. The attribution of symptoms to diffuse brain injury has also been postulated to delay diagnosis in some cases until the signs of midline shift and brainstem compression become evident. Mortality associated with SDH can be high and may be related more to the underlying brain injury than to the SDH itself. Mortality rates increase in the elderly and in patients on anticoagulants.[21]

TABLE 22-2: Appearance of Subdural Hematoma on Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

	CT density	MRI T1	MRI T2
Hyperacute (minutes)	↓	—	↑
Acute (hours to days)	↑/swirl/iso if coagulopathy	—	↓
Early subacute (4–7 days)	—	↑	↓
Late subacute (1–3 weeks)	—	↑	↑
Chronic (3 weeks to 3 months)	↓	↓	↓

↑/—/↓, hyperdense/isodense/hypodense to brain (CT) or hyperintense/isointense/hypointense (MRI).

Guidelines propose that an acute SDH with thickness greater than 1 cm or a midline shift greater than 5 mm should be evacuated regardless of GCS score. Comatose patients (GCS score ≤8) with an acute SDH less than 1 cm in thickness and midline shift less than 5 mm should undergo SDH evacuation if the GCS decreases by 2 points between the time of injury and hospital admission, if the patients present with pupils that are asymmetric or fixed and dilated or if intracranial pressure (ICP) reaches or exceeds 20 mm Hg.[18] A craniotomy to evacuate an acute clot should be performed as soon as possible. Over time, as solid blood clots pass through subacute to chronic stages, they liquefy and may be amenable to drainage via burr holes.

INTRACEREBRAL HEMATOMA AND CONTUSION

Traumatic intracerebral hematomas (TICHs) and contusions may expand rapidly. Worsening perilesional edema and rapid hematoma growth may produce increasing mass effect and neurologic deterioration. If patients demonstrate neurologic decline referable to an expanding TICH, surgical intervention may be warranted. Surgical decompression is often necessary in patients when TICH volume exceeds 50 cm^3 or when patients present with GCS scores of 6 to 8 with frontal or temporal contusions greater than 20 cm^3 in volume with midline shift of 5 mm or greater and/or cisternal compression on CT scan.[18] Surgical procedures range from localized frontal or temporal craniotomy with resection of underlying focal clot to more extensive craniectomy with duraplasty, evacuation of severely contused brain, and temporal lobectomy.

SUBARACHNOID HEMORRHAGE

Subarachnoid blood occupies the space between the pial and arachnoid membranes. Traumatic SAH (tSAH) results from venous tears in the subarachnoid space. The injured vessels are often quite small, and the resulting hemorrhage frequently appears as a thin, diffuse hyperdensity over the sulci and gyri of the cerebral convexity (Fig. 22-7) and as a

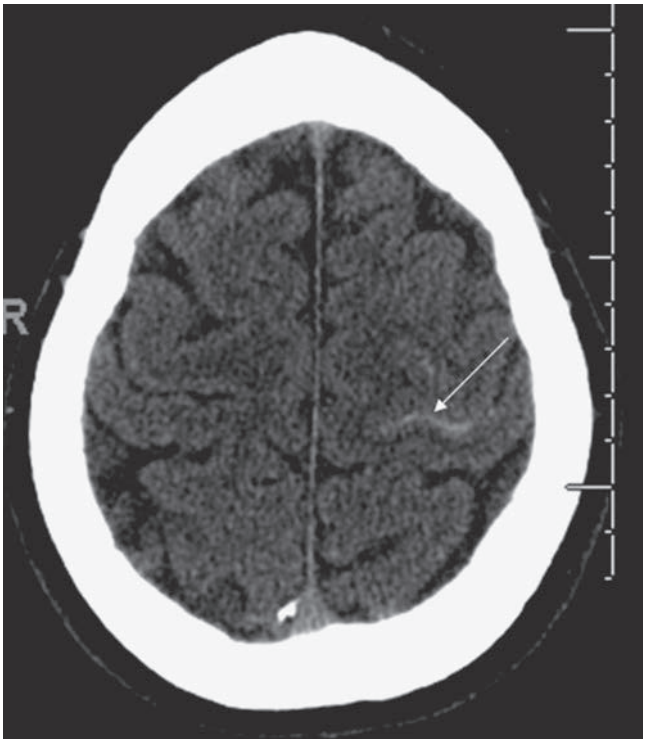

FIGURE 22-7 Computed tomography scan with arrow pointing to a small traumatic subarachnoid hemorrhage in left central sulcus.

thin hyperintensity on fluid-attenuated inversion recovery (FLAIR) MRI. The usual convexity location of tSAH distinguishes it from SAH caused by spontaneous rupture of a cerebral aneurysm, in which the blood is usually most prominent in the basilar cisterns and appears thicker on CT scanning. Occasionally, tSAH can have a CT appearance similar to that of aneurysmal SAH, and if a detailed history cannot help distinguish between spontaneous and traumatic SAH, imaging of the vasculature via CT, magnetic resonance, or catheter angiography may be required. In general, no specific treatment is needed for tSAH, and patient management is dictated by associated injuries.

Vasospasm refers to narrowing or even closure of a vessel. Severe cases may lead to subsequent ischemia or infarction in the associated vascular territory. Although much more common after rupture of a cerebral aneurysm and associated spontaneous SAH, it has also been reported after tSAH, especially in association with blast injury. The classic time course of vasospasm after spontaneous SAH is onset as early as 2 or 3 days after injury, peak incidence from days 3 to 14, and duration of up to 3 weeks.

VASCULAR INJURY

Posttraumatic stroke may result from injuries to the internal carotid artery (ICA), common carotid artery (CCA), or vertebral artery (VA) in the neck. Rarely, injury may be due to penetrating trauma with direct ICA, CCA, or VA injury. More often, vessel dissection is sustained in motor vehicle accidents, falls, extreme neck rotation, spine fracture, or through iatrogenic injury, such as surgery or chiropractic maneuvers.

Traumatic dissection is more common in the ICA and can occur anywhere from a few centimeters above the carotid bifurcation to the skull base. Less frequent is VA dissection, which is seen most commonly at the C1–C2 level. Vessel dissection allows blood to collect between the adventitia and media (pseudoaneurysm formation) or between the intima and media of the vessel wall (luminal stenosis). This intramural hematoma may expand or propagate, with distal propagation occurring more commonly than proximal.

Spontaneous dissections occur in younger to middle-aged adults; 70% occur between the ages of 35 and 50 years. A much lower proportion occurs in adolescents, and spontaneous dissection is rare in children. Most patients present with headache and neck pain that is often unrelenting. Symptoms and subsequent diagnosis may occur hours to weeks after the initial trauma and may include transient ischemic attack or stroke, Horner syndrome, and, less often, carotid bruits, pulsatile tinnitus, and lower cranial nerve palsies (CN IX–XII).

On CT scanning, dissection is seen as a linear lucency within an enhancing vessel. This represents the flap separating the true and false vessel lumens. MRI shows a crescentic band surrounding the native flow void.

Twenty percent of cases have an associated injury, such as cervical spine injury or silent dissection of another vessel. Treatment often consists of heparin anticoagulation (if not contraindicated by other injuries) followed by longer-term anticoagulation. Balloon angioplasty may be employed in select cases.

CLINICAL ASSESSMENT

Glasgow Coma Scale

The GCS has become the standard for clinical grading of TBI severity.[2] A patient is scored in three parameters: best motor function (M), best verbalization (V), and best eye opening (E). The sum of these individual scores represents the overall GCS score (Table 22-3). A neurologically intact patient can achieve a maximum score of 15. The most severely injured patients have a total score of 3. If a patient is intubated, the verbal score cannot be assessed. Instead of assigning an arbitrary verbal

TABLE 22-3: Glasgow Coma Scale (Recommended for Age ≥4)

Best motor		Best verbal	Best eye opening
6	Obeys		
5	Localizes	Oriented	
4	Withdraws	Confused (fluent speech)	Spontaneously
3	Flexes	Inappropriate (words)	To speech
2	Extends	Incomprehensible (sounds/grunts)	To pain
1	None	None	None

score in such cases, it is best to note that the verbal score cannot be determined reliably. Because the same GCS score can be derived from different combinations of motor, verbal, and eye opening scores, it is important that practitioners record each of the subscores and not just the overall number.

The GCS allows practitioners to communicate quickly and reliably about a patient's neurologic status. The postresuscitation GCS score is also effective for stratifying patients by injury severity. Patients with GCS scores between 13 and 15 are traditionally considered to have mild TBI. They are usually awake and have no focal deficits. Patients with GCS scores of 9 to 12 are often described as having moderate TBI. In general, they usually have alterations of sensorium and may have focal deficits. Those with the lowest GCS scores (3–8) have severe TBI. They usually will not follow commands and are often described as comatose.

Confounding factors that may alter the neurologic examination must not be present if the examiner expects a GCS evaluation to be accurate. Alcohol and other drugs may depress neurologic function, as can hypotension, hypoxia, sepsis, hypothermia, and other systemic factors. Sedating agents and paralytics may also interfere with accurate assessment. Spinal cord injury and long bone fractures can affect the motor component score of the GCS and should be sought if suggested by the mechanism of injury. Hearing deficits, lack of hearing aids, or a language barrier should also be taken into consideration. The pediatric population represents a special group for whom a modified version of the GCS is often used (Table 22-4).[22]

Pupils

The pupillary light reflex can be easily and rapidly assessed in the unconscious patient. Damage or hypoperfusion affecting the Edinger-Westphal nucleus in the midbrain, or compression of the third cranial nerve as the uncus (located in the medial temporal lobe) herniates into the tentorial notch from displacement by a space-occupying mass lesion, may result in pupillary dilatation. If these pathologic processes are sufficiently severe, the pupil will be fixed in the dilated position, with no constriction in response to bright light. Direct orbital trauma can also cause pupillary dilation and fixation in a sizable minority of cases. This possibility should be considered (quickly) before automatically assuming that a dilated pupil is caused by intracranial hypertension.

To facilitate performance of fundoscopy in patients in coma or with orbital or periorbital trauma, facial fractures, abnormal eye movement, or other pathologies, it may be necessary to instill mydriatics. To avoid confusion, this practice should only be permitted after concerns regarding elevated ICP have been addressed. Clear notation should be made, in the chart and at the bedside, as to when and which mydriatics have been used and for how long their effect will persist.

TABLE 22-4: Glasgow Coma Scale for Children (Recommended for Age <4)

Best motor		Best verbal		Best eye opening
6	Obeys			
5	Localizes	Smiles, oriented to sound, follows objects, interacts		
		Crying	**Interaction**	
4	Withdraws	Consolable	Inappropriate	Spontaneously
3	Flexes	Inconsistently consolable	Moaning	To speech
2	Extends	Inconsolable	Restless	To pain
1	None	None		None

Neurologic Examination

An accurate neurologic examination is essential to determine diagnosis, treatment, and prognosis in TBI patients. The examination may be limited due to a patient's age, level of education, native language, presence of sedating or paralytic medication, illicit drugs, hypotension, hypoxia, hypothermia, hypoglycemia, or other factors. Examination of the pediatric patient may be further limited by other considerations, including inability to visualize the pupils or fundi of the premature or newborn infant, limited cooperation, inability to understand language, and so on.

Monitoring the overall trend of a neurologic examination over time is critical. It must be understood that these examinations can and will fluctuate based on a patient's improving or declining condition, the evolution of disease processes, and the ability of medical personnel to minimize or eliminate sedation and other factors that confound an accurate neurologic assessment.

In the uncooperative patient or unconscious patient with severe TBI, the examination may be limited to the GCS, pupillary reactivity, and testing of various reflex actions (Table 22-5). As the patient becomes more alert and cooperative, a more complete neurologic examination will provide greater sensitivity for assessment of neurologic injury. The extent of the examination must be tailored to the patient's ability to interact with an examiner.

Systemic Evaluation

Assessment and treatment of TBI patients begin in the prehospital setting, often with input from family or bystanders. Care continues with the primary care physician or emergency medical technician, transfers to the physician in the emergency department, and eventually involves the neurosurgeon and other members of the trauma team. Treatments may be started at any point along a patient's journey as dictated by recognition of signs of neurologic injury and by availability of appropriate medication, equipment, and personnel.

The nervous system does not function in isolation. Patients with TBI often have additional injuries. Treatment specific to TBI is often complementary or adjunctive to treatment

TABLE 22-5: Neurologic Examination for Trauma

	Uncooperative patient	Cooperative patient
Level of consciousness	Glasgow Coma Scale	Orientation Comprehension, verbalization Fluency of language
Cranial nerves	Pupil reactivity (ambient and bright light) Afferent pupillary defect Facial asymmetry	Visual acuity/visual fields Funduscopic examination (papilledema, retinal hemorrhage) Complete cranial nerve examination
Motor	Movement to central and peripheral noxious stimuli (differentiate from flexion-withdrawal spinal reflex) Resting tone of anal sphincter	Strength assessment of muscle groups in four extremities Tone of voluntary anal sphincter contraction
Sensory	Grimace/grunt/withdrawal to noxious stimulus	Detailed examination to light touch and pinprick in major dermatomes (C5, C6, C7, C8, T4, T10, L2, L4, L5, S1) Joint position sense (posterior column function)
Reflexes	Deep tendon reflex Plantar reflex (Babinski), clonus Anal wink, bulbocavernosus reflex	Same as in uncooperative patient

of the trauma patient without neurologic injury. The basic principles of trauma resuscitation should be followed. These include rapid assessment and maintenance of airway, breathing, and circulation.

A detailed medical and surgical history should be obtained, including the events preceding a trauma, a description of the accident scene, accurate description of the patient's neurologic baseline, and any subsequent changes in neurologic status. Long-term medications as well as medications administered in the prehospital setting should be identified. Special attention should be paid to medications with the ability to alter the neurologic examination, including sedatives or psychopharmacologics (to restrain a combative patient), paralytics (for intubation or transportation), atropine (for cardiac resuscitation), and other mydriatics (for evaluation of ocular trauma), in addition to the possible presence of alcohol and other recreational drugs.

Primary and secondary surveys should be undertaken to evaluate for systemic injuries. Open scalp lacerations with vigorous hemorrhage can lead to fatal hemorrhagic shock. In the newborn or premature infant, cephalohematoma may allow enough displacement of blood to produce hemodynamic instability. Raccoon eyes (periorbital ecchymosis), Battle's sign (postauricular ecchymosis), and otorrhea or rhinorrhea suggest the presence of a basilar skull fracture. Palpable fractures or depressions may indicate bony injury and a higher likelihood of underlying hemorrhage or parenchymal injury, but care must be taken not to confuse significant soft tissue edema for a bony step-off. Periorbital edema or proptosis may suggest local ocular or orbital trauma. Puncture wounds may indicate the existence of serious penetrating injury to the brain, spinal cord, sympathetic plexus, or vasculature. Bruits of the carotid artery or globe of the eye may reveal the presence of carotid dissection or carotid-cavernous fistula, respectively. Multiple areas of swelling or bruising may indicate prior seizure activity or repeated syncopal episodes, as well as serially inflicted injuries.

IMAGING

Computed Tomographic Scan and Skull Radiography

Advances in imaging technology have relegated plain x-rays to a very limited role in the contemporary evaluation of trauma patients with potential head or spine injuries. Some clinicians still use skull films to identify pneumocephalus, skull fractures, and the tracks of penetrating objects. In the vast majority of cases, however, CT scanning provides more information. Also, it must be remembered that intracranial ricochets of projectiles may occur, and CT is far superior to plain films for characterizing such complex events.

Overwhelmingly, CT scanning has become the preferred initial imaging modality for patients presenting after head trauma. In a single rapid scanning session, and without patient repositioning, scans of the head, neck, chest, abdomen, and pelvis can be performed. From these, cervical, thoracic, and lumbar spine images can be reconstructed without additional radiation exposure. Administration of contrast allows for CT angiography and three-dimensional reconstruction to evaluate the vasculature of the head and neck.

Magnetic Resonance Imaging

MRI scans provide higher-resolution images of the brain, spinal cord, and other soft tissues than CT scans. This superior visualization of neural parenchymal tissue is ideal for the evaluation of infarction, ischemia, edema, and DAI. MRI is

also helpful for detecting ligamentous injury of the spine as well as spinal cord injury. However, disadvantages of MRI compared to CT scanning include slower image acquisition time, increased cost, restricted access to patients during image acquisition, and the magnet's incompatibility with ferromagnetic monitoring and supportive equipment that is commonly used in trauma patients. Use of MRI for the initial assessment of trauma is not routinely recommended since CT scanning permits detection of acute hemorrhage and fractures, which are the pathologies of greatest immediate concern in TBI patients.[23] In addition, once patients have stabilized in the ICU, MRI usually contributes little to prognostication beyond what has already been learned from other imaging studies and from the patient's clinical course.

Angiography

When the track of a penetrating injury passes near known locations of major vessels or when a delayed intracranial hemorrhage occurs, angiography may be used to look for pseudoaneurysms or other direct injuries to vessels. In prior decades or even nowadays when CT or MRI scanning is unavailable, angiography could reveal midline shift or other types of vascular displacement indicative of compressive mass lesions that might require immediate intervention.

MANAGEMENT

General Measures

Numerous guidelines based on critical evaluation of the pertinent literature have been created and disseminated. The best known among these is the *Guidelines for the Management of Severe Traumatic Brain Injury.*[24] Subsequent companion guidelines have been created for prehospital management of TBI,[25] pediatric TBI,[26] surgical management of TBI,[18] penetrating TBI,[27] and field management of combat-related head trauma.[28] The reader is referred to these documents for further background on creation of treatment recommendations. See Fig. 22-8 for a management algorithm.

Interventions for TBI may be initiated in series or in parallel. Some treatments can be started in the field. Others may be added as more advanced equipment or qualified personnel become available in the emergency department, operating room, or ICU.

Basic measures should be implemented in all TBI patients undergoing monitoring. These patients often require a setting with the capability for careful assessment of vital signs, fluid balance, and neurologic status. Initial goals are normothermia and euvolemia, with administration of isotonic fluids (ie, 0.9% NaCl + 20 mEq KCl/L). Many practitioners avoid dextrose-containing intravenous fluids because of concerns about potential deleterious effects of anaerobic metabolism of glucose in injured or ischemic brain. Patients usually receive prophylaxis against Cushing (stress) gastric ulcers, which are frequently seen in patients with severe TBI and elevated ICP. The head of bed is generally elevated to 30°. The neck should be kept midline, and the fit of the patient's cervical collar and endotracheal tube stabilizer should be assessed to prevent compression of the jugular veins. Most important is frequent assessment of the patient's condition, evaluation of responses to therapies, and willingness of providers to modify care strategies in a timely manner to help ensure optimal patient outcome.

Another basic measure is maintenance of hemoglobin (Hgb) concentration above a specified minimum level. Historically, this level has been commonly set at 10 g/dL, which was felt to represent the optimal trade-off between blood viscosity and oxygen-carrying capacity. Numerous reports have questioned the benefit of such a high threshold, and most practitioners came to accept a Hgb as low as 7 g/dL. But the question remained as to whether the exquisite sensitivity of the injured brain to hypoxia made TBI patients a special subgroup in which the traditional higher Hgb level was still required. A prospective randomized trial failed to confirm this hypothesis,[29] leading many clinicians to accept the lower Hgb of 7 g/dL as the minimum acceptable value even in TBI patients—assuming, of course, that there exists no other indication for targeting a higher goal.

Over the past two decades, it has become common to advocate for systematic, evidence-based treatment of TBI patients by dedicated neurosurgeons, neurologists, intensivists, surgical trauma and critical care teams, nurses, and allied health care workers. Several publications claim improved outcomes as a direct result of the arrival of an intensivist to a specific ICU. More likely, however, is that the very process of standardizing care and eliminating unwarranted excessive variation in care was the real driver behind improvement in outcomes compared to historical controls. The exact background or specialty of the clinician driving that standardization is less important.

BLOOD PRESSURE AND OXYGENATION

Medical practitioners cannot undo the events surrounding a primary brain injury. However, every effort must be made to mitigate or eliminate secondary insults, which may be even more devastating than the primary insult. Prior to, or during, transport to a hospital setting, a significant portion of patients may experience periods of hypoxemia or hypotension.[30] These are among the most common and most deleterious secondary insults. Occurrence of a single episode of hypoxemia or hypotension is an independent predictor of worse outcome after TBI.[31,32]

Oxygen saturation and blood pressure monitoring should start in the field and continue in the hospital setting. The goal is to prevent hypoxemia and hypotension or, if they occur, to identify and treat them as rapidly as possible. Crystalloid, colloid, blood products, or even intravenous pressors may be required to avoid hypotension. Empiric oxygen administration should start as early as possible. Endotracheal intubation may be required. Of interest, several studies have demonstrated worse outcomes in TBI patients who are

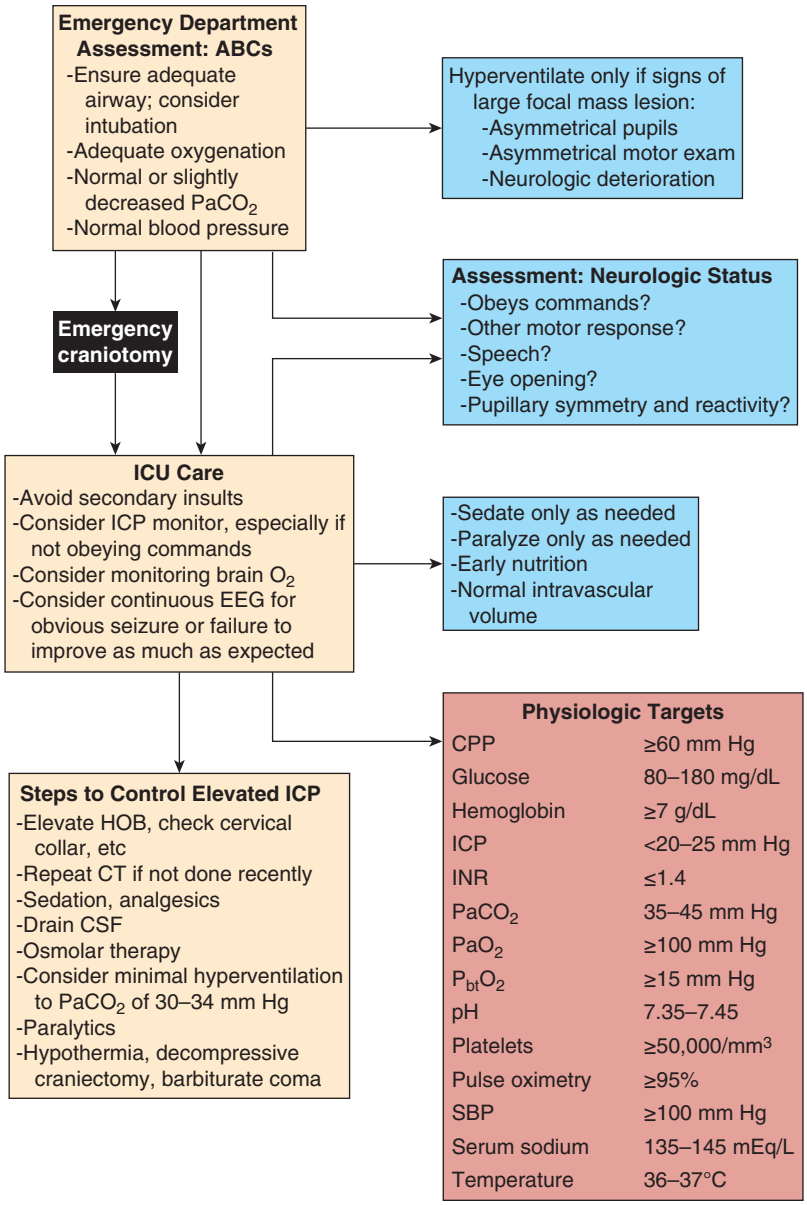

FIGURE 22-8 Algorithm for management of traumatic brain injury. CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; HOB, head of bed; ICP, intracranial pressure; ICU, intensive care unit; INR, international normalized ratio; O_2, oxygen; SBP, systolic blood pressure.

intubated in the field. One possible reason is that the frequently chaotic prehospital environments surrounding TBI patients and the relative inexperience of some first responders in performing difficult intubations may combine to cause prolonged hypoxemia during attempts at endotracheal intubation. Another factor may be unintentional hyperventilation of intubated patients (and consequent cerebral vasoconstriction and reduction in cerebral blood flow [CBF]) from excessively rapid and forceful squeezing of the bag/valve system if patients are manually ventilated. Consequently, for many TBI patients, careful oxygenation and ventilation via a facemask may be preferred over attempts at prehospital endotracheal intubation.

NUTRITION

TBI patients usually exhibit an increase in basal energy expenditure (BEE). Patients who are sedated and paralyzed may show BEE increases up to 120% to 130% of baseline. Comatose patients (GCS score ≤8) with isolated TBI may have BEE approximately 140% of baseline (range, 120%–250%).[33] Mortality is reduced in patients who receive full caloric replacement by 1 week postinjury.[34] At least 15% of calories should be supplied as protein. Since it may take 2 or 3 days to ramp up feedings to desired levels, nutritional replacement should begin as soon after injury as possible.

Enteral feeding is preferred over parenteral nutrition because it enhances immunocompetence and reduces risk

profile.[35] If a patient has diminished gastric motility, a jejunal feeding tube can be placed since patients with severe TBI can tolerate early jejunal feeding even in the presence of gastric dysfunction and limited small bowel activity. Total parenteral nutrition can be considered if enteral feeding is not possible or if higher nitrogen intake is required.

PROPHYLAXIS

Seizures. Posttraumatic seizures (PTS) are potentially harmful in TBI patients for many reasons, including subsequent increased ICP and elevated metabolic demand that may exacerbate the effects of ischemia. TBI patients at increased risk for PTS include those with GCS score below 10 and those with depressed skull fractures, cortical contusions or intracranial hemorrhage, and penetrating injury or seizure within 24 hours of brain injury. Phenytoin has been shown to effectively reduce the risk of PTS during the first 8 days after injury, but not later.[24,36] Despite the absence of high-quality studies showing equivalent efficacy of levetiracetam for early PTS prevention, many centers are now using it because of ease of administration and a lower rate of adverse reactions.

Infection. Trauma patients may develop infections from grossly contaminated wounds, from immunosuppression following the stress of severe trauma or other causes, or from such necessary interventions as open surgical procedures, intubation for mechanical ventilation, and use of invasive monitoring equipment. In general, antibiotic coverage should be targeted toward specific organisms and stopped as soon as possible to minimize the risk of development of drug-resistant strains of bacteria or alterations in normal floral patterns.

Perioperative antibiotics are generally recommended only for a single dose preoperatively or at most for the first 24 hours after surgery. This same principle applies to insertion of external ventricular drains (EVDs). Maintaining patients on prophylactic antibiotics for the entire period that an EVD is in place is not recommended. Routine flushing or exchange of ventricular catheters is also not recommended. Use of ventriculostomy catheters impregnated or coated with antibiotics may result in an overall decrease in infection rate.[37]

Hemorrhage. Most critically ill trauma patients have decreased levels of plasma antithrombin (AT) activity. TBI patients, however, tend to have increased rates of coagulopathy, with supranormal AT activity that can progress to disseminated intravascular coagulation and fibrinolysis (DICF), as well as expansion of existing cerebral contusions and delayed development of additional hemorrhages.[38] Coagulopathy may be especially severe after penetrating brain injury.

For all trauma patients, medical history and review of systems should specifically inquire about history of excessive bleeding or clot formation, use of specific antiplatelet or anticoagulant medication (eg, aspirin, warfarin, or novel oral anticoagulants), medications that have antiplatelet compounds as a component, and medical disorders that pose an increased risk of bleeding. Measurements of prothrombin time, activated partial thromboplastin time, international normalized ratio, platelet count, and occasionally bleeding time, platelet function assay, or thromboelastography are often helpful in guiding the management of hemorrhage.

Effects of warfarin anticoagulation may be reversed by administration of vitamin K, fresh frozen plasma, or prothrombin complex concentrate; effects of heparin may be reversed with protamine sulfate; and thrombocytopenia or platelet dysfunction may be treated with donor platelet transfusion. Unfortunately, these interventions require time for preparation and administration, which may limit their usefulness in patients with life-threatening intracranial hemorrhage and rising ICP. Recombinant activated coagulation factor VII (rFVIIa) rapidly forms a complex with tissue factor to produce thrombin and, separately, converts factor X to its active form, factor Xa, resulting in a "thrombin burst" at the site of tissue damage. It is US Food and Drug Administration–approved for treating or preventing bleeding in hemophiliacs and in those with congenital factor VII deficiency. Studies of off-label uses for intracerebral hemorrhage and TBI have not demonstrated improved survival and also suggest an increased risk of thromboembolism. The novel oral anticoagulant (NOAC) dabigatran can be counteracted by a direct inhibitor, idarucizumab, but no specific reversal agent is yet available for other NOACs.

Deep Venous Thrombosis. Trauma patients in general, and TBI patients in particular, are at risk for venous thromboembolic complications such as deep venous thrombosis (DVT) and pulmonary embolus (PE). Risk factors for DVT and PE include stroke or spinal cord injury, prolonged surgery or prolonged bed rest, SAH or TBI causing altered coagulation or dehydration, and increased blood viscosity from cerebral salt wasting and treatment of cerebral edema.[39] Low-risk, prophylactic measures against DVT include passive range of motion, early ambulation, rotating beds, and electrical stimulation of calf muscles. If DVTs are not already present, pneumatic compression boots (PCBs) and sequential compression devices may be safely used and can reduce the incidence of DVT and PE.

Pharmacologic anticoagulation can increase the effectiveness of DVT prophylaxis but with the risk of additional hemorrhagic complications. Low-molecular-weight heparins have a higher ratio of anti–factor Xa to anti–factor IIa activity versus unfractionated heparin, have greater bioavailability after subcutaneous injection, and have more predictability in terms of plasma levels. They can be added to use of PCBs without significantly increased risk of hemorrhage,[40] and their use has been recommended in postoperative neurosurgery patients. Because there are no universally accepted recommendations for the method and timing of postoperative anticoagulation, this decision should be tailored individually to each patient. Many centers now initiate pharmacologic DVT prophylaxis within 24 hours of surgery or, in the case of intracranial hemorrhage, within 24 hours of verifying stability of hematoma size on repeat CT scan.

Cerebral Metabolism and Pathophysiology

INTRACRANIAL PRESSURE

To understand the rationale behind ICP management, one must first recognize that pressure in the intracranial space differs from that in other body compartments. If a patient sustains an injury to an arm or leg, the surrounding soft tissue may expand outward from the humerus or femur. By contrast, in cases of TBI, the brain is unable to expand because it is confined within the rigid skull.

The modified Monro-Kellie hypothesis assumes that the skull is completely inelastic, that the ventricular space is confluent, and that pressures are equally and readily transmitted throughout the intracranial space. This hypothesis states that there is a balance between the brain, intravascular blood, and CSF contained in the intracranial space. Increases in the volume of one constituent (eg, cerebral edema, hyperemia) or addition of new components (eg, tumor, hemorrhage) mandate compensatory decreases in other constituents in order to maintain constant ICP.

Mildly increased localized pressure in part of the brain may cause neurologic dysfunction confined to the affected area. More severe increases in pressure may cause local tissue compression as well as shift of intracranial structures, subfalcine and transtentorial herniation, and both local and distant neurologic dysfunction. In the most severe cases, transtentorial herniation produces compression at the level of the brainstem, potentially causing direct tissue damage to the midbrain, occlusion of arteries, infarction, and death.

Normal ICP varies by age. Normal values probably lie below 10 to 15 mm Hg in adults and older children and in the range of 3 to 7 mm Hg in younger children, 1.5 to 6 mm Hg in infants, and possibly even at subatmospheric levels in neonates. Intracranial hypertension (IC-HTN) has been reported in 13% of trauma patients with a normal head CT, 60% of patients with an abnormal head CT (demonstrating hemorrhage, contusion, edema, herniation, or compressed basal cisterns), and approximately 60% of patients with a normal head CT plus two or more of the following criteria: age greater than 40 years, systolic blood pressure greater than 90 mm Hg, and unilateral or bilateral abnormal motor posturing (flexing or extending to a noxious stimulus).[41] Therefore, ICP monitoring is often recommended in patients with severe TBI (GCS score of 3–8) and an abnormal CT scan or in those with severe TBI, a normal CT scan, and two or more of the select criteria listed earlier. ICP monitoring may also be considered in patients in whom a reliable neurologic examination cannot be performed because of sedatives or paralytics required for other reasons, such as difficult ventilator management or extreme agitation, in addition to those who require general anesthesia for nonneurologic surgery.

Higher mortality and worse outcomes have been described in patients with ICP persistently above 20 mm Hg.[42] Therefore, most centers consider ICP to be elevated when it exceeds 20 to 25 mm Hg, and ICP reduction measures are often recommended to bring values below this range.

MONITORING OF ICP

The most accurate, reliable, and lowest-cost ICP monitoring technology is the fluid-coupled ventriculostomy catheter, or EVD, connected to an external strain gauge. Another advantage of EVDs is that they permit CSF drainage as a therapeutic measure to control ICP. Parenchymal ICP monitors based on fiberoptic or miniaturized strain gauge transduction require less tissue penetration and do not require the ability to cannulate the cerebral ventricles (see Atlas Figure 1). They are roughly as accurate as EVDs but carry a higher cost. They cannot be recalibrated in situ and may be subject to measurement drift, although this is currently not as significant a concern as it was with earlier versions of these monitors. Parenchymal monitors do not allow for therapeutic drainage of CSF. Although some neurosurgeons place these devices in the subdural or epidural spaces, such positioning renders their data less accurate.

Of interest, a prospective trial found no difference in outcome between severe TBI patients managed with ICP monitoring and patients in whom elevated ICP was inferred and treated based on clinical and imaging findings.[43] This trial is often incorrectly interpreted as indicating that ICP monitoring is of no benefit in severe TBI patients. A more appropriate interpretation is that ICP was monitored and elevated ICP was treated in both groups, with the difference being invasive monitoring versus noninvasive monitoring based on examination and imaging. This trial did not compare a monitored to an unmonitored group.

CEREBRAL PERFUSION PRESSURE

Neurologic dysfunction may result from direct disruption of tissue or from impaired metabolism in a structurally intact brain. The recently injured brain is highly vulnerable to ischemia both regionally, near contused or otherwise damaged tissue, and also globally, from more diffuse impairment of CBF regulation. In addition, brief periods of hypotension or hypoxia that might be well tolerated by an uninjured brain may have significant deleterious consequences in a brain that has just received a traumatic insult.

For neural tissue to function normally, CBF must be adequate to meet metabolic demand. CBF depends on cerebral perfusion pressure (CPP), which is calculated by subtracting ICP from mean arterial pressure (MAP – ICP). Studies have shown that the injured adult brain is more susceptible to ischemia if the CPP trends below 50 mm Hg.[44] Children have been demonstrated to show improved survival when CPP is sustained above 40 mm Hg.[45] In adults, artificially maintaining CPP above 70 mm Hg results in unacceptably higher rates of adult respiratory distress syndrome without significant improvement in functional outcome.[46,47] Collectively, these data suggest that there exists a "floor" below which CPP should not drop (the exact value varies with age), but above this floor, there is no benefit from driving CPP to higher levels. There is likely an age-dependent continuum of optimal CPP values. Common practice is to avoid CPP less than 40 mm Hg in children, less than 60 mm Hg in adults,

and artificial elevation greater than 70 mm Hg in either population.

MONITORING OF CEREBRAL BLOOD FLOW AND METABOLISM

CT perfusion scanning can measure relative cerebral blood volume, CBF, and mean transit time after injection of iodinated contrast. It has been used extensively in stroke patients and has been investigated in TBI patients to determine the potential viability of contusional and pericontusional tissue and also to help guide judicious use of other therapeutic strategies, such as hyperventilation (HV).

Measurement of cerebral arteriovenous difference in oxygen content or of oxygen saturation in the jugular bulb ($S_{jv}O_2$) can also be used to assess global cerebral perfusion. Normal venous saturation of oxygen is approximately 50% to 69%. The occurrence of multiple episodes of venous desaturation (<50%) or of a sustained and profound single such episode is associated with poor outcome.[48] In addition, excessively high $S_{jv}O_2$ (>75%) is associated with poor outcome, perhaps because such measurements reflect cerebral hyperemia or possibly the existence of significant areas of infarcted tissue that will not extract oxygen.

More focal techniques to measure CBF include transcranial Doppler ultrasonography and parenchymal CBF monitoring. Thermal diffusion probes provide local CBF measurements based on the temperature difference between two points on a probe, the relative conductive properties of cerebral tissue, and convective properties of blood flow.

Cerebral microdialysis requires intraparenchymal placement of a very thin microdialysis catheter. Specific biochemicals diffuse into dialysate through a semipermeable membrane at or near the tip of these catheters. The dialysate is collected and subsequently analyzed. Neurochemical changes indicative of primary and secondary brain injury may be detected. TBI patients with poor clinical outcome have been shown to have elevated levels of specific neurotransmitters, as well as elevated lactate/pyruvate ratios and abnormal lactate and glutamate levels.

Brain tissue oxygen tension ($P_{bt}O_2$) monitoring allows direct measurement of oxygen level in a specific region of the brain. In most cases, $P_{bt}O_2$ mirrors oxygen delivery, but it may also increase if the tissue surrounding the catheter is infarcted and incapable of metabolizing oxygen. Normal $P_{bt}O_2$ has been reported as approximately 32 mm Hg. Patients with multiple or prolonged episodes of $P_{bt}O_2$ below 10 to 15 mm Hg have been shown to have increased morbidity and mortality.[49] Therapies are commonly targeted to keep $S_{jv}O_2$ above 50% and $P_{bt}O_2$ above 15 mm Hg or higher.[24]

Probes are often placed in penumbral tissue that is thought to be "at risk" but still salvageable. Others prefer to place such probes in brain that appears "normal," with the thought that monitors in this area provide data about global cerebral metabolism, as opposed to the local metabolic environment near a contusion or other visible lesion. Favorable results in a phase II study of $P_{bt}O_2$-based management in severe TBI patients[50] have led to the organization, funding, and imminent launch of a definitive phase III trial. At the present time, however, $S_{jv}O_2$ and $P_{bt}O_2$ monitoring are best viewed as adjuncts to ICP and CPP monitoring.

Management of Elevated Intracranial Pressure

ANALGESICS AND SEDATIVES

TBI patients will likely have increased levels of stress, agitation, and discomfort. These may cause increases in sympathetic tone, temperature, and blood pressure and lead to increased ICP, metabolic demand, and resistance to controlled ventilation.

The medications used to treat pain and agitation and their doses must be carefully monitored to achieve a balance between their beneficial effects in reducing pain and anxiety and their potentially adverse effects of hypotension, alteration or masking of the neurologic examination, and rebound ICP elevation when they are discontinued. If heavy sedation or pharmacologic paralysis is needed and a neurologic examination becomes unobtainable, consideration should be given to placement of an ICP monitor.

Short-acting agents are preferred in order to facilitate frequent neurologic examinations. Continuous infusion is often used instead of bolus administration to avoid potential transient ICP increases between doses. Fentanyl and its derivatives (remifentanil and sufentanil) are used increasingly for both acute and longer-term analgesia. They are short acting, reversible, and suitable for administration by continuous infusion.

Midazolam and propofol are two commonly used sedatives. Midazolam is a short-acting benzodiazepine that is effective for sedation of the ventilated TBI patient. Propofol is a hypnotic anesthetic with rapid onset and a very short half-life that facilitates rapid neurologic assessment. It should be limited in both concentration and duration to avoid propofol infusion syndrome.[51] First described in children and later in adults, this syndrome has generally been reported after use of excessively high doses or extensive durations of use of propofol. Features can include hyperkalemia, hepatomegaly, metabolic acidosis, rhabdomyolysis, renal failure, and death. Caution should be exercised if doses exceed 5 mg/kg/h or if duration of treatment exceeds 48 hours.

HYPEROSMOLAR THERAPY

While the exact mechanism of mannitol's beneficial effects is unclear, two primary actions have been postulated. In the first few minutes, it produces immediate plasma expansion with reduced hematocrit and blood viscosity, improved rheology, and increased CBF and oxygen delivery. This reduces ICP and is most notable in patients with CPP below 70 mm Hg.[52,53] Over the next 15 to 30 minutes, and perhaps lasting 90 minutes to 6 hours, mannitol creates an osmotic gradient, with increased serum tonicity and withdrawal of edema fluid from the cerebral parenchyma.

When given as a bolus, mannitol begins to reduce ICP after 1 to 5 minutes. This effect peaks at 20 to 60 minutes.

For acute ICP reduction in cases of neurologic worsening or herniation, an initial bolus of mannitol is often given at 1 g/kg, with subsequent administration at smaller doses and longer intervals, such as 0.25 to 0.5 g/kg every 6 hours. Mannitol opens the blood–brain barrier (BBB). It may cross the BBB itself, drawing water into the brain and transiently exacerbating vasogenic cerebral edema. In the past, furosemide was sometimes used synergistically with mannitol to reduce cerebral edema through increased serum tonicity and reduced production of CSF, although this intervention seems to have fallen out of favor.

There has been concern that continuous mannitol infusions lead to elevated serum levels of mannitol, with sequestering of mannitol within brain tissue, rebound shifts of water back into the brain, and worsening outcomes. It was thought that bolus administration reduced this effect and was more effective than continuous mannitol infusion for ICP reduction, with the added benefit of maximized rheologic increase in CBF. More recent investigations suggest that there are no good data to support this.[54] The significant water shifts caused by mannitol suggest that it may be wise to replace intravenous fluids to maintain euvolemia.

Acute renal tubular necrosis may be seen when mannitol is used in high doses in patients with preexisting renal disease or when other potentially nephrotoxic drugs are administered. Use of mannitol is often stopped when serum osmolality exceeds 320 mOsm/L.[55] Urine output should be followed to help minimize the likelihood of hypotension and hypovolemia.

Although TBI patients usually receive mannitol in conjunction with ICP monitoring, some clinicians employ high-level empiric dosing.[25] No strong evidence supports empiric prehospital administration of mannitol to TBI patients,[56] but mannitol may be of benefit in patients with signs of rapidly expanding mass lesions, such as decreasing level of consciousness with unilateral pupillary dilatation and contralateral hemiparesis. In such cases, mannitol may be used as a bridge toward definitive therapy, such as operative evacuation of mass lesions.

As with mannitol, hypertonic saline (HTS) is thought to lower ICP through two mechanisms. First, hypernatremia produces an oncotic pressure gradient across the BBB and mobilizes water from brain tissue. Second, rapid plasma dilution and volume expansion, endothelial cell and erythrocyte dehydration, and increased erythrocyte deformability lead to improvements in rheology, CBF, and oxygen delivery. HTS is often administered as a continuous infusion of 25 to 50 mL/h of 3% saline (replacing the patient's isotonic intravenous fluid) or bolus infusions of 10 to 30 mL of 7.2%, 10%, or 23.4% saline solution. Clinical response can begin within minutes and may last for hours, making HTS a potentially useful intervention in cases of severe ICP elevation or acute herniation syndrome.

A common target for serum sodium concentration is 145 to 160 mEq/L, and even higher serum sodium levels are sometimes chosen. However, it is unclear if deliberately driving up the serum sodium concentration to supranormal levels can prevent IC-HTN. Instead, high sodium levels are better viewed as a reason to stop administering HTS, rather than as a desired goal. Serum sodium and osmolality levels are often followed serially because excessively rapid increases in sodium, which may occur during HTS administration, may result in central pontine myelinolysis. This occurs most commonly in patients with preexisting chronic hyponatremia and is rarely seen in the patient with baseline normonatremia who receives HTS. HTS may also induce or exacerbate pulmonary edema in patients with underlying cardiac or pulmonary deficits.

Considerable debate attends the question of whether mannitol or HTS is the "better" osmolar agent. No high-quality data are available to provide guidance. In most cases, either agent would be acceptable. Obvious exceptions might include patients with fluid overload or congestive heart failure, in whom the diuretic effects of mannitol might be beneficial and the extra sodium load of HTS could be harmful, and hyponatremic patients, for whom an increase in sodium concentration may be desirable.

HYPERVENTILATION

By lowering PCO_2, HV induces vasoconstriction, reduction of cerebral blood volume, and reduction in ICP. Time of onset of effect ranges from 30 seconds to 1 hour. Peak effect may be seen at 8 minutes and may last up to 15 to 20 minutes. This rapid onset of action makes HV particularly effective in the treatment of an IC-HTN crisis and as a bridge to more definitive therapy, such as surgical decompression, or as a temporizing measure while other ICP-lowering therapies take effect.

Although HV was once used as a first-line therapy, concerns subsequently grew regarding prophylactic or prolonged use in TBI patients. During the first 24 hours after injury, perhaps as many as 50% of patients with severe TBI exhibit cerebral ischemia.[57] Induced vasoconstriction from HV may lower CBF even further. Depending on the degree of functional autoregulation, the brain may undergo increases in the oxygen extraction fraction or shunting of blood to ischemic areas, with the net result being an increase in the total ischemic volume.

Severe TBI patients should be kept normocarbic (PCO_2 = 35–45 mm Hg). If HV becomes necessary, brief periods of mild HV (PCO_2 = 30–35 mm Hg) may be effective for bringing ICP down while other treatment strategies are initiated. Prophylactic HV is contraindicated because it has been associated with worse outcomes.[58] If HV is used, consideration should be given to tracking cerebral oxygenation via monitoring of $S_{jv}O_2$ and/or $P_{bt}O_2$.

DECOMPRESSIVE CRANIECTOMY

If the above therapies fail to provide adequate control of ICP, additional interventions that may be considered include decompressive craniectomy (DC), barbiturate coma, and hypothermia.

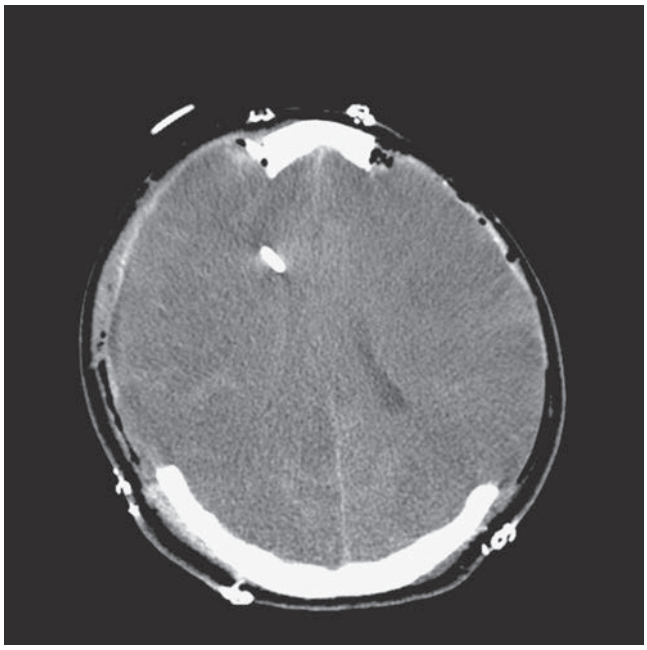

FIGURE 22-9 Computed tomography scan showing bilateral hemispheric decompressive craniectomies performed in a patient with severe cerebral edema.

Some patients with TBI require emergency craniotomies to evacuate focal hemorrhagic lesions. The bone is removed, the lesion resected, dura closed, and bone replaced. More severe cases of TBI may develop diffuse cerebral edema, contusions of large size in adjacent areas, or multiple, coalesced contusions. In these cases, it may be preferable to leave the bone flap off. Additionally, when ICP is refractory to the previously mentioned management techniques, DC effectively expands the intracranial space to lower the ICP.

The most common DC technique is a unilateral hemispheric decompression. Bifrontal and bilateral hemispheric craniectomies (Fig. 22-9) have also been described and may be more appropriate in some cases. The dura is opened widely, and areas of noneloquent contused or devitalized brain can be removed if required. The larger the size of the decompression, the better. The brain is then contained only by the augmented dural covering and the more compliant scalp.

DC is most commonly used in patients with IC-HTN refractory to maximal medical management. Ideally, operative intervention should occur before ICP has been dangerously elevated for sustained periods of time. Success depends largely on patient selection. Regardless of the preoperative indications or patient profile, continuing postoperative IC-HTN greater than 35 mm Hg has been associated with very high mortality rates.[59]

Early surgical intervention may be an option for potentially salvageable patients presenting with severe unilateral or bilateral cerebral edema, parenchymal lesions resistant to initial medical management of ICP, or other injuries whose management conflicts with standard ICP control measures (eg, patients with acute respiratory distress syndrome requiring elevated ventilatory pressures).

DC can be effective for reducing ICP, but improvement in outcome has been difficult to demonstrate because most reports describing this practice consist only of case series, lack appropriate control subjects, and/or do not achieve statistical significance with regard to all end points.[60] The prospective, randomized, controlled DECRA trial of bifrontotemporoparietal DC in patients with diffuse TBI who exhibited increasing ICP was essentially an investigation of "prophylactic" DC intended to prevent IC-HTN and its sequelae. The results demonstrated that DC not only failed to improve outcome, but was actually associated with worse outcomes. However, post hoc statistical adjustment for imbalance of rates of baseline pupillary reactivity between groups caused differences in outcome to disappear.[61] Thus, very early (essentially prophylactic) DC in patients with diffuse TBI does not improve outcome and may even make things worse.

RESCUE-ICP was another trial investigating the role of DC not as an up-front prophylactic intervention, but as a salvage procedure after other interventions have failed to control elevated ICP.[62] The investigators found that DC was effective at lowering mortality, but at the price of increased numbers of vegetative and severely disabled patients; the likelihood of favorable outcome was not improved by DC.

DC is not a benign procedure. Complications are common. These include infection, subdural hygroma, hydrocephalus, syndrome of the trephined, CPP breakthrough, and cerebral infarction.

BARBITURATES

Barbiturates benefit TBI patients by decreasing the cerebral metabolic rate of oxygen ($CMRO_2$), decreasing formation of free radicals and intracellular calcium influx, and lowering ICP. Side effects such as immunosuppression and hypotension from reduced sympathetic tone and mild myocardial depression often limit the use of these agents. TBI patients in coma (GCS score ≤8) receiving barbiturate therapy demonstrate infectious and respiratory complication rates in excess of 50%,[59] and significant systemic hypotension may occur in 25% of patients[63] despite adequate intravascular volume and pressor therapy. Barbiturates clearly reduce ICP, but studies have shown both worsened and improved outcomes for TBI patients receiving barbiturate therapy.

Patients with hemodynamic instability, sepsis, respiratory infection, or cardiac risk factors are excluded from barbiturate therapy. Those receiving barbiturates should be closely monitored for signs of cardiac compromise or infection, with cessation of therapy if systemic effects of the treatment become significant and unmanageable. A pretherapy echocardiogram and intratherapy use of a pulmonary artery catheter should be considered.

There is no role for prophylactic barbiturate therapy in TBI patients because it increases hypotension without significantly improving outcome.[64] It should be reserved for use in controlling ICP only after other treatments have failed.

A typical pentobarbital regimen is a loading dose of 10 mg/kg over 30 minutes, followed by a 5 mg/kg/h infusion

for 3 hours. A maintenance dose of 1 mg/kg/h should then be started. Serum barbiturate levels of 3 to 4 mg/dL should be maintained, although poor correlation exists between serum level, therapeutic benefit, and systemic complications. Titration to clinical effect is commonly done. Continuous electroencephalographic evaluation is preferred by some. Dosing to the point of burst suppression produces near-maximal reductions of $CMRO_2$ and CBF.

HYPOTHERMIA

Induced therapeutic hypothermia in TBI patients may reduce cerebral metabolism, ICP, inflammation, lipid peroxidation, excitotoxicity, cell death, and seizures. Adverse effects of hypothermia include decreased cardiac function, thrombocytopenia, elevated creatinine clearance, pancreatitis, and shivering with associated elevations in ICP. Interest in induced hypothermia was fueled by a large body of preclinical evidence, anecdotal observations (such as children trapped under the ice in frozen lakes), single-center clinical trials, and several meta-analyses.[65-69] Although its use in TBI patients has been adopted by some trauma centers, and level 1 evidence supports its use in patients with cardiac arrest from ventricular fibrillation or ventricular tachycardia and in neonatal hypoxic-ischemic encephalopathy, clinical trials to date have not shown significant improvements in outcome from induction of hypothermia in TBI patients. This lack of effect includes both immediate prophylactic use and later use as a salvage therapy after other measures have failed to control IC-HTN.[70-72]

Meta-analyses of more recent data and subsequent guidelines[24] note a nonsignificant trend toward mortality reduction (compared to normothermic controls) when target temperatures are maintained for greater than 48 hours. Hypothermia-treated patients have been reported to reach significantly better outcomes. Similarly, retrospective analyses suggest that perhaps patients with traumatic intracranial hematomas that require surgical intervention fare better if their temperature is lowered to or below 35°C within 90 minutes of the start of surgery.[73] Additionally, patients who are hypothermic on admission seem to have improved outcomes if hypothermia is maintained, as opposed to rapidly warming them to normothermia. Interpretation of these results is limited, however, by small sample sizes and potential confounding factors in each study.

Many practitioners aim for a target temperature of 33°C and, if possible, maintain that degree of hypothermia for 48 hours or longer. This temperature may be carefully titrated upward to 34°C or 35°C while ICP is monitored because some patients may still demonstrate the ICP-lowering benefit of hypothermia at these temperatures, with perhaps less risk of adverse systemic events from lower temperatures. Monitoring for untoward effects of hypothermia should include attention to potential electrolyte abnormalities and cardiac rhythm disturbances. Rewarming of these patients should take place very slowly, not exceeding 1°C per 4 to 6 hours, or more slowly (or even returning to a lower temperature) if ICP begins to rise precipitously.

STEROIDS

Glucocorticoids are not recommended for treatment of TBI.[24,74,75] Increased mortality has been reported in trials investigating the effect of steroids on outcome after TBI. Of course, this restriction does not apply in cases when patients require steroids for treatment of other medical problems.

Progesterone is another steroid that has been investigated as a potential therapy for TBI. Despite supportive preclinical and early-phase clinical data, progesterone failed to confer benefit to TBI patients in two large multicenter trials.[76,77]

OUTCOME

Prognostic Data

To interpret and compare the effectiveness of various treatments, common end points are necessary for communication between practitioners or comparison of studies. The Glasgow Outcome Scale (GOS)[78] (Table 22-6) is a widely used outcome grading scale, with many studies separating patients into those with good outcome (GOS = 4 or 5) and those with poor outcome (GOS = 1–3). Although its separation of patient categories is relatively coarse and may not identify the subtleties of recovery in many TBI patients, it remains a useful tool for describing patient outcome, just as the GCS is a useful tool for tracking a patient's neurologic examination. The subsequent GOS-Extended permits slightly more refined discrimination by expanding the original five categories into eight.[79] Importantly, a patient's ultimate neurologic outcome may not be fully evident until weeks or months of treatment have taken place in hospitals, rehabilitation centers, and at home.

The medical practitioner is often called upon early in a patient's course to make predictions of outcome based on

TABLE 22-6: Glasgow Outcome Scale

Score	Meaning	Notes
5—good recovery	Resumption of normal life	May have minor deficits, ± return to work
4—moderate disability	Disabled but independent	Can use public transportation and work in sheltered environment
3—severe disability	Conscious but disabled	Dependent for daily support, ± needs institutionalization
2—persistent vegetative state	Unresponsive, speechless	May open eyes spontaneously after several weeks and achieve sleep/wake cycles
1—death	Dead	

limited information. Various studies and meta-analyses[80-82] show that worse prognosis is seen in patients with bilaterally dilated pupils or absent pupillary light reflexes, absent oculocephalic or oculovestibular reflexes, increased Injury Severity Score (>40), extremes of age (>60 years and possibly <2 years), hypotension (systolic blood pressure <90 mm Hg, worse with concomitant hypoxemia), abnormal CT scan (extensive tSAH, compression or obliteration of basal cisterns), persistent ICP greater than 20 mm Hg, elevated ICP during the first 24 hours, or presence of apolipoprotein E4 allele. Probability of poor outcome increases with worsening initial total GCS score (especially GCS <9), and some studies show worse prognosis based on lower GCS subscores (motor ≤3, eye opening ≤2, verbal response ≤2).

Brain Death

"Brain death" refers to the irreversible absence of any brain function. Ancillary tests are sometimes used to support the clinical diagnosis, but they should not supplant the clinical examination as the primary means of making this diagnosis. Many people, including some in health care fields, think that brain death is somehow not "real" death. Uninformed discussion of this condition by popular media often contributes to this misunderstanding. It must be emphasized that brain death is a legally binding death, with the same degree of finality and certitude as cessation of cardiopulmonary function. The required components of diagnosing brain death may vary between states and between different hospitals, but the core elements are comparable.

No confounding factors may be present if brain death is to be diagnosed. Examples include hypothermia, hypotension, sedatives, paralytics, alcohol or other drugs of abuse, hepatic encephalopathy, hyperosmolar coma, atropine, recent cardiopulmonary resuscitation/shock/anoxia, and similar factors. Patients must have nonreactive and usually dilated pupils and no observable corneal, oculocephalic, oculovestibular, gag, cough, or other brainstem-mediated reflexes. No spontaneous breathing is present. Patients demonstrate no movement or other response to pain.

If the clinician chooses to forgo apnea testing because of a patient's inability to tolerate it or because of institutional protocols, other types of ancillary testing may be used if desired. These include cerebral radionuclide testing to confirm lack of uptake in brain parenchyma, cerebral angiography to verify absence of intracranial blood flow, and specialized electroencephalography techniques to verify electrocerebral silence, among other methods.

TBI patients who progress to brain death may be candidates for organ donation. Specialized organ procurement organizations are present in most states and represent a party separate from the treating team, with no conflict of interest regarding the patient's care. In many of these tragic cases, a patient's family members may receive a small measure of comfort from the knowledge that their decision to donate has helped other suffering patients (see Chapter 54).

FUTURE DIRECTIONS

Although much has been learned about the pathophysiology and treatment of TBI, translation of this knowledge to effective treatments has been challenging. One major change in the conceptualization of TBI has been the realization that TBI is actually a heterogeneous category composed of different subtypes of diseases, such as nonoperative diffuse injury versus large focal hematoma requiring immediate surgery. Future trials will likely be more focused in terms of the subtypes of TBI patients that are enrolled. Clinical studies are already moving beyond simple classification of outcome as "good" or "bad" by incorporating more sophisticated statistical techniques.

Another change in approach to clinical research is the growing recognition of the value of high-quality patient registries. There are far too many questions and far too few patients, investigators, and funds to subject every research question to a randomized, prospective, blinded, controlled trial. Conducting such trials for surgical interventions in emergency and critical care patients is especially problematic. Although the traditional approach to clinical trials will continue to predominate for the foreseeable future, the awareness that registries can supplement such trials and even represent a better method of investigation in some cases will allow many important questions to be addressed in a more expeditious manner than in the past.

Eye

Hampton Addis • Joshua Brozek • F. Lawson Grumbine

KEY POINTS

- Mechanical trauma to the eye is divided into open globe injury, where the sclera and/or cornea (eyewall) have a full-thickness wound, and closed globe injury, where these structures do not have a full thickness-injury.
- The six extraocular muscles are attached directly to the sclera, which is covered by the thin clear conjunctiva, which itself terminates at the cornea.
- In the patient's history, posttrauma floaters and a visual field defect are highly suggestive of a retinal detachment.
- When trying to measure vision between 1/200 and 20/20, the patient should be wearing his or her eyeglasses.
- The pupil may be peaked if the iris is sealing (plugging) a corneal or anterior scleral laceration.
- Computed tomography imaging is used to evaluate orbital fractures, orbital foreign bodies, and intraocular foreign bodies.
- After the application of appropriate medication, corneal abrasions heal faster without patching.
- Prior to consultation with an ophthalmologist, routine treatment for a hyphema can be initiated with topical steroid eye drops four times a day and a topical cycloplegic agent.
- Intraocular foreign bodies are associated with an increased incidence of endophthalmitis that results in poorer visual outcomes after penetrating injury.
- One of the signs of an orbital floor fracture is decreased skin sensation on the cheek of the affected side.

EPIDEMIOLOGY OF EYE TRAUMA

Worldwide 1.6 million people are estimated to be blind from ocular trauma, and another 19 million people suffer from severely impaired vision in one eye due to trauma.[1] Published literature from England looking at more than 39,000 patients treated for major trauma over 15 years found that 2.3% of patients had associated ocular injuries. Given that the eyes represent only 0.27% of the total body area, it is a curious phenomenon that the eyes are affected so often. In this series, the most common injuries involved the cornea, optic nerve, conjunctiva, and sclera.[2]

Men are reported to be four times more likely to suffer from ocular trauma compared to women, and in the same series from England, 75.1% of major trauma patients with ocular injuries were men. While ocular trauma most commonly results from motor vehicle accidents, workplace injuries and recreational injuries are also very commonly seen. Most injuries were due to sharp objects (54.1%), followed by blunt objects (34.4%); chemical injuries accounted for 11.5% of ocular injuries.[3]

EYE TRAUMA: TERMINOLOGY AND CLASSIFICATION

Eye trauma is divided first by etiology into mechanical, chemical, thermal, and electric. Thermal (eg, corneal burn from curling iron) and electric (eg, lightning) eye traumas are very uncommon, and treatment of complications will be by an ophthalmologist in an outpatient setting after discharge from the emergency department/urgent care setting. Chemical injury (alkali and acid burns) is not uncommon, and its management will be discussed in detail because immediate intervention by first responders and emergency department physicians can be sight-saving.

Mechanical eye trauma is the most common form of eye injury. It is divided into open globe injury, where the sclera and/or cornea (eyewall) have a full-thickness wound, and closed globe injury, where the eyewall does not have a full-thickness wound (Fig. 23-1).[4-6] Closed globe injuries are further subdivided into contusion injuries, lamellar laceration (ie, partial-thickness laceration), and superficial foreign body (ie, foreign body lodged on cornea, conjunctiva, or under

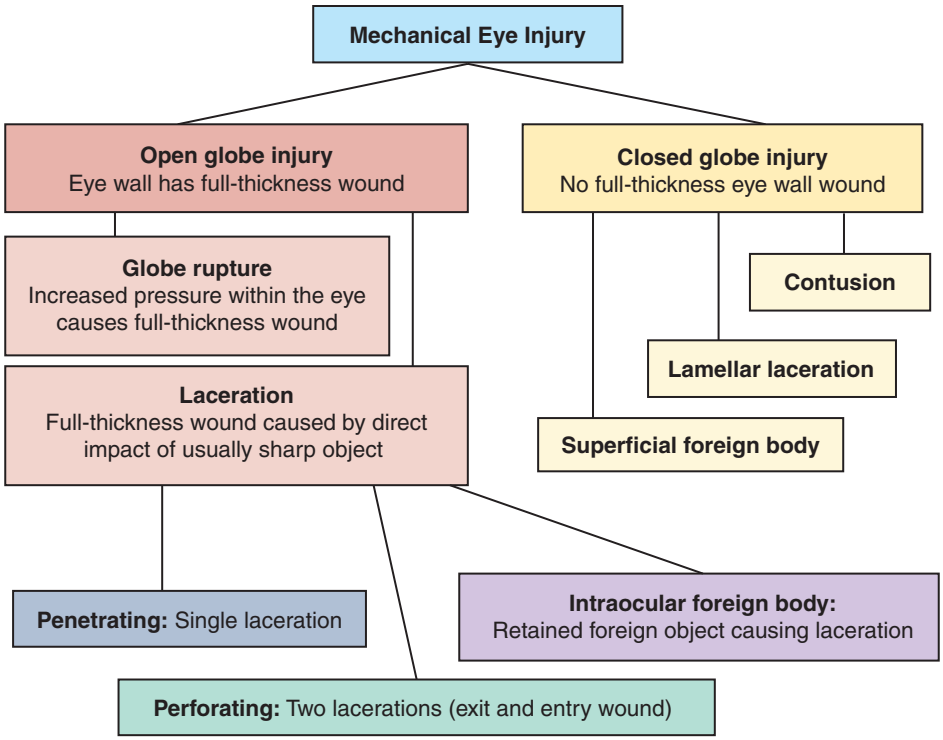

FIGURE 23-1 Injury classification.

the conjunctiva but *without* full-thickness wound of the eyewall).[6] Open globe injuries are further divided into ruptured globes and globe lacerations.[4,5] Ruptured globes result from blunt trauma, due to an extreme elevation of intraocular pressure at the moment of impact causing a rupture of the eyewall at the weakest site of the globe (force from inside out), usually away from the site of impact and frequently with significant herniation of intraocular contents.[4-6] Globe lacerations result from sharp trauma (usually) due to the direct impact on the eyewall (force from outside inward).[4,5] Perforating injury is a specific type of open globe injury in which the projectile or sharp object has caused an entry as well as an exit full-thickness eyewall wound.[4,5] In a laceration (also sometimes referred to as a *penetrating injury*), only a single full-thickness eyewall wound is present per projectile/object (there is no exit wound).[4,5] Finally, an intraocular foreign body (IOFB) is a type of laceration in which the offending foreign object is retained within the globe.[4-6]

The above classification is not simply an academic exercise. It provides an effective means of communication between treating physicians, and the type of injury has critical implications to management and visual prognosis.[4-6] For example, an open globe injury needs urgent operative repair, whereas a closed globe injury typically does not. Among open globes, globe rupture portends a poorer prognosis for final visual outcome than globe laceration.[7,8] Finally, an IOFB is usually best removed by a vitreoretinal surgeon and may require vitrectomy (sometimes not available in general ophthalmology operating rooms), whereas a simple laceration or perforating injury can be managed by any ophthalmologist in an operating room with an ophthalmic operating microscope. Certainly, in needed circumstances, primary closure can be achieved and the patient can be referred to a retina specialist for removal of an IOFB at a second procedure.

CLINICAL APPROACH TO EYE TRAUMA

It is imperative that concomitant nonocular injuries be evaluated and assessed on presentation to the emergency department. Involvement of the ophthalmologist in a timely manner and in the absence of life-threatening injury before transfer to the operating room is important. Sight-threatening injury needs to be recognized and treated within an appropriate time interval.

History

Every effort should be made to take a focused history—if not from the patient (if he or she is unconscious, distracted by other severe injuries, or under the influence of alcohol or drugs), then from relatives, bystanders, or first responders. In the setting of trauma, being time efficient is obviously of the utmost importance.

The most important aspect of the history is the mechanism of injury, as specific mechanisms suggest specific injuries that must be assessed for and treated. For example, hammering is associated with intraocular metallic foreign bodies, whereas fireworks injury is commonly associated with chemical

injury that must be treated emergently (as well as contusion injury—rarely open globe). Injury to the forehead as a result of a bicycle accident followed by loss of consciousness is a common scenario in which traumatic optic neuropathy may develop, whereas injuries from BB guns are associated with globe lacerations with particularly poor prognosis. Additionally, it is important to elucidate the setting of the injury: lacerations in a rural setting are associated with higher rates of endophthalmitis. Documenting whether protective eyewear was worn at the time of the injury is important for medicolegal reasons.

Patient symptoms are also important: floaters and a visual field defect are highly suggestive of a retinal detachment, whereas pain with sensitivity to light without compromise in the vision suggests a traumatic iritis (although a globe laceration and even an IOFB remain a possibility).

Ocular history is important for two reasons. First, it may modify the effects of trauma, for example, in the case of a patient who has previously had a corneal transplant, an open globe due to graft dehiscence will occur with much less force than normally expected. Similarly, in patients with previous cataract, glaucoma, or radial keratotomy surgery, the globe ruptures at the site of the previous wound. Second, ocular history is important because preexisting pathology may dictate different treatment decisions following trauma. For example, the threshold for surgical evacuation of a hyphema would be much lower in a patient with advanced glaucomatous optic neuropathy than in a patient with healthy optic nerves.

Past medical history is similarly important because it can modify treatment decisions. For example, hyphema is managed differently in patients with sickle cell disease. Another example would be patients with pseudoxanthoma elasticum who invariably have angioid streaks and have a much higher risk of choroidal rupture. There are also several systemic conditions that result in eye conditions unrelated to trauma, an obvious example being diabetes mellitus causing diabetic retinopathy that can cause nontraumatic vitreous hemorrhage.

An important aspect of the drug history is whether the patient is on anticoagulants or antiplatelet agents as this will complicate operative repair. Additionally, determining allergies to medications is critical.

Review of systems must assess for the patient's ability to survive anesthesia and surgical repair. Patients who cannot undergo surgery safely may be better managed medically even though the risk of losing their sight in one eye is inevitable rather than dying from complications of anesthesia.

Ocular Anatomy

Understanding the anatomy of the eye is critical in diagnosing ocular trauma. The eye sits inside the bony orbit with six attached extraocular muscles. The extraocular muscles are attached directly to the sclera. Overlying the sclera is a thin clear membrane called the conjunctiva, which terminates at the cornea. The cornea is the clear, most anterior surface of the eye that overlies the iris and, more posteriorly, the lens. The anterior chamber exists between the cornea and iris and is filled with aqueous fluid. The vitreous cavity separates the anterior segment from the retina. The retina contains light-sensitive photoreceptors, which transmit signal to the optic nerve. See Figure 23-2.

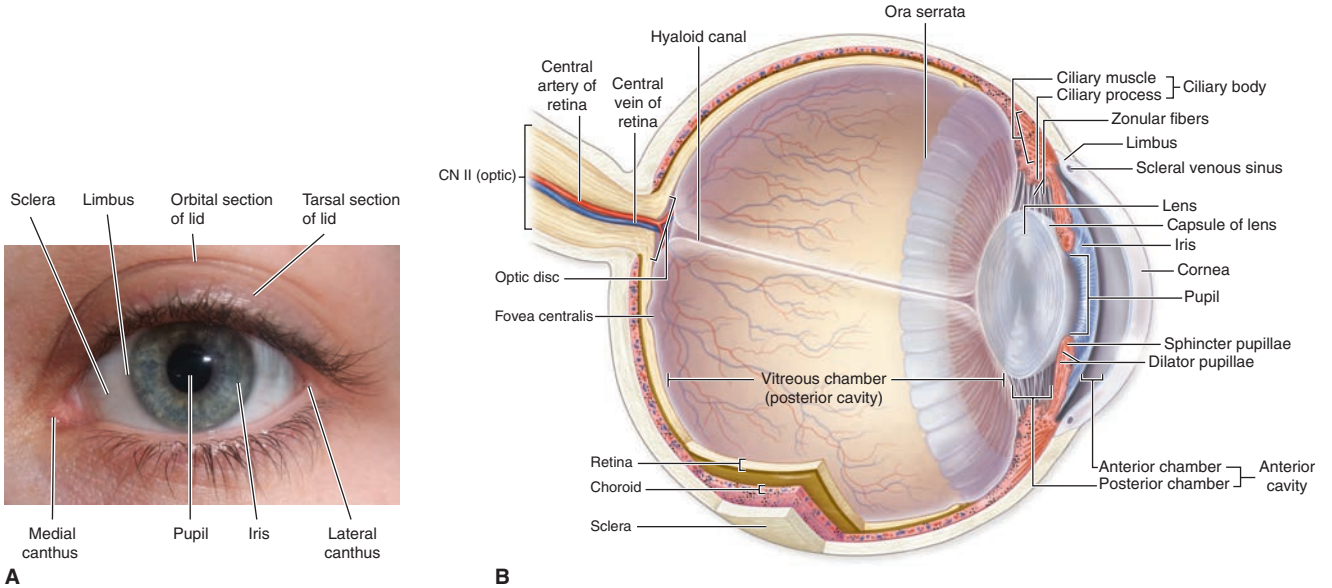

FIGURE 23-2 Anatomy of the eye. (***A:*** Reproduced with permission from Riordan-Eva P. Anatomy & embryology of the eye. Clinical Examination

In the blunt multisystem trauma patient, the presence of periocular facial injuries or, when able to be provided, complaints related to vision should prompt a screening ophthalmic evaluation. This will help to determine if an ophthalmology consultation is needed and, if so, how urgently. A screening ophthalmic examination should include visual acuity (each eye tested separately), pupillary examination, motility, measurement of intraocular pressure, and a penlight exam of the external eye. Clinical examination can be challenging due to pain or poor patient cooperation due to the influence of alcohol, drugs, or severe eyelid swelling, yet it is essential for proper diagnosis and management of ophthalmic trauma. The basic tool kit needed for rudimentary eye examination includes penlight, near vision card, topical anesthetic, fluorescein strip, and eye wash.

VISUAL ACUITY

Every ophthalmologic exam should begin with an assessment of visual acuity if the patient's clinical status allows. It is no exaggeration to state that failure to document the visual acuity is inexcusable and akin to failure to document the pulse! Measuring visual acuity is relatively easy.

Each eye is tested separately by having the patient read from a near card from one eye while the other eye is covered. The best means of covering the nontested eye is with an occluder, but the patient's hand or a 4×4 will suffice. The smallest line that the patient can read is what should be documented. The goal is to determine whether the patient has no light perception (NLP—cannot even see the light from a strong pen torch right in front of the injured eye with the room darkened), light perception only (LPO—can see the light but no hand movements), hand motions only (HM—can see hand movements but cannot count fingers), or vision between 1/200 and 20/20. When trying to measure vision between 1/200 and 20/20, the patient should be wearing his or her spectacles (if these are available). If a formal vision testing card is not available, documentation of ability to read the newspaper title (approximately 20/200) or normal magazine print (approximately 20/40) is still extremely helpful. In a blunt multisystem trauma patient, documentation of visual acuity is not always possible. In this scenario, it should be noted in the chart why the vision could not be assessed.

When possible, measuring visual acuity is crucial for three reasons. First, a specific level of vision prompts the examining physician to search for a diagnosis explaining it. For example, HM vision is not explained by a subconjunctival hemorrhage and requires the examiner to carefully examine for the other signs of a scleral rupture. Another example would be the patient who had trauma 3 days previously and presents to the emergency department with photosensitivity, mild lid edema, and vision of 20/400: before knowing this level of vision, traumatic iritis could have been contemplated, but with vision of 20/400, endophthalmitis with a self-sealed corneal or scleral laceration becomes a strong possibility.

The second reason it is important to measure the visual acuity is to document a baseline so that later in the course it can be established whether there is improvement or deterioration. For example, a patient with a vitreous hemorrhage and vision of HM is seen by a vitreoretinal surgeon for examination to rule out retinal tears and detachment; if a week later the vision is 20/200 (and there are no retinal tears or detachment), further observation is reasonable as it appears that the vitreous hemorrhage is spontaneously resolving. In contrast, if a week later the vision is light perception, this suggests that a retinal detachment has occurred due to an undetected retinal tear.

The final reason why it is important to measure visual acuity is that visual acuity at presentation is a strong predictor for final visual outcome.[7,8] Therefore, having an initial visual acuity is essential if discussing the prognosis of the injury with the patient.

PUPILLARY EXAMINATION (SHAPE, REACTION, AND RELATIVE AFFERENT PUPILLARY DEFECT)

After visual acuity, the pupillary exam is a critical component of the physical examination in ocular trauma. A bright, handheld light can be used to examine the pupils as the patient looks off into the distance. The size in millimeters and shape of each pupil should be noted. The pupils should constrict briskly and equally after application of bright light. Any discrepancy between the size and shape of the pupils between the two eyes should alert the clinician for possible ocular injury. The pupil may be peaked if the iris is sealing (plugging) a corneal or anterior scleral laceration. The pupil may also be irregular if there has been injury to the iris sphincter muscle (typically a result of blunt trauma, commonly associated with hyphema).

The pupil will be dilated and not react to light if there is compression or damage to the third cranial nerve intracranially (following head trauma); if this is suspected, urgent neurosurgical consultation and computed tomography (CT) imaging is required. Additionally, an orbital compartment syndrome (due to retrobulbar hemorrhage or any cause for swelling within the orbit) may cause compression of the third nerve (and all the other nerves) and result in a fixed dilated pupil. Finally, if there has been damage or ischemia of the iris sphincter (very elevated intraocular pressure or torn iris sphincter), the pupil will not react to light.

A relative afferent pupillary defect (RAPD) is important to document for two reasons. First, its presence means that there is injury to the retina or optic nerve. This is important as it prompts the examiner to carefully consider the diagnoses that may be affecting the retina and optic nerve and not satisfy himself or herself with a diagnosis involving the anterior segment only. Second, the absence of an RAPD is a strong predictor of visual survival, with only 97% of eyes without an RAPD maintaining some vision.[9]

RAPD is measured by alternately shining a strong light into each eye. At least 2 seconds should be spent shining each eye with 1 second in transit. When the pupils dilate when the

light is shone into one of the eyes, it is said that an RAPD is present in that eye. It is important to note that it is the first movement of the pupil when the light is shone into it that matters. From the above, it should be obvious that, even in a patient with a pupil that is immobile in the injured eye, determination of the presence or absence of an RAPD in that eye is possible since the contralateral pupil movement can be observed while shining the light into the injured eye.

MOTILITY

Examination of motility should be performed in all patients in need of a screening ophthalmic examination. In a normal state, the two eyes will move in unison fully in all directions. If the motility of one eye is limited, the patient will experience double vision when looking in the direction of the limitation. This is because the eyes will become misaligned.

Examination of motility is performed by asking the patient to follow an extended second digit or pen in all directions of gaze. It is important to ascertain whether the patient has diplopia when looking at any of these directions, as this indicates that the two eyes are not moving in synchrony.

EXTERNAL AND OCULAR ADNEXAL EXAMINATION

Examination of the ocular adnexa involves looking at the eyelid position with eyes both open and closed, contour, and evidence of laceration. It is important also to evaluate for proptosis, and in patients with proptosis, testing for resistance to retropulsion may point toward elevated intraocular pressure and congested orbital compartment. After the integrity of the globe has been established, the clinician may apply gentle digital pressure to the closed eyelids. Any resistance with digital pressure and asymmetry between the two eyes may indicate a retrobulbar hemorrhage. As part of the routine external examination, the examiner should palpate the orbital rim for "step-off" in cases of suspected orbital fractures. In cases of suspected orbital floor fractures, testing sensation along the distribution of cranial nerve V on either cheek can be an early sign.

ANTERIOR SEGMENT EXAMINATION

The slit lamp biomicroscope is the ideal instrument to examine the anterior segment. Portable versions exist for patients who cannot sit up to be examined with the regular slit lamp. If not even a portable slit lamp is available, a direct ophthalmoscope offers high magnification and can be used, and if even this is unavailable, a penlight with a blue filter and a magnifying lens can be used.

Throughout the examination of the anterior segment, it is important to remember that pressure should not be exerted on the globe (as it may be open and it is uncomfortable to the patient); rather, the lids should be lifted and held up by applying pressure against the orbital rim.

Examination of the anterior segment starts with inspection of the conjunctiva and sclera. Subconjunctival hemorrhage is a common finding sometimes even after trivial trauma but can be a sign of an open globe; therefore, the other signs of an open globe should be sought. Additionally, a subconjunctival hemorrhage can be a sign of a retrobulbar hemorrhage, especially if its posterior margin cannot be defined; therefore, the other signs of this condition should also be sought. Uveal tissue, vitreous gel, or even retina is sometimes evident on or under the conjunctiva in cases of scleral rupture or laceration.

Inspection of the cornea should be performed, actively searching for a corneal laceration, a corneal foreign body, a corneal abrasion, and a corneal concussive injury to the endothelium (appears as opacity on the endothelium). A corneal abrasion may be more easily seen by applying fluorescein drops or a fluorescein strip in the tear lake and using the cobalt blue filter.

Examination of the anterior chamber should be performed looking for hyphema, hypopyon (layering of white cells inferiorly diagnostic of endophthalmitis in the setting of trauma), a shallow anterior chamber suggestive of open globe, an anterior chamber foreign body, and anterior chamber cell (white cells in the anterior chamber—are seen in endophthalmitis or traumatic iritis). Examination of the iris should be performed looking for iris tears or iris dialyses.

Finally, examination of the lens should be performed to determine whether it is present or not (it may have been lost in the case of a corneal laceration with extrusion of ocular contents or in the case of rupture at the site of prior cataract surgery with extrusion of the intraocular implant), whether it is subluxed, whether there is an intralenticular foreign body, or whether cataractous changes have developed.

INTRAOCULAR PRESSURE

There is no need to check the intraocular pressure if the globe is obviously open, but if not, measurement of the intraocular pressure is mandatory. Several methods are available for measuring intraocular pressure. The gold standard is the Goldmann applanation device used with the slit lamp, but a Tono-Pen is a convenient device for use in the emergency department setting. To measure the intraocular pressure, a drop of topical anesthetic is administered to each eye. The handheld tonometer can then be applied to the corneal surface repeatedly to obtain a pressure reading. Take care not to press on the eye when performing this exam element, as it will yield a falsely elevated reading.

A high pressure can be seen with hyphema or with a retrobulbar hemorrhage (due to transmission of the elevated intraorbital pressure), whereas a low pressure is seen with an open globe or severe intraocular inflammation. It should be noted, however, that the intraocular pressure may, on occasion, be normal (rarely high) with an open globe.

DILATED FUNDOSCOPY

Dilated fundoscopy is best performed using indirect ophthalmoscopy, a skill beyond the remit of a trauma surgeon. This will be performed by your consulting ophthalmologist.

Ancillary Studies

B-mode ultrasonography is very useful for examination of the posterior segment in the presence of media opacities not allowing ophthalmoscopy. Retinal tears, detachments, and IOFBs can be detected. It should be noted that the investigation is strongly operator dependent and that, even in experienced hands, severe vitreous hemorrhage cannot be reliably distinguished from a retinal detachment.[10]

CT imaging is important in evaluating for orbital fractures, orbital foreign bodies, and IOFBs, especially metallic. An orbital CT scan with thin slices should be ordered. Note that the dimensions of foreign bodies are commonly exaggerated on CT images.[10] It should also be noted that vegetable matter (eg, wood) in the orbit is not well imaged by CT.

Initial Management of the Patient with Ocular Trauma

After the patient is stabilized (ie, life-threatening injuries have been stabilized), other organ-threatening injuries need to be managed in parallel to evaluating the injured eye. The following are priorities when managing the injured eye:

1. Rule out a chemical injury by history (splash of liquid into the eye, explosion at chemical facility, firework injury). If there is suspicion of a chemical injury, a pH strip should be checked (from the fornix) and irrigation should be started at once (see Chemical Injury section).
2. Rule out an open globe if possible: look for the specific signs (corneal/scleral laceration, prolapse of uveal tissue, hemorrhagic chemosis of the conjunctiva, low intraocular pressure, asymmetry in anterior chamber depth, vitreous hemorrhage). If there is reasonable suspicion of an open globe, exploration in the operating room should still be carried out (eg, appendectomy; while one endeavors to reduce the rate of negative exploration, it is better to have a negative exploration than to miss the diagnosis). If there is an open globe or an open globe is suspected:
   a. The patient needs urgent (as soon as possible and certainly within 12 hours) repair in the operating room by an ophthalmologist, and the necessary arrangements need to be made (this may include transfer to a center with an operating microscope and available ophthalmologist, ophthalmology consult, etc). The patient should be made NPO (nothing by mouth), and appropriate fluids for their systemic status should be given.
   b. If there is any suspicion that the globe could be ruptured or a rupture is confirmed, the eye should be shielded. If there is ever any doubt, the eye should be shielded until a formal ophthalmic evaluation can occur. Proper placement of the shield is such that the edges of the shield contact the bony orbital rim while the shield vaults over the soft tissues of the eyelids and eye. Patients should be instructed not to squeeze their lids or strain because this may cause further extrusion of intraocular contents. If a metal shield is not available, a cut Styrofoam cup may be taped over the eye.
   c. Order a CT scan of the orbits to rule out an IOFB. This should be performed for all open globe injuries.
   d. Administer tetanus toxoid.
   e. An intravenous fluoroquinolone antibiotic (moxifloxacin, levofloxacin, or ciprofloxacin) should be administered.
   f. Repair of lid lacerations or orbital fractures should *never* be undertaken before an open globe has been ruled out or repaired.
3. Identify other orbital or ocular injuries and treat accordingly.

OCULAR IMAGING

Various imaging modalities can be used to provide further information to supplement the clinical examination. Typically, B-scan (brightness-amplitude scan) ultrasonography is performed when there is no clear view to the posterior segment of the eye on dilated examination. This typically occurs as a result of a media opacity located anywhere along the visual axis. For example, if corneal scarring, significant hyphema or hypopyon, lens opacity, or vitreous hemorrhage occurs, it may be impossible to adequately assess the status of the retina. B-scan ultrasonography uses 10 MHz to provide high-resolution images with low penetration to determine if lens dislocation is present or retinal detachment has occurred. If a retinal detachment has occurred, it will be seen as a thick, hyperechoic, billowing sheet just anterior to a fluid-filled hypoechoic space. Typically, this specialized form of ultrasound will not be available to the trauma surgeon, and the decision about whether or not B-scan is necessary will be made by your consultant ophthalmologist.

In general, CT is the imaging modality of choice in the acute setting of ocular trauma. As mentioned earlier, a CT of the orbits should obtained in any open globe injury to rule out an IOFB. Since this modality provides excellent visualization of osseous structures, it is exceedingly useful in evaluating fractures around the orbit. As a reminder, entrapment in the setting of orbital fracture is a clinical diagnosis based on multiple exam findings including extraocular motility restriction, diplopia, or observation of oculocardiac reflex.

Magnetic resonance imaging (MRI) is not routinely used for the initial evaluation of the trauma patient. Orbital fractures, IOFBs, and retrobulbar hemorrhage can be identified quickly and effectively with CT scan. If a patient requires an MRI, it is important to first rule out an intraocular metallic foreign body with CT scan. If optic neuropathy persists and is suspected secondary to trauma, an MRI may be ordered to further evaluate the optic nerve after the initial injuries are stabilized.

WHEN TO CONSULT OPHTHALMOLOGY

The decision to consult ophthalmology will be provider dependent, depending on the comfort level and knowledge of the trauma physician in dealing with the current ocular

issue. The following list of ophthalmic issues, while not all-encompassing, should prompt a consult to ophthalmology:

1. Suspected penetrating injury to the globe necessitating exploration
2. Orbital fracture with suspicion for extraocular muscle entrapment
3. Eyelid laceration, especially when involving the margin or when medial to the puncta
4. Suspicion for retrobulbar hemorrhage resulting in orbital compartment syndrome
5. Suspected retinal detachment
6. Marked decrease in vision from patient's baseline despite use of corrective lenses

PROGNOSIS OF EYE TRAUMA

Prognosis of eye trauma involves discussion of three entities: whether the patient is going to retain his or her globe, what the patient may expect his or her vision to be in the long term, and finally, whether this will affect the uninjured eye (see later discussion on sympathetic ophthalmia).

Whether a patient is going to retain his or her globe depends on the specifics of the traumatic injury. It is rare that enucleation will be required for an eye sustaining an injury other than an open globe. Primary enucleation is rare (0.17% of open globes) and reserved for eyes where the sclera and cornea have been injured so severely that they cannot be sutured back together (usually due to a blast injury where the eye has been blown away or a gunshot injury directly to the eye).[11] Secondary enucleation (reported in 6%–20% of open globes) is much more common for ruptures than lacerations and is usually performed for a blind (NLP), painful eye.[7,9,11,12] An RAPD, NLP or LPO, visible uveal tissue, and concomitant eyelid laceration at presentation are risk factors for enucleation.[7,11,12] Enucleation to prevent sympathetic ophthalmia is also sometimes performed, although it is controversial (see later).

The best system that predicts long-term visual outcome (after appropriate management including surgical treatment) is the ocular trauma score (OTS).[8,13] In the OTS, a functional outcome (initial visual acuity) and five signs or diagnoses (rupture, endophthalmitis, RAPD, retinal detachment, and perforating injury) are used to estimate the likely visual outcome (Table 23-1).[8]

Many patients worry that a poorly seeing eye will cause "straining" of the other eye—this is unequivocally not true. However, the uninjured eye may develop sympathetic ophthalmia, a rare (incidence 0.03/100,000 per year),[14] bilateral uveitis that may occur 2 weeks to 50 years usually following eye trauma or surgery.[15,16] While originally described as a consequence of trauma, currently it is more common following eye surgery.[14] This is a consequence of improved management of ocular trauma, including prompt primary repair. Indeed, most cases with sympathetic ophthalmia following eye trauma present to the ophthalmologist several weeks after the initial trauma when the vision in the second eye is affected.[17] Tellingly, since World War II, there had been no cases of sympathetic ophthalmia reported in any military conflict until a single case was reported in the recent war in Iraq.[15] With current treatments, eyes affected with sympathetic ophthalmia commonly maintain functional vision, with the majority maintaining reading vision.[18] While removing the injured eye (when the vision is NLP) may decrease the rates of sympathetic ophthalmia, this is quite controversial given that sympathetic ophthalmia is rare (especially with appropriate management of the injured eye) and treatable.

TABLE 23-1: Determination of Ocular Trauma Score (OTS)

Determination of OTS	Variable	Raw score
Vision	No light perception (NLP)	60
	Light perception only (LPO) or hand motions only (HM)	70
	1/200 to 19/200	80
	20/200 to 20/50	90
	≥20/40	100
Diagnoses	Globe rupture	–23
	Endophthalmitis	–17
	Perforating injury	–14
	Retinal detachment	–11
Sign	Relative afferent pupillary defect	–10

Probability of a Given Visual Outcome Given OTS Score

Score	OTS	NLP (%)	LPO/HM (%)	1/200 to 19/200 (%)	20/200 to 20/50 (%)	≥20/40 (%)
0–44	1	74	15	7	3	1
45–65	2	27	26	18	15	15
66–80	3	2	11	15	31	41
81–91	4	1	2	3	22	73

CHEMICAL INJURY

Chemical injuries to the eye are true ocular emergencies, and time is of essence when treating acute chemical exposure. They represent 7.7% to 18% of ocular trauma.[19-21] Immediate and copious irrigation is vital to limiting the extent of damage to the ocular surface. Alkaline agents tend to penetrate the eye more rapidly due to saponification of cell membranes and lead to liquefactive necrosis. Acidic agents cause coagulative necrosis with protein precipitation within the tissue; thus, acidic injuries tend to cause less severe injury compared to alkali agents due to less penetrative damaging effects.[22] The nature of the toxic agent should be identified and brought into the emergency center if possible so that pH can be tested.

Following toxic chemical exposure to the ocular surface, irrigation should begin immediately with water, saline, or any commercially available eyewash with a neutral pH, and continued if possible while en route to the nearest emergency center. On arrival to the emergency center, an initial pH should be taken by placing pH testing paper in the inferior fornix. Irrigation should continue until the measured pH is neutral (7.2–7.4) for at least 5 minutes after irrigation has stopped. It is important to note that irrigation can last up to an hour or more depending on the severity of the splash injury in order for the eye's pH to normalize.

Irrigation can be performed by directly pouring saline from intravenous tubing to the surface of the eye. Placing one drop of topical ophthalmic anesthetic such as proparacaine may help the patient to keep the affected eye open. Caution should be exercised when placing irrigation lenses such as a Morgan lens since retained particulate matter or foreign body can be trapped in the fornices of the eye. If an irrigation lens is to be used, the superior eyelid should be everted to look for embedded foreign body, and both the superior and inferior fornices should be swept clean with a moist cotton swab to remove any particulate matter.

Chemical injuries are classified using the Dua classification system (Table 23-2), which reflects the amount of limbal involvement and the percentage of conjunctival involvement. Corneal epithelial defects can be easily detected using topical fluorescein staining, such as a moistened fluorescein strip or manufactured combination of fluorescein and topical anesthetic eye drops. Limbal ischemia appears as blanching of normal conjunctival and limbus blood vessels. Hyperemia in the setting of chemical injury presents better prognosis than a white eye.

The goals of treatment for chemical ocular injury are to stop ongoing tissue degradation, promote reepithelialization of the surface, minimize inflammation, and prevent infection. For grade I damage, the patient can be treated with an antibiotic (eg, erythromycin) or antibiotic/steroid mixed combination eye ointment (eg, dexamethasone/polymyxin/neomycin) four times a day to the affected eye and a topical cycloplegic agent (eg, atropine) to decrease ciliary spasm and decrease formation of posterior synechiae.[22] For grade II, topical steroid eye drops may need to be added to the regimen to decrease the inflammatory response for the first 1 to 2 weeks after injury. In grades III and IV, high-dose vitamin C, 10 ascorbate eye drops, and 10% citrate eye drops have been associated with more rapid recovery and better vision.[23] Oral doxycycline is a collagenase inhibitor and may reduce the risk of corneal thinning and perforation in severely burned eyes.[24,25]

Consultation with an ophthalmologist is necessary for follow-up and ensuring that the treatment regimen is leading to clinical improvement. Rarely is immediate surgical intervention needed in chemical injury patients.

MECHANICAL INJURY

Subconjunctival Hemorrhage

Subconjunctival hemorrhage is a very common condition that presents as an ocular emergency. Clinically, subconjunctival hemorrhages appear as flat, bright red blood noted under the bulbar conjunctiva (Fig. 23-3). It can be alarming in appearance, and although severity can be variable, in general it is rather benign and poses no threat to vision.

TABLE 23-2: Dua Classification for Ocular Surface Burns

Grade	Prognosis	Clock hours of limbal involvement	Conjunctival involvement	Analog scale*
I	Very good	0	0%	0/0%
II	Good	≤3	<30%	0.1–3/1–29.9%
III	Good	>3–6	>30–50%	3.1–6%/31–50%
IV	Good to guarded	>6–9	>50–75%	6.1–9/51–75%
V	Guarded to poor	>9–<12	75–<100%	9.1–11.9/75.1–99.9%
VI	Very poor	12	100%	12/100%

*The analog scale records accurately the limbal involvement in clock hours of affected limbus/percentage of conjunctival involvement. While calculating percentage of conjunctival involvement, only involvement of bulbar conjunctiva, up to and including the conjunctival fornices, is considered.

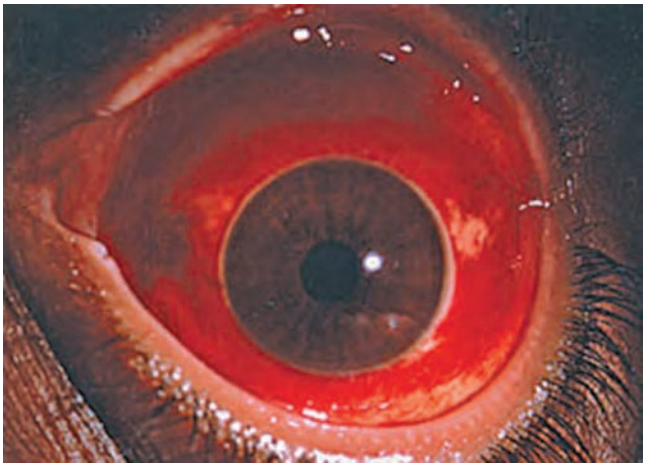

FIGURE 23-3 Subconjunctival hemorrhage.

Spontaneous subconjunctival hemorrhage can be due to Valsalva maneuvers, coughing, sneezing, vomiting, or heavy lifting. Minor trauma such as excessive eye rubbing can also cause subconjunctival hemorrhages. Often, no specific etiology can be found. When subconjunctival hemorrhage is noted with other signs of facial or ocular trauma, one must rule out occult globe injury. Obtaining a good history is vitally important to determining if further workup is needed. A history of blunt trauma may present with subconjunctival hemorrhage, but the patient may also have orbital fractures that need to be evaluated.

Patients who present with complete 360° of subconjunctival hemorrhage from blunt trauma should be examined by an ophthalmologist to rule out open globe injury. Clues that may indicate occult open globe injury include peaked pupil, asymmetric anterior chamber depth, asymmetrically low intraocular pressure, and subconjunctival pigment.

In cases of isolated subconjunctival hemorrhage, no treatment is needed. The hemorrhage will usually resolve spontaneously in a few weeks. Patients need to be informed that the hemorrhage will change color over the next few days and may expand as the bruising process evolves. These patients typically do not require ophthalmic follow-up.

Conjunctival Lacerations

Conjunctival lacerations may present in isolation or in combination with damage to deeper layers of the eyewall and the sclera. Isolated conjunctival lacerations do not require surgical repair unless they are large (eg, >2 cm) or lie over an extraocular muscle insertion. Often it is difficult to assess if the sclera is involved without manipulation using a cotton tip swab to gently push away the conjunctiva exploring the scleral wall beneath. For large conjunctival lacerations or those that may involve the sclera, ophthalmic consultation is warranted.

Scleral penetration can be associated with vitreous hemorrhage, and if the scleral defect is large enough, vitreous prolapse can be seen as well. If there is vitreous hemorrhage, the patient's vision may be compromised. It is important to not engage the vitreous prolapsed through a scleral defect since traction on the vitreous strands can lead to retinal tears, leading to rhegmatogenous retinal detachments.

CORNEAL ABRASION

Patients with corneal abrasions typically present with intense pain and photophobia. Trauma to the cornea from a fingernail, paper cut, thrown objects, and contusive injury (eg, air bag) can result in the superficial corneal epithelium being stripped away from the underlying stroma. Simple corneal abrasions can be one of the most painful injuries that patients experience because beneath the corneal epithelium lies an extensive plexus of sensory nerves from the ophthalmic division of the trigeminal nerve, and when they become exposed, severe pain results.

Corneal abrasions can be diagnosed clinically when topical fluorescein dye is taken up by the area devoid of epithelium and turns bright green viewed with a cobalt blue light. The size and location of the abrasion can be documented using a circle to represent the cornea. Traditional teaching advocated patching for corneal abrasions in the past. Currently, evidence shows that patients heal faster without patching, and also with patching there is no benefit with regard to pain reduction. Small corneal abrasions without concomitant ocular injury can be managed and treated with antibiotic ophthalmic ointment, topical cycloplegic agent, and topical ophthalmic nonsteroidal anti-inflammatory drugs (eg, ketorolac or diclofenac). Although there is no good evidence that topical ophthalmic antibiotic is indicated in cases where there was no recent history of contact lens wear or injury with organic material, use of a topical ophthalmic antibiotic is not unreasonable given the devastating sequelae of corneal infection and scarring.[26-33]

History of contact lens wear or injury with organic material raises the risk of infection. These patients should never be patched given the elevated risk of infection and should all be referred for prompt ophthalmic consultation. Patients with large corneal abrasions may benefit from bandage soft contact lens placed by an eye care professional for comfort. If the affected eye is patched, the patient should follow up the next day with an eye care professional to monitor healing and assess for early signs of infection.

CORNEAL FOREIGN BODIES

Corneal foreign bodies are one of the most common forms of ocular trauma, presenting second in frequency only to corneal abrasions in emergency centers.[34] Most patients present with small superficial corneal foreign body with good or mildly affected vision. Individuals can have debris blown into the eye while walking outdoors or while performing high-risk activities such as grinding, drilling, hammering, and using a leaf blower. There are many causes for corneal foreign body, but lack of protective eyewear contributes to increased risk.

Specific questions regarding hammering metal on metal or grinding metal need to be asked, and a detailed history

regarding the exact mechanism of injury helps to highlight patients at increased risk for penetrating ocular injury or IOFB. An initial examination should include looking at the corneal surface with magnification; if slit lamp is not readily available, surgical loupes can offer a better examination than the naked eye. Often a superficial corneal foreign body will be obvious, but it is important to evert and inspect under the upper eyelid and to look in the inferior fornix as well.

After a penetrating injury has been ruled out, superficial corneal foreign bodies can sometimes be easily removed with a moist cotton swab. Instill a topical ophthalmic anesthetic and moisten a sterile cotton swab with anesthetic, and then gently roll across the surface of the cornea and the foreign body may stick to the cotton tip. Irrigation with eyewash can also be used to loosen and remove the foreign body. If these maneuvers fail, ophthalmic consultation should be considered. Those foreign bodies that are moderately embedded in the anterior one-third of the cornea can be removed at the slit lamp with a tuberculin syringe or 25-gauge needle. Care must be exercised to not go too deep into the corneal tissue. The average central corneal thickness measures only 550 µm.

After removal of the corneal foreign body, start treatment as a corneal abrasion with ophthalmic ointment, cycloplegic agent, and topical antibiotic. Follow up with eye care provider to assess if further debridement is indicated and to look for early signs of infection.

CORNEAL LACERATIONS

Corneal rupture is unusual unless the patient has had previous penetrating keratoplasty (corneal graft) or radial keratotomy. In the former case, dehiscence at the junction of the graft with the host cornea is common. In the latter, rupture occurs along the keratotomy as the cornea is very thin in that location. Loss of the crystalline lens or intraocular implant through the rupture site is sometimes observed. Management is by emergent operative repair, by closing the rupture site with 10-0 nylon sutures.

Corneal and/or scleral lacerations have better prognosis than ruptures, with about 50% retaining vision of 20/40 or better (driving vision).[35,36] Scleral/corneal lacerations limited in location to being anterior to the insertion of the recti muscles and those having a length of greater than 5 mm are associated with a better prognosis.[37] Endophthalmitis is a major concern following penetrating injuries. An IOFB also needs to be ruled out.

A corneal laceration is evident on examination with a slit lamp biomicroscope, although it can be usually seen by oblique illumination with a penlight. It is important to realize that smaller corneal lacerations can self-seal or be plugged by the iris (which can result in a peaked pupil), allowing normal vision and a formed anterior chamber with normal or near-normal intraocular pressure. It is critically important to realize that eyes that have sustained a self-sealing laceration are still at risk of endophthalmitis, particularly if there is an IOFB, and are at risk for further extrusion of intraocular contents or low intraocular pressure if the patient applies pressure immediately behind the laceration (eg, by rubbing the eye). Sadly, we have seen several eyes with undiagnosed self-sealed lacerations that developed endophthalmitis that was erroneously treated as traumatic iritis with steroids by unsuspecting emergency department physicians or pediatricians (with disastrous effects for the eye).

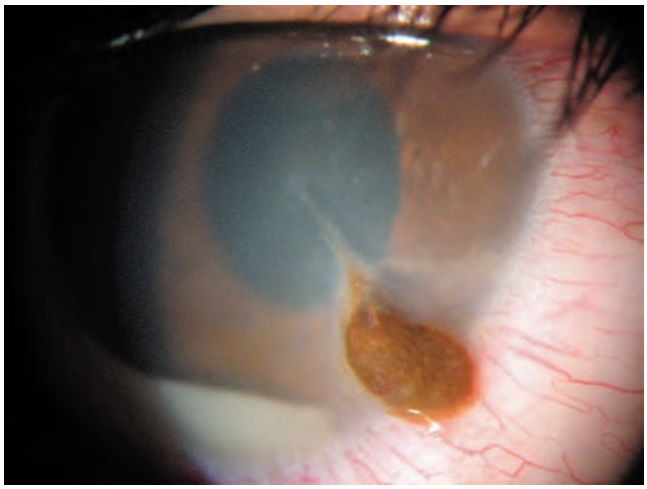

FIGURE 23-4 Corneal laceration with protrusion of iris.

Corneal lacerations can be full thickness or partial thickness (lamellar laceration). A full-thickness laceration is classified under the general diagnosis of open globe. With lamellar or partial-thickness lacerations, the globe is considered closed. The diagnosis of a full-thickness corneal laceration is often easy to recognize when there is protruding iris or uveal tissue (Fig. 23-4). In these cases, the anterior chamber may also be shallow or flat, which can be seen when shining a penlight from the lateral or temporal side of the eye.

Some corneal lacerations may be combined and encompass the limbus and extend into sclera (ie, corneal–scleral laceration). As with all open globe injuries, extreme care must be taken to prevent any direct pressure on the eye that may result in extrusion of intraocular contents. If corneal laceration is suspected, a metal shield (ie, Fox shield) should be placed over the affected eye. The goal is to prevent any direct pressure or contact on the globe; soft eye patches should be avoided.

For partial-thickness lacerations, depending on the size and depth of the laceration, simple observation with topical antibiotic prophylaxis up to suturing the partial-thickness flap may be warranted. Due to the expertise needed to evaluate the depth of the laceration with a slit lamp, ophthalmic consultation should be sought in corneal lacerations.

SCLERA LACERATION OR RUPTURE

Scleral rupture occurs in about 3.5% of eyes with severe blunt trauma.[38] It most commonly involves the sclera immediately posterior to the recti muscle insertion (about 6–7 mm posterior to the limbus) as the sclera is thinnest at that location; in patients who have had previous surgery involving the sclera

(most commonly, a glaucoma filtration surgery), rupture at the site of the previous scleral wound may also occur.

Scleral rupture is invariably accompanied by rupture of the highly vascular choroid or ciliary body. As a result, hemorrhagic chemosis, hyphema, vitreous hemorrhage, or a combination of these is invariably present.[38] Prolapsed uveal tissue appears dark brown or black, whereas prolapsed vitreous gel appears as a transparent or blood-tinged blob of gel; since the mechanism of scleral rupture is due to an extreme elevation of intraocular pressure at the moment of blunt impact, the force causing the rupture is from the inside. Prolapse of intraocular contents is therefore not uncommon, although it can be difficult to discern clinically because it may be covered by the hemorrhagic chemosis of the conjunctiva. Signs with the greatest specificity are a low intraocular pressure (<6 mm Hg), anterior chamber depth asymmetry (can be abnormally shallow or deep compared to fellow eye), and vision poorer than HM.[35,38]

Scleral rupture generally has poor outcomes, with only 30% to 35% of eyes regaining ambulatory vision (ie, vision that allows getting around without a guide).[36] Moreover, scleral rupture is a risk factor for enucleation, with up to 40% of eyes with scleral rupture being enucleated.[7,12,35,36] Particularly poor predictors are scleral rupture greater than 11 mm, golfball injury, and presenting vision of HM or worse.[12,35]

Treatment is by operative repair for scleral ruptures anterior to the equator that consists of excising necrotic uveal tissue, repositing viable uveal tissue and retina into the globe, and approximating the scleral edges using 8-0 nylon sutures. Posterior scleral ruptures are not accessible for repair (to access the posterior sclera, one would have to disinsert one or more of the recti muscles and pull to turn the eye, which would cause further extrusion of intraocular contents, making matters worse) and are allowed to heal by secondary intention.

SPECIAL SITUATION: TRAUMA IN LASIK PATIENTS

In 2007, more than 800,000 Americans underwent laser-assisted in situ keratomileusis (LASIK) vision correction surgery.[39] The first clinical trial for LASIK refractive surgery was performed in 1995, and it has been a growing surgical procedure for the past 10 years. To perform LASIK, a thin corneal flap is first made and folded back to allow for laser remodeling of the corneal stroma. The flap is most commonly hinged either superiorly or nasally and floated back into position once laser remodeling is completed without any need for suturing. Since this is commonly done as an outpatient procedure in an ophthalmologist's office or laser center, most patients do not consider this a significant part of their medical history.

It is important to recognize that both early and late traumatic flap dislocation and amputation have been reported in the literature. There are case reports of LASIK flap complications up to 7 years after surgery. Minor blunt traumas with fingernail or sports-related injuries have been the reported cause of flap dislocation and amputation.[40-42] Patients with LASIK flap dislocation and amputation will typically present with decreased vision and pain and a very similar history to simple traumatic corneal abrasion patients. In fact, a complete amputation of the LASIK flap can look very much like a large corneal abrasion with fluorescein staining since the corneal epithelium is lost with the flap.

LASIK flap dislocation and amputations are treated very differently than a simple traumatic corneal abrasion, and patients will need consultation with an ophthalmologist, preferably a corneal-refractive surgeon. Prognosis for early flap dislocation has generally been good, and with later flap dislocation, vision recovery is generally acceptable. For patients with flap amputation, prognosis is poor due to development of irregular astigmatism and corneal haze and scarring. Given the large number of patients who have undergone this very popular procedure over the past 15 years, it is crucial to always ask specifically regarding prior history of refractive or LASIK surgery.

Traumatic Hyphema

Hyphema refers to blood accumulating in the anterior chamber (Fig. 23-5). It can present even after minor trauma in patients with impaired coagulation either idiopathic or medically induced. The presentation includes pain, photophobia, and decreased vision, and on further examination with a penlight, a reddish pool of blood can be seen layered toward the inferior half of the anterior chamber due to gravity. If a patient has been recumbent due to gravity, the hyphema may be layered over the pupil precluding a clear view to the posterior segment.

The estimated incidence of hyphema is 17 per 100,000. The mean age of presentation is 25 years old with a higher prevalence in men than women. A hyphema does not rule out an open globe injury, and up to one-third of patients with traumatic hyphema can have concomitant open globe injury.[43] Patients can also present with eyelid injuries or orbital fractures concurrently with hyphema (Fig. 23-6).

Concussive injury causes equatorial expansion of the eyeball with resulting damage to the iris, ciliary body, and major

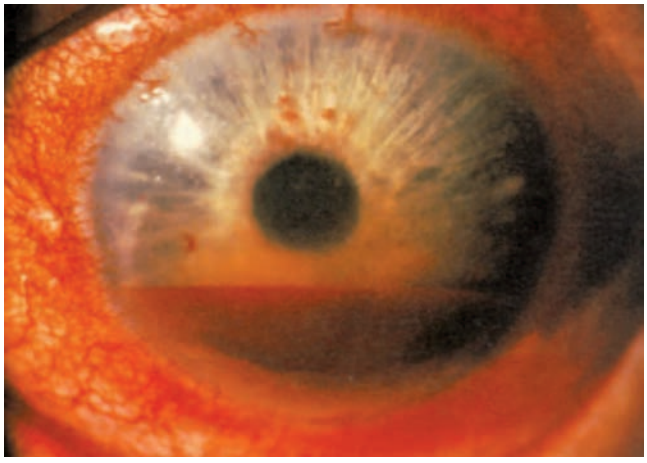

FIGURE 23-5 Hyphema.

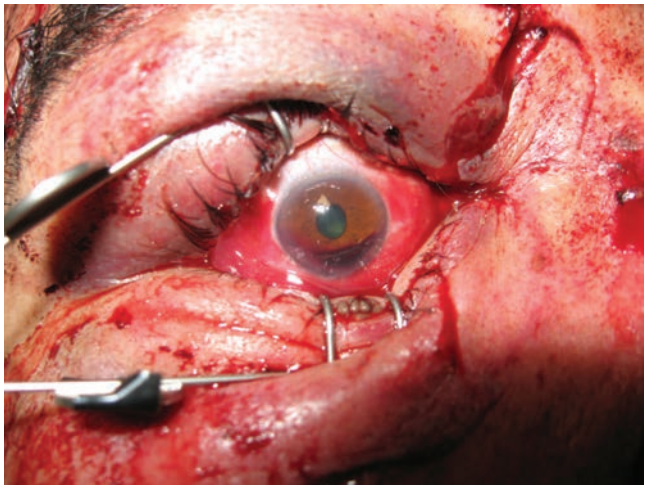

FIGURE 23-6 Hyphema and lid laceration.

arterial circle of the anterior segment. Depending on the level of force exerted, differing levels of bleeding can be seen. Some patients may only have a microhyphema, where a very small amount of red blood cells circulates in the anterior chamber but not enough blood is present to collect in the inferior part of the anterior chamber. These patients generally have very mild symptoms and can be managed similarly to traumatic iritis patients.

For patients who suffer more severe bleeding, the hyphema may completely fill the anterior chamber, also known as a total hyphema when filled with bright red blood. If the anterior chamber is filled with dark blood, this is referred to as an "eightball" hyphema. An eightball hyphema indicates lower oxygen concentration secondary to decreased aqueous circulation, and the patient is at greater risk of secondary angle closure glaucoma. Typically, the grading scale for hyphema is described by using an estimated percent layered in the anterior chamber. For example, a hyphema reaching mid-pupil level could be described as a 50% layered hyphema.

At the initial encounter, visual acuity, intraocular pressure, and grading of the hyphema severity should be documented. For patients of African American descent and others with known risk factors for hemoglobinopathies, a sickle cell prep or hemoglobin electrophoresis should be ordered along with other initial laboratory workup. This information is important for guiding targets for intraocular pressure management. When considering topical ophthalmic drops, β-blockers such as timolol are commonly used as first-line treatment when intraocular pressure is elevated. For individuals with sickling hemoglobinopathies, carbonic anhydrase inhibitors are contraindicated because the resultant metabolic acidosis can precipitate sickling. If those individuals have a sustained increase in intraocular pressure, other interventions, including surgery with anterior chamber washout, may be necessary.

For any patient with a layered hyphema regardless of percentage, an ophthalmic consultation is warranted since these patients will need close follow-up for the first 5 days after initial injury when the risk of rebleeding is highest. In addition, patients who suffer concussive injury great enough to cause a layered hyphema are likely to have concomitant injury to other intraocular structures and have an increased risk of traumatic glaucoma, resulting in permanent blindness in the future.

For patients who will need to be transferred for ophthalmic consultation, a clear or metal eye shield should be placed on the affected eye to protect from further injury. Depending on the interval until the patient is seen by an ophthalmologist, routine treatment for hyphema can be initiated with topical steroid eye drops (ie, prednisolone acetate 1% four times a day) and a topical cycloplegic agent (eg, cyclopentolate 1% or 2%, two or three times a day, or atropine 1% daily).

Traumatic Iritis, Mydriasis, Iris Sphincter Tears, and Iridodialysis

With minimal blunt trauma to the eye, patients may suffer a mild inflammatory reaction known as traumatic anterior uveitis or traumatic iritis. Patients generally present with mild blurry vision, eye pain, and light sensitivity or photophobia. The symptoms can be immediate or delayed for 24 to 48 hours, and examination often will reveal nothing more than mildly red eyes or conjunctival injection. However, if a slit lamp examination is done, an inflammatory reaction with circulating cells and flare can be seen in the anterior chamber.

Most cases will resolve within 1 to 2 weeks with topical steroid eye drop (1% prednisolone acetate, four times a day) and topical cycloplegic agent (1% or 2% cyclopentolate, twice a day, or 1% atropine, once a day). When prescribing cycloplegic agents, it is important to inform the patient that near objects will be blurry in the treated eye due to the loss of accommodation from pharmacologic dilation. In patients who have longstanding anterior uveitis from any etiology, posterior synechiae (iris-lens adhesions) can form. The use of a topical cycloplegic agent is not only for patient comfort, but also as a preventative measure against formation of posterior synechiae (Fig. 23-7).

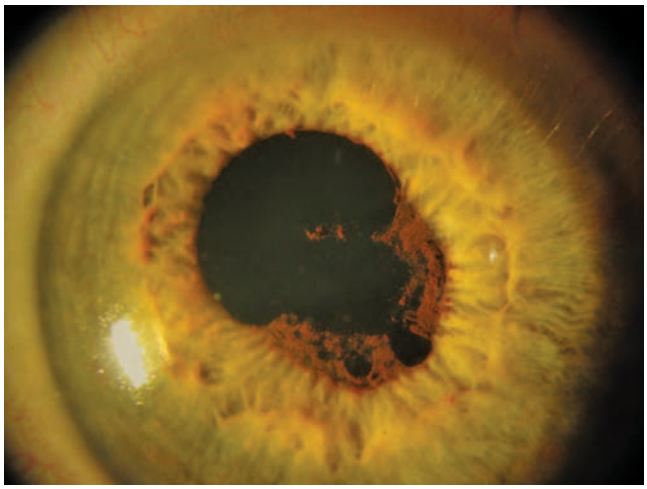

FIGURE 23-7 Posterior synechiae.

With more forceful blunt trauma, patients may suffer direct damage to the iris sphincter causing tears or traumatic mydriasis (seen near the pupil) or to the iris base causing iridodialysis (seen near the limbus). On initial examination, patients with traumatic mydriasis (dilation) or iris sphincter tears will have unequal pupil size and irregularity to the pupillary border. Most patients may not complain acutely of symptoms, but some will note the difference between the affected and unaffected eye in a mirror and question the etiology. There is no acute treatment for sphincter tears and traumatic mydriasis other than to treat the associated traumatic iritis.

With significant blunt force trauma, the longitudinal and radial fibers of the iris root can be torn apart at the ciliary body causing an iridodialysis. The diagnosis can easily be made with a penlight exam. The separation can occur at any clock hour and often will look as though a second pupil has been formed near the limbus, the area where the white sclera and clear cornea meet. Sometimes patients with large iridodialysis will complain of diplopia (seeing double) in the affected eye due to images being projected through the pupil and also simultaneously, through the new iris defect.

Patients who suffer iris trauma need proper follow-up with an ophthalmologist to monitor resolution of the inflammatory reaction and intraocular pressure and assess potential damage to other anterior segment structures. For some patients with extensive iris damage, reconstructive anterior segment surgery may be warranted.

Traumatic Lens injury

LENS DISLOCATION/SUBLUXATION

The lens is suspended like a hammock behind the iris by fibers called zonules that attach to the ciliary body and to the equator of the lens capsule. The lens is part of the total visual system and helps with vision and accommodation. Without the natural lens in position, patients would need a contact lens or intraocular lens placed to help visual rehabilitation. Thus, patients who suffer from lens dislocation will complain of decreased vision as well.

Three major traumatic injuries to the lens are lens dislocation/subluxation, traumatic cataract, and intralenticular foreign body. With blunt trauma, the zonules may break and cause the lens to dislocate either partially or completely depending on the amount of support remaining. A sign of zonular fiber loss may be seen at the slit lamp as iridodonesis, where the iris "jiggles" with rapid eye movements, or phacodonesis, where the lens shakes or moves with rapid eye movements. Typically, emergent intervention is not needed for lens subluxation or dislocation unless the lens is dislocated into the anterior chamber causing pupillary block, where the lens is obstructing aqueous flow from behind the pupil, or corneal endothelial decompensation, where the lens is in contact with the corneal endothelium.

Patients who have a history of prior cataract surgery with artificial intraocular lens placement can also experience artificial lens dislocation. They will also experience a decrease in vision since the artificial lens acts as a substitute for the natural lens and is part of the total visual system. Surgical intervention can usually be done to reposition or replace the intraocular lens as an outpatient on an elective basis.

TRAUMATIC CATARACT

Traumatic cataracts are generally seen months to years after the acute episode. They can result from blunt trauma, penetrating trauma, electrical shock, and ionizing radiation. Unilateral vision loss in young adults is most commonly due to unilateral traumatic cataract, most likely due to not only accidental trauma, but also sports-related activities that routinely have associated blunt trauma, such as boxing, soccer, and martial arts. Although traumatic cataracts may pose additional intraoperative risks, modern techniques for cataract removal are quite successful and yield excellent vision provided there are no retinal or optic nerve abnormalities.

LENTICULAR FOREIGN BODY

Lenticular foreign body refers to the unusual occurrence of a small foreign body, usually metallic, being retained within the crystalline lens.[44-46] On many occasions, these have been well tolerated for many years without adverse effect as the anterior capsule heals over the site of entry into the crystalline lens. A potential consequence of this type of injury would be cataract formation, requiring surgical removal by phacoemulsification.

Vitreous Hemorrhage

Vitreous hemorrhage occurs in 30% of eyes with serious trauma. Its presence attests to the severity of the injury and is a marker for concomitant injury that is harder to detect due to its presence. Vitreous hemorrhage is invariably present in eyes with scleral rupture and may be present in penetrating injuries. In closed globe injury, it may be associated with iris sphincter tears, hyphema, and lens dislocation, while in the posterior segment, associated findings include retina tear/detachment, traumatic macular hole, choroidal rupture, and traumatic optic neuropathy.[47]

Eyes with vitreous hemorrhage need to be examined carefully to rule out occult scleral rupture or laceration and concurrent retinal tears or detachment. If the severity of the vitreous hemorrhage does not allow sufficient visualization of the retina, B-mode ocular echography to detect retinal tears or detachment can be used as an acceptable alternative to direct visualization. It should be noted that when the vitreous hemorrhage is very severe, it is impossible to reliably detect a retinal detachment.

In the case of closed globe injury, management includes observation for 4 to 6 weeks, as spontaneous resolution is common, with vitrectomy if faster visual rehabilitation is desired or at a later date for nonclearing vitreous hemorrhage. Recently it has been suggested that early vitrectomy can prevent retinal complications, although convincing evidence for this is lacking thus far.

Intraocular Foreign Body

IOFBs are present in 30% to 40% of open globe injuries.[48-50] In the vast majority (>85%), the patient is male.[48,50-52] The IOFB is typically metallic (90%), usually iron, and results from hammering (60%–70%) or use of a high-speed rotary tool.[49,51,52] Glass foreign bodies can be found after car accidents, explosive blast injuries typically associated with terrorism, or assault with beer bottle.[53] Stone and concrete represent less than 2% of IOFBs, except in combat trauma, where they are common after eye injury following explosion of roadside improvised explosive devices (IEDs).[49-51] The majority of IOFBs are in the posterior segment (75%).[52]

Patient symptoms are dictated by the possible concomitant injury or complication (corneal laceration, scleral laceration, cataract, vitreous hemorrhage, endophthalmitis, retinal detachment). In every case of corneal or scleral laceration, even when self-sealing (ie, not requiring operative repair), it is critically important to rule out IOFB by helical CT of the orbits. Additionally, any time a patient presents with ocular pain after hammering and subconjunctival hemorrhage, CT is essential to rule out IOFB as a scleral laceration may be present under the hemorrhage.

IOFBs are associated with an increased incidence of endophthalmitis that results in poorer visual outcomes after penetrating injury.[54,55] Additionally, copper foreign bodies may incite severe inflammation, and in the long term, retained IOFBs may lead to retinal toxicity (eg, iron IOFBs lead to ocular siderosis, which among other effects leads to loss of vision due to retinal toxicity).[56]

Although there is agreement that primary repair of open globe injury should be undertaken emergently, the timing of IOFB removal is controversial.[52,54,57-59] IOFB removal from the posterior segment is usually performed by pars plana vitrectomy, although for ferromagnetic IOFBs, an external magnet can be used for smaller IOFBs if the requisite expertise for performing pars plana vitrectomy is not available.[58-60]

Retinal Contusion

Commotio retinae, also known as Berlin edema when it involves the posterior pole, is the term used to describe the opacified retina observed as a result of closed globe contusion injury to the retina. If the macula is involved, the vision will be affected. Spontaneous resolution is the rule, with the long-term prognosis determined by concomitant retinal pigment epithelium injury.

Contusion of the retinal pigment epithelium is infrequently described, yet it is a common sequela of closed globe injury characterized by atrophic changes and mottling of the retinal pigment epithelium in the long term. It is an important cause of limited vision following such injury.[61] Patients with this injury require serial dilated examinations with an ophthalmologist as an outpatient to determine if late sequelae (days to weeks) develop such as retinal holes, tears, or detachments.

Retinal Detachment

Retinal tears/dialyses and detachment may arise following closed or open globe injury. The difference between retinal tears and dialyses is beyond the scope of this text but is significant when considering surgical repair of a detachment.

Following closed globe injury, the sudden expansion of the equatorial region of the eye results in the forced separation of the vitreous from the retina; in young individuals, the vitreous may adhere strongly to the retina, and its forced separation may result in tears in the retina or retinal dialysis. Usually vitreous hemorrhage (which can be very minor) occurs at the same time due to bleeding from the vascular retina. In about 85% of patients with retinal tears or dialyses, fluid passes under the tear/dialysis, causing the retina to separate from the choroid, which is a retinal detachment.[62]

Patients with retinal tears may report floaters (black dots or "spider"-like opacities in their vision that move as the eye moves), whereas patients with a retinal detachment report a visual field defect ("dark area" or "curtain" in the vision, "like seeing underwater"). If the retinal detachment advances to include the fovea, patients will also report blurred vision. Timely treatment of retinal tears with laser retinopexy (or cryopexy) to reinforce the adhesion between retina and retinal pigment epithelium will prevent retinal detachment. Given that most traumas involve young individuals whose vitreous is more gel than fluid, only 12% to 30% of traumatic retinal detachments present immediately after trauma, whereas 20% present more than 1 year after trauma.[62-64] Therefore, there is ample opportunity to prevent retinal detachment after closed globe injury, and it is imperative that a thorough examination of the fundus by indirect ophthalmoscopy by an experienced ophthalmologist is performed within a few days of such injury.

If a retinal detachment occurs, timely treatment (before the fovea is involved) can lead to preservation of excellent vision; therefore, a retinal detachment not involving the fovea needs to be repaired within 24 hours. Once the fovea is involved, the vision will never be normal; patients presenting with fovea-involving retinal detachments need to undergo repair within 1 week of presentation. When retinal detachments are not treated promptly, proliferative vitreoretinopathy (a process of scar formation in the vitreous cavity) supervenes and surgical outcomes are poorer (both anatomic and visual outcomes), and there is a greater risk of phthisis bulbi (globe becoming shrunk with opacification of the cornea). Treatment of retinal detachments is by scleral buckling if the cause is a dialysis, pars plana vitrectomy if there is a giant retinal tear, and pars plana vitrectomy or scleral buckling if the cause is a retinal tear.[65,66]

In open globe injury, retinal tears commonly arise by the same mechanisms as in closed globe injury but may also be the direct result of the penetrating or perforating injury (eg, a sharp projectile penetrating the eyewall and the choroid and retina causing a retinal tear); IOFBs may cause further retinal tears at the site of internal impact on the retina. Moreover, a hemorrhagic retinal detachment may arise from bleeding under the retina. Retinal detachment occurs in approximately

20% to 29% of open globe injuries.[67,68] Treatment is by pars plana vitrectomy following primary repair.

Traumatic Macular Hole

Traumatic macular holes usually arise as a consequence of blunt ocular trauma, typically from a fist or finger, a champagne cork, a ball (baseball, softball, soccer ball, tennis ball usually), or rubber band.[69-71] The typical symptom is a blurring of the central vision. It should be noted that development of a traumatic macular hole may be delayed by a few days or weeks following trauma.

Anatomic closure occurs spontaneously in 44% to 64% of cases within the first 4 to 6 months.[72,73] Pars plana vitrectomy with lifting of posterior hyaloid face and gas endotamponade successfully closes macular holes in up to 96% of patients and is indicated after a period of observation for spontaneous closure, typically about 3 to 4 months.[69-71] Improvement in vision usually accompanies anatomic closure but may be limited by retinal pigment epithelium mottling or atrophic changes due to retinal pigment epithelium concussive injury.

Chorioretinitis Sclopetaria

Chorioretinitis sclopetaria is a rare type of closed globe contusion injury due to a high-velocity projectile passing adjacent to the globe without penetrating it. On dilated eye examination of the retina, a white area seen as sclera is visible surrounded by hyperpigmentation adjacent to the path of the projectile. Remote to the path of the projectile is an area of hyperpigmentation, and retinal pigment epithelium atrophic changes are present with a characteristic severe epiretinal membrane, usually at the macular area.[74,75] These appearances become apparent several weeks after the injury, whereas immediately, they are typically obscured by vitreous hemorrhage.[74,75]

Endophthalmitis

Endophthalmitis is a devastating complication of ocular trauma occurring in 1% to 11% of open globes,[52,55,76-79] with a higher incidence (4%–30%) when IOFBs are present.[52,54,77] Delayed primary closure, presence of IOFB, disruption of the lens capsule, rural setting of injury, and possibly posterior segment involvement increase the risk of endophthalmitis.[54,55,76,79] Common microorganisms are streptococci, staphylococci (especially with IOFBs), and *Bacillus cereus*, whereas gram-negative organisms occur in about 10% and fungi in fewer than 5% of injuries.[54,78-80]

Symptoms include severe to extreme pain, sensitivity to light, and decreased vision. Hypopyon (white blood cells/pus collection in the anterior chamber), fibrin in the anterior chamber (Fig. 23-8), vitreous inflammation, and sheathing of vessels are characteristic.[79] Other signs commonly present are chemosis and erythema of the conjunctiva (which can be severe), severe tenderness, and lid edema. Sadly, this may be misdiagnosed as the patient having only traumatic iritis, which rarely would present with hypopyon or severe tenderness.

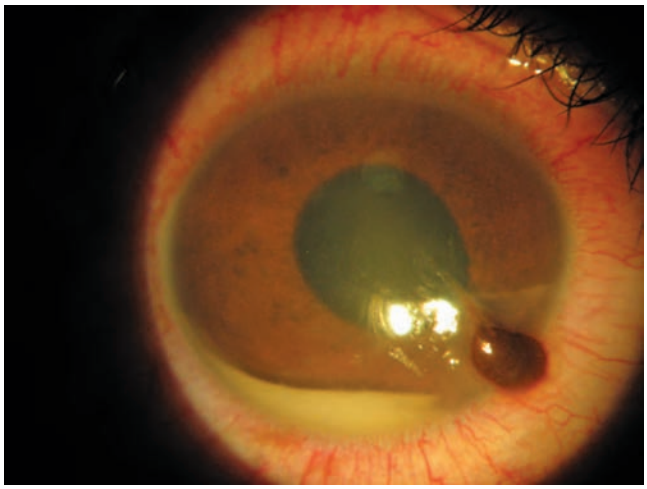

FIGURE 23-8 Hypopyon in an eye with corneal laceration and iris protrusion.

Endophthalmitis is a true ophthalmic emergency, and in the case of virulent microorganisms such as *Bacillus*, a few hours can make the difference between retaining the globe and losing it to phthisis. Suspicion of endophthalmitis should prompt an emergent ophthalmology consult and institution of systemic treatment with a fluoroquinolone (ideally fourth generation) because fluoroquinolones have excellent penetration into the vitreous and they are effective against *B cereus*.[81] Definitive management is by injection of intravitreous antibiotics, with vitrectomy for selected cases.

Choroidal Rupture

Rupture of the choroid accompanies closed globe trauma more often than open globe trauma and is usually a consequence of injury with a ball (soccer ball), other large projectile (eg, rock, shoe), or fist.[82,83] The choroidal rupture appears as a white crescent, typically concentric to the optic nerve and within the macula (>70%).[82,83] Vision immediately following injury may be limited if the choroidal rupture is through or adjacent to the fovea or from associated subretinal hemorrhage (which resolves).

A treatable, long-term complication of choroidal ruptures in the macula, especially in older individuals, is the formation of choroidal neovascular membranes (CNVMs; growth of new vessels from the choroid under the retina, which tend to leak fluid or cause hemorrhage). Anti-vascular endothelial growth factor inhibitors injected intravitreally or photodynamic therapy for CNVM due to choroidal rupture may lead to excellent visual outcomes if the patient presents early.[84,85] Therefore, it is critically important to inform patients with choroidal rupture at risk of developing CNVM that if they develop a sudden change in vision or metamorphopsia (distortion in vision so that straight lines appear curved), they should see an ophthalmologist at once.

Traumatic Optic Neuropathy

Sharp objects, projectiles, or bone fragments may directly damage the optic nerve (direct traumatic optic neuropathy). Direct optic neuropathy is associated with severe loss of vision with little prospect of improvement. If suspected, imaging of the optic nerve (orbital CT) is recommended to detect the rare case where surgical relief of impingement of the optic nerve may improve vision.

More commonly, however, traumatic optic neuropathy results from concussive head injury, especially involving impact to the forehead (indirect traumatic optic neuropathy). In indirect optic neuropathy, impact forces are transmitted from the frontal bone to the orbital bones and are concentrated in the area of the optic canal, causing a shearing injury to neuronal axons of the intracanalicular portion of the optic nerve.[86,87]

Patients with indirect traumatic optic neuropathy are usually young, male (85%), have commonly lost consciousness, and have typically sustained their injury as a result of involvement in a motor vehicle or bicycle accident (about 50%), fall, or assault.[88,89] Patients notice a typically unilateral decrease in vision immediately or after regaining consciousness.[88,89] The severity of visual loss is often dramatic (40% have NLP and a further 23% only have light perception or HM vision). In cases with less dramatic visual loss, symptoms may include visual field defects and abnormalities of color vision.[88,89] On examination, a RAPD is present, but the fundoscopic examination is normal until several weeks after the injury when optic nerve pallor or atrophy becomes apparent.

Spontaneous improvement has been reported in up to 57% of patients with indirect traumatic optic neuropathy.[88,89] The regimen employed in the Second National Acute Spinal Cord Injury Study (NASCIS) of an initial dose of 30 mg/kg of methylprednisolone followed by continuous infusion of 5.4 mg/kg/h for 24 to 48 hours has been used for the treatment of traumatic optic neuropathy despite lack of evidence for efficacy in this condition.[88-93] Indeed, several comparative studies have failed to show benefit from the use of megadose or high-dose corticosteroids over placebo for indirect traumatic optic neuropathy.[88,89,94] Moreover, recently the CRASH study demonstrated excess mortality for patients with significant closed-head injury who were given corticosteroids compared to placebo.[95] Therefore, the role, if any, of megadose steroids in the treatment of this condition is controversial. Finally, surgical decompression has been performed with encouraging results in several case series but with no evidence that results are superior to observation.[96]

OPTIC NERVE AVULSION

Optic nerve avulsion is a specific type of indirect traumatic optic neuropathy with a distinct pathogenesis. In optic nerve avulsion, a blunt object (typically a finger, unusually a snooker cue or golf club) is inserted between the globe and orbit and causes abrupt rotation of the globe as well as a sudden increase in intraocular pressure resulting in retraction of the optic nerve within its dural sheath. The clinical appearance is striking once the accompanying hyphema or vitreous/subhyaloid hemorrhage clears: there is a hole or cavity where the optic disc has retracted within its dural sheath.[97,98] Prognosis is guarded, with limited potential for spontaneous improvement and no effective treatment.

Eyelid Lacerations

The approach to a patient with eyelid trauma must be systematic and take into account a detailed history to rule out open globe injuries that may preclude repair of the eyelid until the globe can be surgically closed. There are multiple types of eyelid injury, and a patient can have more than one type depending on the mechanism of injury. These include the following:

1. Contusion: blunt impact injury with superficial soft tissue swelling and ecchymoses
2. Abrasion: scraping causing superficial epithelial skin loss
3. Avulsion: shearing or tearing away of tissue
4. Puncture: defect through multiple tissue planes caused usually by sharp objects
5. Laceration: cut tissue can be superficial or deep, usually caused by sharp objects

For patients with isolated eyelid contusion and abrasion, conservative medical management with ice packs and antibiotic ointment is usually all that is required. Given time, the healing and reepithelialization of the skin give good results.

For eyelid avulsion, puncture, and laceration, surgical repair is generally needed. Depending on the patient's age, mental status, and size of injury, repair may be done at the bedside with local anesthesia, preferably with 2% lidocaine with epinephrine for better hemostasis. Deeper tissue involvement, full-thickness, marginal, or lacrimal duct involvement will generally require involvement of an ophthalmologist or oculoplastic surgeon to repair. Signs that may clue into deeper tissue involvement include orbital fat prolapse, exposed sclera under the laceration, and medial canthal involvement. Of note, lacerations of the eyelid medial to the puncta should raise concern for potential injury to the lacrimal drainage system, requiring further exploration and possible probing and irrigation prior to repair.

Once an eyelid laceration is suspected, a plan to explore the extent of the injury needs to be formulated. Since soft tissue swelling can distort the natural anatomy and create the false impression of missing tissue due to excessive tension when approximating tissue margins, ice packs applied to the wound can help to decrease swelling before manipulation. It is important to be sure that an occult open globe injury has been ruled out before exploration of the eyelid laceration (Fig. 23-9).

When exploring an eyelid laceration, anesthetize the tissues prior to cleansing and gently pull lacerated tissues apart during your inspection, as fibrin tends to hold these lacerated edges together giving an inaccurate impression on the level of deep tissue involved. It is important to reapproximate the deep tissue layers to avoid undue excess tension on the

FIGURE 23-9 Lid laceration.

superficial layers. The timing of eyelid laceration repair is more forgiving than most other ocular injuries due to the well-vascularized tissues of the eyelid. In some cases of extensive swelling, waiting 24 to 72 hours for eyelid repair can give a better anatomic and cosmetic result.

For subcutaneous closure, an absorbable suture is preferred, such as 5-0 polyglactic acid (Vicryl, Ethicon, Somerville, NJ) on a spatulated needle, to close deeper tissues. This same suture size can be used above and below the brow or to secure tissue to the periosteum. For skin closure, nylon suture is preferred because it creates the least amount of inflammation, but if follow-up for removal of the sutures in 7 to 10 days cannot be assured, it is better to use an absorbable suture. For closure above and below the brow, 6-0 sutures can be used; some oculoplastic surgeons advocate using a smaller suture size such as 7-0 for closure below the brow.

Orbital Fractures

Patients with orbital injuries such as orbital wall and floor fractures typically will have concomitantly significant facial trauma. These patients will need to be simultaneously managed with head and neck, oral maxillofacial, or plastic surgeons. An orbital CT scan should be obtained to optimally diagnose and manage orbital injuries. Many times, specific orbital cuts can be added to a standard face CT scan protocol when initially ordered to evaluate the patient with facial trauma.

Neurosurgery consultation may be necessary for patients with orbital roof fractures, which can be sustained as a result of significant trauma, usually from motor vehicle accidents or falls from heights. These fractures can often include complications of cerebrospinal fluid leaks due to dural tears, intracranial hemorrhage, traumatic encephalocele, and brain abscesses or meningitis.

The orbit is composed of many bony structures, with the purpose of protecting the globe. The orbital roof and lateral wall have the thickest walls. The thinnest wall is the medial wall, composed of the ethmoidal bone, also known as the lamina papyracea, and the orbital floor medial to the infraorbital groove. Contusive orbital injuries can lead to a "blowout" fracture of these thin areas.

The quality of the thin bones in orbital blowout fractures actually provides a protective feature, where a large area of the orbital floor and medial wall has given way allowing for decompression of the orbital contents. This expanded volume into the sinuses allows for decreased congestion in the orbital space. A pure blowout fracture does not include fracturing of the orbital rim.

When evaluating a patient with possible orbital fracture, one of the signs of an orbital floor fracture is decreased skin sensation on the cheek of the affected side. The infraorbital nerve, a branch of the trigeminal nerve, travels through the infraorbital canal and within the floor to exit just under the inferior orbital rim at the infraorbital foramen. This nerve is often affected when traumatized by orbital floor fractures and presenting with hypoesthesia of the cheek. Another clue can be subcutaneous emphysema that often results from the patient blowing his or her nose, forcing air into the tissues.

Since up to one-third of patients with orbital blowout fractures will have other accompanying ocular injuries, such as corneal abrasion, iritis, hyphema, ruptured globe, retinal detachment, and retinal hemorrhage, it is important to examine these patients systematically with the eight-point eye examination to diagnose correctly and treat more sight-threatening conditions first.

Once an orbital wall or floor fracture has been diagnosed, patients must be given instructions to not blow their nose since this can cause further expansion of air into the orbital tissue and can lead to a tight orbit and elevated intraocular pressure. Patients can use ice packs during the first 48 hours to help with reduction of the soft tissue swelling, and for patients who need surgical repair, this is usually done in the next 1 to 2 weeks.

Management and treatment of orbital floor fractures are discussed in Chapter 24.

Intraorbital Foreign Bodies

Intraorbital foreign bodies can result from both blunt and sharp objects, usually as a result of assault, industrial accidents, accidents at home, or recreational activities. They can cause vision loss if the globe is involved, or in the case of neurologic damage from intracranial extensions. A high index of suspicion is important in evaluating patients with recent or remote history with persistent periocular inflammation. Signs and symptoms of retained intraorbital foreign bodies include the following:

1. Orbital mass
2. Proptosis
3. Painful or restricted eye movements
4. Diplopia
5. Ptosis
6. Lagophthalmos
7. Orbital cellulitis

8. Draining sinus tract
9. Gaze-evoked amaurosis (transient loss of vision)

An orbital CT scan is the preferred imaging modality since metallic foreign bodies, which are the most common type of intraorbital foreign body,[99] are a contraindication for MRI scan; once a metallic foreign body is ruled out, an MRI scan may be better at detecting organic matter such as wood. Depending on the size and extension of the foreign body, neurosurgery and/or otorhinolaryngology consultation may be necessary to safely remove the foreign body.

Not all orbital foreign bodies need to be removed. Certain inert metals, glass, plastic, and silicone can be left in place as long as there is no optic nerve impingement. Foreign bodies made from iron should be removed since long-term toxicity can occur leading to vision loss and retinal damage from siderosis. A detailed history of the mechanism of injury will be crucial in deciding the most likely composition of the foreign body.

Orbital Compartment Syndrome

The orbit is susceptible to compartment syndrome due to its small size and the bony walls of the orbit lacking the ability to stretch or flex. The normal orbital volume is 30 cm^3. Trauma directly to the orbit or to other regions of the face resulting in fractures can cause bleeding into retrobulbar, subperiosteal, extraconal, and/or intraconal spaces of the orbit with rapid expansion in orbital distention. Rapid escalation in orbital compartmental pressure can cause ischemia of the orbital tissues, and increased intraocular pressure can lead to damage and permanent vision loss. Patients with large orbital floor and wall fractures have less risk for developing orbital compartment syndrome since the orbital contents can be decompressed into the sinuses.

Proptosis and taut orbital content or increased resistance to retropulsion on examination are always seen in orbital compartment syndrome. Depending on the extent of orbital congestion, patients with mild compartment syndrome have only mildly elevated intraocular pressures without visual compromise and can be treated with glaucoma agents topically or orally. Once intraocular pressures exceed 40 mm Hg despite antiglaucoma therapy in an orbital compartment syndrome patient, associated with vision loss and likely with an associated afferent pupillary defect, a lateral canthotomy and cantholysis would be indicated (see Atlas Figure 5).

On rare occasions, a patient may have bleeding into the optic nerve sheath, causing direct impingement and compression of the optic nerve, or a bony fragment from posterior fractures can compress on the optic nerve, causing an RAPD. Thus, reviewing the orbital imaging is important to rule out such cases that will need to be referred to an oculoplastic surgeon for urgent optic nerve sheath fenestration.

Patients with mild compartment syndrome should not have any signs of optic nerve compromise, and a patient with an RAPD and decreased vision may need urgent decompression with emergent canthotomy and cantholysis of the lateral canthal tendon performed at the bedside. This works to allow the taut orbital content to prolapse anteriorly out of the orbit. Success is measured by improved vision, lower intraocular pressure, and reversal of optic nerve compromise or RAPD. If the orbital compartment syndrome is not decompressed adequately with a lateral canthotomy and cantholysis, consultation with an oculoplastic surgeon is warranted to decompress the orbit via bony decompression.

Steps to perform a lateral canthotomy and inferior cantholysis are as follows:

1. Obtain informed consent if patient is able to cooperate.
2. Prep and drape the affected eye.
3. Anesthetize with 2% lidocaine with epinephrine in the lateral canthal region. Make sure to infiltrate subcutaneously and subconjunctivally.
4. Allow the anesthetic to take effect, and clamp a hemostat over the lateral canthus vertically; this will help direct the cut in the next step.
5. Using Steven scissors, place one blade on the conjunctival side of the lateral canthus and the other blade on the skin surface, and then cut the lateral corner of the eyelid while applying lateral pressure.
6. The inferior crus of the lateral canthal tendon will need to be cut to release the lower eyelid from the lateral orbital wall. Taking the scissors with blades closed, strum the inferior tendon inside the cut canthotomy wound. The attachment should feel like a firm, tense cord. Now, open the blades of the scissors and cut the cordlike structure until the lower eyelid becomes freely mobile.
7. Hemostasis can be achieved with pressure or the use of handheld cautery if available.

CONCLUSIONS

Although in some cases need of a consultation with ophthalmology will be grossly evident (Fig. 23-10), others may be more subtle, such as an occult scleral laceration or open globe injury from a full-thickness eyelid laceration (Fig. 23-11). The key in successfully managing patients with ocular injury

FIGURE 23-10 Intraocular foreign body.

FIGURE 23-11 Open globe.

is to perform a systematic exam and use a common vocabulary to communicate those findings with the consultant.

The role of the emergency care provider or trauma surgeon with regard to ocular trauma is to recognize common traumatic eye injuries that can be managed immediately and be able to refer sight-threatening conditions appropriately for ophthalmic follow-up. While there are a few true ophthalmic emergencies—open globe, chemical injury, endophthalmitis, and orbital compartment syndrome—many isolated ocular injuries in an otherwise healthy individual can be managed outside of the emergency department setting. Like injury to any other organ system, potential long-term complications require follow-up with specialists.

Face

Raj D. Dedhia • D. Gregory Farwell

KEY POINTS

- A thorough understanding of head and neck anatomy is critical in identifying the true extent of injuries to soft tissue and underlying viscera.
- Early documentation of facial nerve function is critical in guiding management of facial nerve injuries, particularly in critically ill patients in whom sedation may confound later examination.
- The goal of bony reconstruction in maxillofacial trauma is to restore function, structure, and symmetry.
- Long-term follow-up and postoperative imaging are often required to confirm correct skeletal repair and to watch for skeletal or soft tissue complications that would benefit from revision surgery.

INTRODUCTION

The face is the centerpiece of human interaction and expression. Facial structures are also integral in essential functions such as breathing, vision, eating, and communication. Patients with facial deformity pay a significant social penalty[1] and suffer functional impairment. Therefore, restoring facial form and function can greatly improve a patient's quality of life.

The evaluation of any trauma patient should begin with a primary survey that is focused on airway, breathing, circulation, disability, and exposure, or the "ABCDEs." After the appropriate Advanced Trauma Life Support (ATLS) algorithms are instituted and the patient is acutely stabilized, secondary survey begins, including a thorough evaluation of facial injuries (Fig. 24-1). The anatomy, evaluation, and management of soft tissue and bony trauma of the face are reviewed.

MANAGEMENT OF FACIAL SOFT TISSUE TRAUMA

Scalp and Forehead

ANATOMY

The scalp is a multilayered soft tissue structure that envelopes the calvarium, extending from the external occipital protuberance to the supraorbital rim. The forehead aesthetic subunit of the scalp includes the arc from the supraorbital rims to the hairline, or trichion. The soft tissue of the scalp and forehead consists of five layers and can be remembered using the mnemonic SCALP: *s*kin, sub*c*utaneous tissue, *a*poneurosis galea, *l*oose areolar tissue, and *p*eriosteum (Fig. 24-2).

The arterial supply to the scalp comes from five named vessels off of the internal and external carotid arteries.[2] The external carotid branches include the occipital artery, superficial temporal artery, and the posterior auricular artery. Internal carotid artery branches include the supraorbital and supratrochlear arteries. These ultimately form extensive anastomoses in the subcutaneous tissue layer of the scalp, providing a robust blood supply and vascular redundancy that limits watershed areas of compromised blood supply. Injury to vessels in this layer can result in significant blood loss as the vessels remain tethered open from their dense connective tissue attachments.

The layers of the lateral scalp overlying the temporal regions are more complex (Fig. 24-3). The skin and subcutaneous layers in this region are continuous with the remainder of the scalp. The galea is continuous with temporoparietal fascia (TPF) and contains the superficial temporal artery and temporal branch of the facial nerve.[3] Deep to the TPF lies the deep temporal fascia, which splits into superficial and deep layers and envelops the intermediate (or middle) temporal fat pad above the level of the zygomatic arch.[3] The deep temporal fat pad, temporalis muscle, periosteum, and temporal bone lie deep to the deep temporal fascia.[4]

EVALUATION

Scalp injuries, even when small, can present with extensive bleeding. Manual pressure or pressure dressings should be the initial measures to stop bleeding. If the bleeding does not tamponade, the wound edges should be examined for vessels that can be controlled with vessel clips, scalp hemostatic clips such as Raney clips, suture ligature, or cautery. Care should be taken to limit prolonged scalp hemostatic clips or cautery as damage to hair follicles can worsen alopecia along the wound.[5] Mild bleeding is frequently controlled by wound closure.

Once hemostasis is achieved, the scalp wound should be thoroughly irrigated and examined for size, depth, tissue loss, and involvement of the hairline. Open calvarial and dural injuries in severe traumas require earlier intervention and combined reconstructive efforts with a neurosurgeon.

MANAGEMENT

Lacerations without soft tissue loss are closed in a multilayer fashion. The galea and subcutaneous tissue are reapproximated with 3-0 sized braided suture for strength. The skin can be closed with absorbable or nonabsorbable 4-0 monofilament suture. Stainless steel skin staples are an alternative for skin closure and have similar aesthetic outcomes in hair-bearing scalp closures in the pediatric population, with the added benefit of decreased procedure time.[6]

When avulsion injuries result in a defect, wound management involves more complex reconstruction. The reconstruction method should take into consideration patient factors (eg, health and healing potential), size of the wound, relation to the hairline, and need for underlying cranioplasty.[4]

Critically ill patients who cannot tolerate an anesthetic may require healing by secondary intention with local wound care. This is ideal in bald patients, areas of concavity and light skin, and vascular wound beds that will promote granulation (ie, at least pericranium).[2] In addition, split-thickness skin grafting can be a quick reconstructive option used for wounds of any size. This can be done in one stage when there is a vascularized wound bed. Single- or two-staged techniques have been described for skin grafting denuded calvarium where a more vascular wound bed is created by drilling down to the diploic space.[7]

Scalp defects can be classified as small (<9 cm^2), medium (10–30 cm^2) and large (>30 cm^2).[2] Small defects can be closed by primary intention with the help of galeotomies to allow advancement and decrease tension. Medium and large wounds require skin grafting, tissue expanders, locoregional flaps, or free tissue transfer. Flaps should be designed in a manner that maintains the hairline when possible. When there is a calvarial or dural defect with cerebrospinal fluid (CSF) leak, large locoregional flaps or free tissue transfer is beneficial to protect the cranioplasty site and dural repair.

Cheek

ANATOMY

Understanding the intricate anatomy of the cheek is critical to the management of soft tissue injuries of the face. Beyond addressing lacerations and defects of the soft tissue, potential injuries to the parotid gland, parotid duct, and facial nerve must also be considered.

The soft tissue envelope overlying the cheek demonstrates continuity with the layers of the scalp and has several unique considerations. Below the skin and subcutaneous layers, the cheek contains the superficial musculoaponeurotic system (SMAS),[8] which is continuous with the TPF and galeal layers of the scalp as well as the platysma of the neck. In the lateral cheek, the parotidomasseteric fascia lies deep to the SMAS and covers the parotid gland and masseter muscle.

The parotid duct exits the anterior portion of the parotid gland and runs parallel and inferior to the line running from the tragus to the midportion of the upper lip.[9] Van Sickels[10] subdivided the parotid duct into three anatomic segments: (1) duct within parotid parenchyma, (2) duct overlying the masseter muscle, and (3) duct anterior to the masseter muscle as it pierces the buccinator and buccal fat prior to entering the oral cavity. These subdivisions predict risk of duct injury and guide approaches to repair.

An understanding of the course of the facial nerve branches within the parotid gland is critical to recognizing potential injury and instituting appropriate intervention. The facial nerve enters the parotid gland in very close proximity to the nerve's exit from the temporal bone through the stylomastoid foramen. As it traverses the parotid gland, the facial nerve branches into five main divisions: (1) temporal, (2) zygomatic, (3) buccal, (4) marginal mandibular, and (5) cervical.

The temporal branch exits the gland early, and its course can be projected by a line described by Pitanguy and Ramos[11] that begins 0.5 cm below the tragus and passes 1.5 cm above the lateral extent of the eyebrow. The nerve is at risk in penetrating trauma in the vicinity of that line and during surgical approaches to the zygomatic arch (Fig. 24-4).

The marginal mandibular nerve courses deep to the platysma and is superficial to the deep cervical fascia overlying

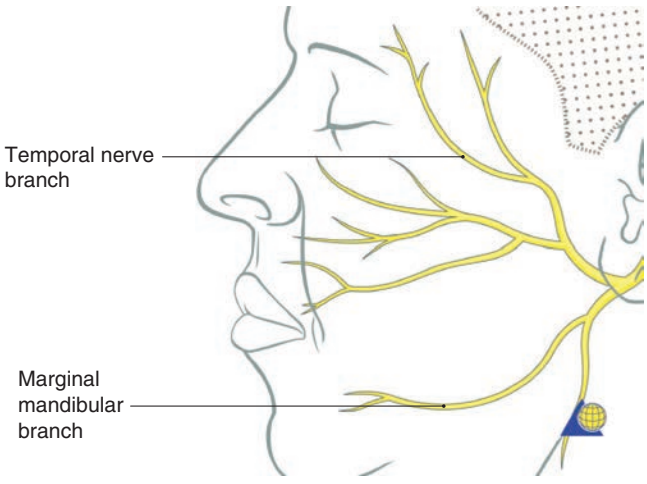

FIGURE 24-4 Orientation of facial nerve branches. Branching patterns can be variable. (Reproduced with permission from AO Surgery Reference. www.aosurgery.org. Copyright by AO Foundation, Switzerland.)

the submandibular gland. The nerve has a variable course inferior to the angle and body of the mandible and must be considered during transcervical approaches to the mandible.

EVALUATION

Evaluation of facial nerve function at the initial trauma evaluation is critical in determining need for surgical intervention and predicting degree of recovery. Facial nerve paralysis can lead to significant functional and social handicap from impairment in eye closure, oral competence, and facial expression.

Facial movement in the distribution of each of the five major branches of the facial nerve should be promptly assessed and documented because this will anatomically guide any surgical intervention. Assessing patients with severe trauma who are intubated and sedated can be difficult. Painful stimuli can elicit facial movement in these patients. Several facial nerve grading systems have been developed to describe facial nerve paresis and recovery, including the House-Brackmann[12] and Sunnybrook[13] facial grading systems. However, these can be difficult to interpret and do not substitute for a thorough descriptive visual exam.

Wounds should be evaluated for depth of injury. Penetrating injuries that violate the SMAS or platysma increase the risk for facial nerve, parotid gland, and parotid duct injury. Massage of the cheek with expression of saliva in the wound would be indicative of parotid gland or duct injury. The oral cavity should be examined for full-thickness injuries and the integrity of the parotid duct papilla. The parotid duct integrity can be assessed by cannulating the duct with a lacrimal probe intraorally via the papilla. Exposure of the probe in the wound would indicate injury to the duct. Others have advocated retrograde injection of methylene blue via the papilla and assessing for blue discoloration in the wound.[14] This has been used less frequently due to discoloration of the surgical field and obscuration of critical structures.[15] Diagnostic sialography is not routinely performed due to cost, challenge of cannulation in setting of edema and poor patient cooperation, and procedural time.[16]

MANAGEMENT

Parotid Gland Injury. Early identification of and intervention for parotid glandular injuries can avoid late complications that are difficult to manage, such as sialoceles and salivary-cutaneous fistulae. Lacerations to the gland without ductal injury can be managed with multilayer closure of the wound, including the parotid capsule and SMAS, and application of a pressure dressing for at least 48 hours.[17] Concomitant medical management with antisialagogues (eg, glycopyrrolate) helps decrease saliva excretion during the healing process. Some advocate for placement of a parotid duct stent to help maintain patency and flow in the setting of edema and pressure dressing.[15,17]

Most investigators believe that parotid duct injuries should be surgically managed and preferably early.[15] There are three general methods to manage duct injury depending on location and severity of injury. These include (1) primary repair with microsurgical reanastomosis, (2) salivary diversion by creation of oral fistula, and (3) ductal ligation with suppression of salivary gland function.[14] The method of repair is often dictated by the location of the injury, which Van Sickels[10] divided anatomically into three regions:

- Region A: duct injuries occurring in the glandular area
- Region B: duct injuries over the masseter muscle
- Region C: duct injuries anterior to the masseter muscle as the duct enters the oral cavity

Region B injuries often have adequate proximal and distal duct length to facilitate primary reanastomosis. In this case, the duct is stented with a silicone catheter or angiocatheter, and the duct is repaired with 8-0 or 9-0 nylon (Figs. 24-5A and B). The stent is then sutured in place to the buccal mucosa and kept in place for 10 to 14 days[14] (Fig. 24-5C).

Region A and C injuries can also be repaired with primary microsurgical reanastomosis if there is adequate identifiable proximal and distal stump. When this is not the case, region A injuries can be managed as a parenchymal injury with multilayer closure and pressure dressing or ligation of the proximal duct with subsequent edema and atrophy of the gland.[17] In region C injuries where the distal stump is too proximal to the papilla, the proximal stump can be diverted to a separate location in the buccal mucosa and stented to keep the new papilla patent during the healing process.[14]

Late complications of sialocele and salivary-cutaneous fistula can be difficult to manage. Mainstay therapy for these complications includes aspiration of the fluid collection and salivary gland suppression with antisialagogues. Botulinum toxin has been shown to effectively treat sialoceles and salivary-cutaneous fistulae in traumatic and postparotidectomy cases.[18] Persistent fistula could require parotidectomy and excision of the tract if medical management fails; however, parotidectomy in a posttraumatic setting can pose a higher risk of facial nerve injury due to scar and obscuration of tissue planes.

Facial Nerve Injury. Incomplete eye closure from facial nerve injury and orbicularis oculi muscle impairment can result in poor ocular protection, exposure keratopathy, and even blindness. Therefore, initial therapy includes ocular lubrication, moisture chamber, and eyelid taping if the patient has incomplete eye closure on exam.

For penetrating facial nerve injuries, early wound exploration and repair should be performed. If the patient is medically stable, facial nerve exploration should be done immediately. Electromyographic monitoring can be used to identify distal ends of transected nerve branches if exploration is performed within 72 hours of the injury (ie, prior to Wallerian degeneration).[19]

Primary neurorrhaphy has been shown to provide the best chance for recovery.[20-24] Nerve cooptation is performed with three interrupted sutures using 8-0 to 10-0 monofilament suture[19,20,22,25] in the epineurial layer (Fig. 24-6). Perineurial sutures have been supported by some to help reduce synkinesis but are technically challenging and more time consuming.[25]

When primary neurorrhaphy in a tension-free manner cannot be performed, cable grafting is the next preferred method of repair.[19,22,25] Options for donor nerves include great auricular, sural, and medial antebrachial cutaneous nerves.[25] When primary neurorrhaphy or cable grafting is not possible or recovery is not obtained, facial reanimation procedures can be performed secondarily at a later date.

Eyelid

ANATOMY

The upper and lower eyelids are complex, multilayered structures (Fig. 24-7). The anterior lamella consists of the skin and orbicularis oculi muscle, and the posterior lamella consists of the eyelid retractors, tarsal plate, and palpebral conjunctiva. The orbital septum that separates the preseptal space from the postseptal orbital contents is referred to as the middle lamella, although this terminology is not consistently used in the literature.[26]

The medial and lateral canthal tendons serve as a fibrous, aponeurotic sling for the upper and lower eyelids. The medial canthal tendon has bony attachments to the anterior and posterior lacrimal crest, surrounding the lacrimal sac. The lateral canthal tendon has bony attachments to Whitnall's tubercle, a bony prominence of the lateral orbital wall posterior to the orbital rim. The lateral canthal tendon and medial canthal tendon receive attachments from the tarsal plates, orbicularis oculi muscle, levator aponeurosis, and Whitnall's ligament superiorly and the capsulopalpebral fascia and Lockwood's ligament inferiorly.[26]

The lacrimal drainage system is intimately associated with the eyelids. The lacrimal puncta are located 6 and 8 mm from the medial canthus in the upper and lower eyelids, respectively.[27] These vertically oriented puncta then transition into a horizontally oriented canaliculus of the upper and lower eyelids, which merge into a common canaliculus and drain into the lacrimal sac, medial to the medial canthus. The orbicularis oculi muscle attachments surrounding the lacrimal sac play an important role in the lacrimal pump and drainage. The lacrimal sac drains into the nasolacrimal duct, which extends into the frontal process of the maxilla and ultimately drains at Hasner's valve in the inferior meatus of the medial maxilla.

EVALUATION

Evaluation of periorbital trauma should include a thorough ocular history and examination of the globe, eyelids with their adnexa, and surrounding bony structures. Diplopia should elevate concern for globe displacement or extraocular muscle entrapment. Visual impairment or abnormalities on examination should prompt early ophthalmologic consultation.

Visual acuity testing should be performed using a standard Snellen chart. In patients who have significant visual impairment, finger counting, hand motion, and light perception should also be tested. Pupils should be examined for asymmetry (anisocoria), shape irregularity, and poor reactivity. Abnormalities in the pupillary exam can suggest an afferent pupillary defect, oculomotor nerve injury, intraocular injury, or Horner syndrome. Red color perception should be performed as monocular red desaturation can indicate optic nerve injury.[28]

Extraocular muscle function evaluation for limited movement can indicate direct muscle injury, muscle entrapment, cranial nerve injury, or severe edema. In a sedated patient who cannot participate in examination or when exam findings are equivocal, forced duction testing can be performed with topical anesthetic and toothed forceps.

Intraocular pressure (IOP) can be tested at the bedside with a tonometer. IOPs greater than 20 mm Hg are considered elevated. Significant ocular injury, periorbital edema, or retrobulbar hemorrhage can elevate ocular pressure, resulting in compression of the optic nerve and its vasculature, ultimately leading to visual compromise and even blindness.[29]

The eyelids and their adnexa should be thoroughly examined for lacerations, tissue loss, and deformity. Traumatic telecanthus can manifest as blunting of the medial canthal angle and widening of the intercanthal distance. Laxity on a bowstring test, where the eyelid is pulled laterally and the medial canthal tendon is palpated, can be suggestive of medial canthal tendon disruption. Integrity of the lacrimal system should be assessed for any soft tissue injury medial to the lacrimal puncta. Punctal dilation with subsequent cannulation with a lacrimal probe can assess the integrity of the canalicular system. Obstruction or exposure of the probe is indicative of injury.

MANAGEMENT

Any suspicion for globe injury should prompt emergent ophthalmology evaluation, and further examination of the eye should avoid significant pressure on the globe.

Intraocular injury, periorbital edema, or retrobulbar hematoma can result in orbital compartment syndrome and require emergent lateral canthotomy and cantholysis to relieve that pressure. Decompression of the orbit is indicated to relieve pressure on the optic nerve; however, the exact indications have been debated. Some have suggested IOP greater than 40 mm Hg in addition to optic nerve compression or central retinal artery occlusion as indications for lateral canthotomy and cantholysis.[30] Others have suggested an IOP of greater than 30 mm Hg.[31]

The lateral canthotomy and cantholysis can be performed rapidly at the bedside.[32] The region between the lateral canthus and lateral orbital rim is anesthetized with 1% lidocaine with 1:100,000 epinephrine. The lower eyelid is retracted outward with toothed forceps, and a sharp dissecting scissors is used to make a horizontal incision across the lateral canthus to the lateral orbital rim. Next, the lower eyelid is retracted inferiorly, and the inferior crus of the lateral canthal tendon is incised with the scissors oriented inferiorly (Fig. 24-8).

Partial-thickness lacerations of the eyelids should be explored for potential injury to deeper tissues. In the upper eyelid, injury to the levator aponeurosis necessitates repair to prevent blepharoptosis. This can be done with a 6-0 braided suture in horizontal mattress fashion between the levator aponeurosis and partial thickness of the superior edge of the tarsal plate.[27] The skin can be closed with 6-0 nylon or fast-absorbing gut suture. Care must be taken not to incorporate the septum orbitale, as this may result in eyelid retraction and lagophthalmos of the upper eyelid or ectropion of the lower eyelid.

Full-thickness lacerations and those with margin involvement require a multilayer closure. The conjunctiva is often not closed, particularly if the edges are well approximated, as sutures can cause corneal irritation. The eyelid margin requires meticulous reapproximation and eversion to prevent notching and deformity.[33] Murchison and Bilyk recommend closure beginning with a traction suture of 6-0 silk or polypropylene that is placed at the eyelid margin along the meibomian gland line.[33] The tarsus is then reapproximated with 5-0 or 6-0 polyglactin suture. The eyelid retraction suture is tied down with tails left long. An additional eyelid margin suture is placed at the ciliary line. Furthermore, some advocate yet an additional eyelid margin suture at the gray line, but this risks corneal irritation and is often not necessary.[33] The skin is then closed with 6-0 nylon or fast-absorbing gut suture, incorporating the tails of the eyelid margin sutures[27] (Fig. 24-9).

Avulsion injuries can be addressed with primary closure, local advancement flaps, or skin grafts for partial-thickness wounds depending on amount of tissue loss.[27] Full-thickness tissue loss can be primarily closed when less than 25% of the eyelid margin is lost. Large defects require a combination of skin grafting, local rotation/advancement techniques, Cutler-Beard bridge flaps, and Hughes tarsoconjunctival flaps.[27]

The degree of impairment in lacrimal drainage from a monocanalicular injury is controversial, as there are patients with known obstruction who are asymptomatic.[34] Repair is recommended for all patients with canalicular injury given there is no method to predict those who will develop symptomatic epiphora (ie, persistent or excessive tearing). Studies have demonstrated the best outcomes are achieved when repairs are performed by subspecialty trained surgeons and in the operating room setting.[35] The landmark study by Kersten and Kulwin[36] demonstrated that 96% of patients were asymptomatic after reapproximation of the

pericanalicular orbicular oculi muscle with a 7-0 polyglactin suture and bicanalicular stenting (Fig. 24-10). Studies have demonstrated no difference in outcomes when monocanalicular stents versus bicanalicular stents are used for monocanalicular injuries.[35] The most common monocanalicular stent is a Mini Monoka (FCI Ophthalmics, Marshfield Hills, MA) stent. Bicanalicular stent options include the Guibor (Guibor Canalicular Intubation Set; Xomed Surgical Products Inc, Jacksonville, FL) and Crawford (JedMed, St. Louis, MO) tubes.

Nose

ANATOMY

The nose is frequently injured in trauma to the face given its prominent projection on the facial contour. The nose

consists of a bony and cartilaginous framework that contains a complex external soft tissue envelope and internal mucosal lining. The nasal bones have a pyramidal shape and are bordered by the nasal process of the frontal bone superiorly, frontal process of maxilla laterally, upper lateral cartilage inferiorly, and septum on its deep surface. All of these structures together with the lower lateral cartilages and sesamoid cartilages play an important role in the strength and structure of the nose.

The external nose can be subdivided into nine aesthetic subunits: the midline nasal dorsum, tip, and columella, as well as the paired lateral sidewalls, ala, and soft tissue triangles. The septum plays a critical function in nasal support, appearance, and function. Anteriorly, the septum consists of the quadrangular cartilage. Posteriorly, the septum has bony contributions from the perpendicular plate of the ethmoid superiorly and the vomer, maxilla, and palatine bones inferiorly.

EVALUATION

The nose should be evaluated for any aesthetic and functional changes. Evaluating the frontal and base views of the nose can give insight into any asymmetry or deviation. Palpation of step-offs or bony mobility suggests an underlying fracture. Anterior rhinoscopy evaluates for septal injury, mucosal disruption, and CSF leak. The septum should also be palpated for underlying septal hematoma. Any laceration should be assessed for cartilage exposure or full-thickness injury. Avulsion injuries should be characterized based on nasal aesthetic subunits involved and layers of tissue involved.

MANAGEMENT (SEE ATLAS FIGURE 4)

Lacerations without significant tissue loss should be closed in a multilayer fashion. For full-thickness injuries, the internal mucosal lining of the nose should be reapproximated with 4-0 to 6-0 absorbable sutures.[37] Silastic stents can be placed for 2 to 4 weeks to limit stenosis when the internal lining is violated.[37] Cartilage lacerations are reapproximated with 4-0 polydioxanone, clear nylon, or poliglecaprone suture in horizontal mattress fashion. Deep dermal sutures may be required to decrease tension. The skin layer is then closed with judicious nonreactive suture to limit foreign body reaction and strangulation.[37] Tissue eversion is critical, particularly at the alar rim, and can limit notching.

Avulsion injuries with missing tissues pose a reconstructive challenge. Timing of reconstruction is balanced between delaying reconstruction for adequate debridement in heavily contaminated or bite wounds and early intervention to prevent soft tissue contracture and distortion. Ideal reconstructive method depends on location of defect, need for free cartilage graft coverage, and patient comorbidities. Cartilage grafting is required for missing cartilage, reestablishing nasal support, and preventing contracture and notching at edges such as the alar rim.

For small avulsion injuries, full-thickness skin grafting, composite chondrocutaneous grafts, and rotational advancement techniques (eg, single-lobed, bilobed, and dorsal nasal flaps) can be used.[38] For larger defects or if free cartilage grafts need vascularized tissue coverage, locoregional flaps (eg, nasolabial or paramedian forehead flaps) are preferred.

Lips

ANATOMY

Even minor abnormalities to the lips can be quite noticeable. Additionally, the lip participates in facial expression, speech, and alimentation.[39] Therefore, management of lip trauma must address restoring function and aesthetic units.

The lip consists of three major layers: cutaneous, orbicularis oris muscle, and mucosa. Reapproximating each of these layers is critical in managing lip lacerations and defects. The surface anatomy of the upper lip consists of a cutaneous lip and vermilion lip (Fig. 24-11). The junction of these subunits forms the vermilion-cutaneous junction (VCJ). The cutaneous roll is an area of convexity of the cutaneous lip at the VCJ. Reflecting light at the cutaneous roll makes it a prominent feature of the lip. Even minor disruption of the cutaneous roll or VCJ can be aesthetically unpleasing. The contour of the VCJ is often referred to as the Cupid's bow, with the peaks correlating to the position of the philtral columns and the trough correlating to the philtral dimple. The contour of the lower lip VCJ is curvilinear with simpler surface anatomy. The lower lip junctions with the chin subunit at the mentolabial sulcus.

EVALUATION

Lip trauma can be associated with intraoral and dental injury. Lacerations should be probed to assess full-thickness and intraoral involvement. A thorough dental evaluation for loose, avulsed, or chipped teeth should be performed. Dental consultation and management of dental injury are best performed prior to closure of lacerations to limit traction on soft tissue repair.[40] Extension of wounds into the floor of the mouth or buccal mucosa should be evaluated for salivary duct injury.

MANAGEMENT

Local anesthesia with nerve blocks is critical in lip laceration repair as direct infiltration into the wound can distort landmarks. Infraorbital and mental nerve blocks are used

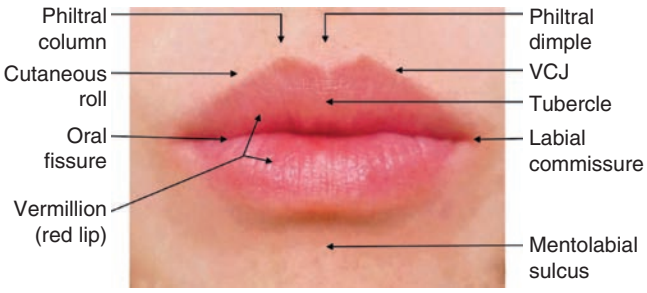

FIGURE 24-11 Surface landmarks of the lip. VCJ, vermilion-cutaneous junction.

for upper and lower lip lacerations, respectively. The superior labial and inferior labial arteries form the major blood supply for the upper and lower lips and can result in significant bleeding. Pressure on the lip with a full-thickness grasp between the thumb and index finger can help with immediate hemostasis. Local anesthetic infiltration with epinephrine in the region of the artery lateral to the oral commissure can help with vasoconstriction.

Primary closure of full-thickness lip defects should be done in a layered fashion, with attention to the mucosa, orbicularis oris muscle, and skin. Muscle closure is performed with 4-0 polyglactin or polydioxanone suture. Dehiscence in the muscle layer can result in an irregular depression, and failure to close the marginal aspect of the muscle can result in notching or a "whistle" deformity. After the muscle is reapproximated, the key step is realignment of the vermilion border, as even a 1-mm error can be aesthetically displeasing.[40] A 6-0 nylon or polypropylene suture is used to reapproximate the vermilion border. A 5-0 chromic suture is used for the remainder of the vermilion and mucosal closure, and skin is closed with 6-0 nylon or polypropylene suture.

Reconstruction of avulsion injuries requires consideration of percentage of tissue loss, philtral or commissure involvement, and degree of resulting microstomia. Generally, defects less than 30% can be closed primarily. Larger defects require complex tissue rearrangement, including bilateral advancement, Abbe or Estlander lip switch, or Karapandzic, Bernard-Burrow, or Gilles fan flaps.[40]

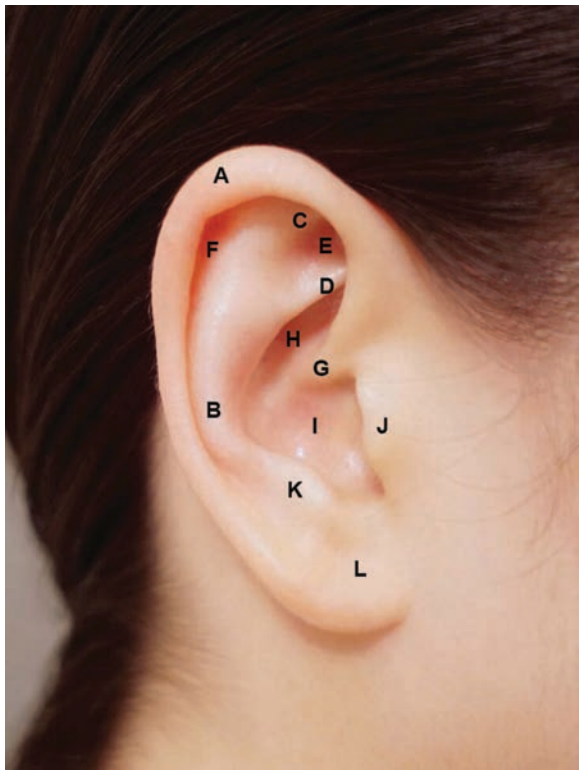

FIGURE 24-12 Surface anatomy of auricle. A, helix; B, antihelix; C, superior crus of antihelix; D, inferior crus of antihelix; E, triangular fossa; F, scaphoid fossa, G, root of helix; H, concha cavum; I, cymba concha; J, tragus; K, antitragus; L, lobule.

Auricles

ANATOMY

The auricle is derived embryologically from the six hillocks of His, with the first three hillocks giving rise to the tragus, helix, and helical crus and the latter giving rise to the antihelix, antitragus, and lobule.[41] The auricle protrudes from the skull base at an angle of 25° to 30° and angles 15° away from the vertical axis.[42] The external anatomy of the auricle is shown in Fig. 24-12.

EVALUATION

Auricular wounds should be examined for depth of laceration, cartilage involvement, and avulsed tissue. Bruising over the mastoid (Battle sign) could be indicative of a skull base fracture and should raise suspicion for underlying temporal bone fracture. Otoscopic examination should asses the external auditory canal for lacerations and tympanic membrane for perforations or hemotympanum.

MANAGEMENT

After local wound care, lacerations can be managed with reapproximation of the skin and perichondrium with the goal of reapproximating the underlying lacerated cartilage.[42] Cartilage sutures are not necessarily required. Significant extension into the external auditory canal warrants consideration for stenting.[42]

Avulsion injuries can be divided into complete and partial avulsions. Avulsion injuries with a wide base or those with a narrow base with small size of avulsed tissue can be primarily repaired with reapproximation of the perichondrium and skin. Avulsion injuries with a narrow base and large size can have a compromised blood supply, and the patient and surgeon should monitor for impending tissue loss with selective debridement and reconstruction of any demarcated tissue.

Completely avulsed tissue can be considered for microvascular anastomosis and reimplantation if tissues are appropriately handled.[43] The avulsed tissue should be wrapped in gauze, placed in a plastic bag, and submerged in a 4°C ice water bath.[42] Postauricular banking techniques have been abandoned by some due to high resorption rates and disruption of the postauricular soft tissue, if needed, for more complex auricular reconstruction.[43] Auricular prostheses are an option for those who do not desire autologous rib cartilage reconstruction or in patients with significant medical comorbidities precluding prolonged anesthetic.

Any area where the perichondrium has been lifted away from the cartilage should be bolstered to prevent blood collection and cauliflower ear deformity. Similarly, auricular hematomas should be drained and overlying soft tissue reinforced with a bolster. Various bolster techniques, including dental rolls or ointment-impregnated gauze with horizontal mattress suture, can be used.[41]

MANAGEMENT OF MAXILLOFACIAL SKELETAL TRAUMA

The facial skeleton can be categorized into horizontal thirds: cranial vault, midface, and mandible. The cranial vault includes the frontal sinus. Midface fractures include orbital, nasal bone, naso-orbito-ethmoid (NOE), zygomaticomaxillary complex (ZMC), and Le Fort fractures. Fractures involving two or more of the facial thirds are considered panfacial fractures.

Radiography

Multiplanar thin-cut (0.6–1.5 mm) facial computed tomography (CT) imaging is the gold standard for maxillofacial trauma. Axial, coronal, and sagittal reconstructions should be available for accurate diagnosis. Three-dimensional CT images improve visualization of the shape, size, and orientation of individual bone fragments in complex fractures and ultimately help with surgical planning and patient counseling.

Occlusion and Intermaxillary Fixation

In dentistry, occlusion represents the static contact between teeth of the maxilla and mandible. In 1899, Edward Angle was the first to classify malocclusion, or the malalignment of teeth when the jaws close.[44] He defined normal occlusion as the dental relationship where the mesiobuccal cusp of the maxillary first molar lies within the buccal groove of the mandibular first molar. Class I malocclusion has the same molar relationship as in normal occlusion with irregularities in spacing or rotation. Class II malocclusion is the dental relationship where the mesiobuccal cusp of the maxillary first molar is anterior to the mesiobuccal groove of the mandibular first molar (retrognathia). Class III malocclusion is defined by the mesiobuccal cusp of the maxillary first molar lying posterior to the mesiobuccal groove of the mandibular first molar (prognathia).

Occlusion plays a critical role in maxillofacial reconstruction. Dental relationships can provide a template for aligning fractures and are the basis of maxillomandibular, or intermaxillary, fixation to ensure that fracture repair is performed in an orientation where the patient's functional occlusion is restored. It is important to note that patients may not have normal occlusion prior to their injuries. Therefore, photographs and dental records play a key role in establishing the patient's premorbid occlusion. Dental ware facets point to areas of prior dental contact and help maxillofacial surgeons reestablish premorbid occlusion.

Options for maxillomandibular fixation include Erich arch bars (gold standard), Ivy loops, intermaxillary fixation screws, embrasure wires, hybrid arch bars, gunning splints, and, more historically, circummandibular-transpyriform wires. In patients with seizure disorders, those suffering from alcohol abuse, and patients who could not protect their airway in the event of vomiting, long-term use of maxillomandibular fixation is contraindicated.

Intraoperative Computed Tomography

The use of intraoperative CT in maxillofacial reconstruction has evolved with the advent of portable CT scanners. Intraoperative CT allows for assessment of reduction in areas where direct visualization is difficult, such as the orbit and zygoma.[45] Intraoperative assessment allows for immediate modification, obviating the need for often more expensive and difficult delayed revisions.[46] Additionally, immediate assessment can eliminate the morbidity of additional fracture exposure sites that would otherwise be required to confirm reduction and, in the case of ZMC fractures with orbital floor involvement, determine the need of orbital floor reconstruction. Shaye et al[45] demonstrated a revision rate of 24% with an average intraoperative imaging time of 14.5 minutes, suggesting that in select cases, intraoperative imaging can be efficient and prevent delayed revision. The rate of revision is biased by the lower threshold to make adjustments while still in the operating room and the bias against additional revision surgery once the patient has left the operating room. Additionally, the risks of radiation must be balanced with the benefit of immediate revision.

Rigid Fixation

Reconstitution of skeletal support is the foundation of maxillofacial reconstruction. Reduction and fixation of fractured skeletal elements restores proper functioning and allows optimal bony healing.[47] The evolution of internal fixation hardware technologies has allowed for optimal rigid fixation of fractures. Rigid fixation prevents micromovements of the fractured segments, allowing formation of a delicate blood supply and promoting primary bone formation without callus formation.[48] Lack of adequate fixation increased the chance of nonunion and wound complications.[48] The added benefit of rigid fixation is to avoid postoperative maxillomandibular fixation and sequelae such as temporomandibular joint ankylosis.[49]

Frontal Sinus Fractures

ANATOMY AND ETIOLOGY

The frontal sinus is the last of the paranasal sinuses to develop and is absent at birth. Pneumatization of the frontal sinus begins around age 2 years and reaches adult size at age 15 years.[50] The frontal sinus is bounded by the anterior table, which contributes to the bone underlying the forehead, glabella, and brow. The posterior table of the frontal sinus separates the sinus from the anterior cranial fossa, and the floor of the frontal sinus is the orbital roof.

The frontal sinus requires significant force to fracture.[51] Given the high-energy mechanism required to generate that force, it is not surprising that 75% of patients with these fractures have serious concomitant injuries.[52] Thirty-three percent of frontal sinus fractures are isolated anterior table fractures, and 67% involve a combination of the anterior table, posterior table, and frontal recess.

EVALUATION

Soft tissue injury overlying the forehead, particularly in the context of high-energy trauma, should raise suspicion for underlying frontal sinus fracture. Palpation of any bony step-offs on the forehead or visible bony depression suggests a fracture, although edema in the acute setting can obscure these findings. The patient should be asked about signs and symptoms of CSF leak, including clear rhinorrhea and salty-tasting drainage. Clear rhinorrhea noted on examination can be collected for a bedside "halo" test, where fluid is placed on filter paper and CSF diffuses faster than blood, leaving a clear halo around the blood. Beta-2 transferrin analysis can also be performed but has limited acute utility given it is generally a send-out laboratory test that can take up to a week to obtain results. A thorough ophthalmologic exam should be performed given the shared wall of the frontal sinus floor and orbital roof.

MANAGEMENT

The goals of frontal sinus fracture management include restoring normal frontal sinus function or obliterating an unsafe sinus, treating CSF leaks, and restoring frontal bone contour. Strong[50] outlined five major considerations that guide management of frontal sinus fractures: anterior table fracture, posterior table fracture, frontal recess injury, dural injury/CSF leak, and fracture comminution (Fig. 24-13).

FRONTAL RECESS INJURY

Patients with frontal recess injury as part of their frontal sinus fracture are at risk of frontal sinus outflow obstruction and late complications of mucocele or complicated sinusitis. Nondisplaced or minimally displaced fractures at the frontal recess can be observed with repeat imaging in 3 months. If there is aeration of the frontal sinus suggestive of restoration of frontal sinus function, the patient can be observed without surgical intervention. If the frontal sinus is opacified, then endoscopic sinus surgery with frontal sinusotomy can be pursued to restore sinus outflow. There has been a trend toward observation and frontal sinus preservation.[53] Studies have demonstrated spontaneous ventilation of the frontal sinus[54,55] in fractures involving the frontal recess. Smith et al[54] demonstrated that five of seven patients with anterior table and frontal recess fractures had spontaneous ventilation. The other two patients were successfully managed with endoscopic sinus surgery after failed medical therapy with antibiotics, systemic steroids, and topical nasal steroids. Jafari et al[55] demonstrated that seven of eight patients with frontal recess fractures had spontaneous ventilation.

For patients with moderate or severe frontal recess fractures and frontal sinus outflow impairment, frontal sinus obliteration or cranialization should be performed depending on the status of the anterior and posterior tables.

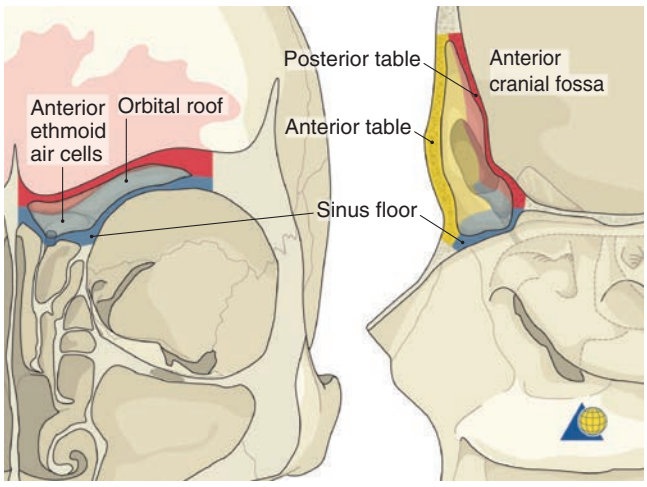

FIGURE 24-13 Anatomy of the frontal sinus. Yellow = anterior table, red = posterior table, blue = sinus floor and frontal recess. (Reproduced with permission from AO Surgery Reference. www.aosurgery.org. Copyright by AO Foundation, Switzerland.)

ANTERIOR TABLE

Anterior table fractures that have less than 1 to 2 mm of displacement can be observed and are unlikely to cause significant frontal contour deformity.[50] Fractures with greater displacement, while posing little risk of mucocele formation, are more likely to have aesthetic deformities. After waiting 2 to 4 months for resolution of postinjury edema, patients can undergo endoscopic repair with porous polyethylene implant to camouflage the frontal contour deformity. By waiting for the edema to resolve, patients can make an educated decision for surgical intervention. Often the deformity is less noticeable than anticipated, and the patient may desire no intervention.[50] Endoscopic repair is performed similar to an endoscopic brow lift with a medial 1- to 2-cm subperiosteal endoscope incision in the hairline and 3- to 5-cm parasagittal working incision. The porous polyethylene is contoured to the defect size and sometimes layered. The implant is then fixated with a percutaneous 1.7-mm self-drilling screw (4–7 mm in length). A prominent forehead or receding hairline may require exposed incisions or preclude the endoscopic approach due to limited visualization around forehead curvature.

Open reduction, internal fixation via a bicoronal approach is an alternative approach. The coronal incision can be designed in a zigzag fashion 4 to 6 cm behind the hairline for patients who wear their hair long and in a straight line, or widow's peak fashion for patients who wear their hair short. The incision is carried down from temporal line to temporal line in the subgaleal plane, protecting the pericranium as a potential flap. Lateral to the temporal line, the dissection plane is carried below the TPF, thereby protecting the temporal branch of the facial nerve. The incision can be carried in a pre- or postauricular position laterally. The pericranial flap is incised from temporal line laterally to 2 cm posterior to the coronal incision and elevated in a subperiosteal plane to the superior orbital rims (Fig. 24-14). Further exposure can be obtained by releasing the supraorbital neurovascular bundle from the foramen with osteotomies. The anterior table fragments can then be reduced with a combination of

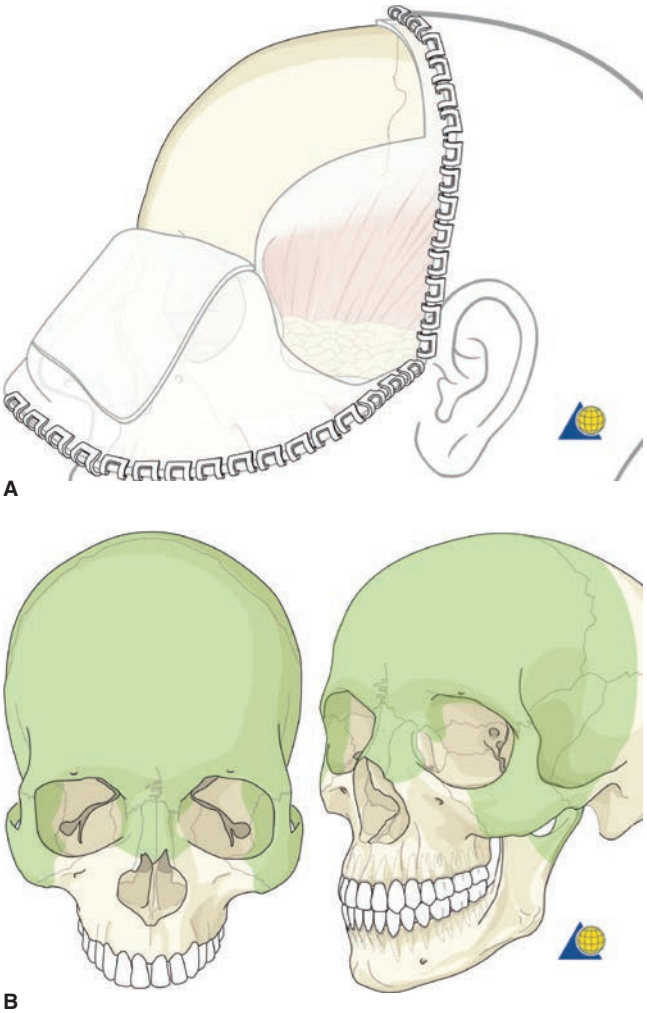

FIGURE 24-14 Exposure of the anterior table of the frontal sinus. (**A**) Coronal flap. (**B**) Access provided by a coronal approach. (Reproduced with permission from AO Surgery Reference. www.aosurgery.org. Copyright by AO Foundation, Switzerland.)

bone hooks or 1.5- to 2.0-mm screws placed in the depressed segment and retracted with a heavy hemostat. Fragments can be plated with 1.0 to 1.3 microplates, with small gaps of 4 to 10 mm being reconstructed with titanium mesh.[50] Mucosa in the fracture lines should be removed thoroughly. If reduction cannot be performed, sinus obliteration may be required.

POSTERIOR TABLE

Posterior table fractures with minimal displacement (less than one table width) can be observed. In the presence of CSF leak, these fractures can be observed with the patient on strict skull base precautions for 7 days. These precautions include bedrest, no nose blowing, no open mouth sneezing, no Valsalva maneuvers, and no noninvasive positive-pressure ventilation. Persistent CSF leak after a period of observation generally requires frontal sinus obliteration or cranialization. Similarly, significantly displaced fractures (greater than one table width) benefit from frontal sinus obliteration or, in the presence of significant comminution or CSF leak, cranialization for repair of dural injury.[50]

Obliteration begins with exposure of the anterior table with a coronal approach. Multiple methods for identifying the boundaries of the anterior table include transillumination, 6-foot penny Caldwell x-ray, surgical navigation, or use of bayonet forceps with one tine inside the sinus palpating the edges and the exterior tine serving as the marker for the outline of the sinus. The anterior table is drilled out, and the mucosa is meticulously removed from the undersurface and the remainder of the sinus cavity. The residual mucosa of the frontal sinus infundibulum is inverted toward the nasal cavity and plugged with temporalis muscle. Fat harvested from the abdomen is used to fill the sinus cavity, and the anterior table bone set aside previously is plated using microplates.

Cranialization is usually performed in consultation with a neurosurgeon. The procedure begins similarly to the obliteration. After the mucosa is removed from the sinus, the posterior table bone is removed and any dural injury is repaired. The frontal recess is plugged with temporalis muscle fascia, and if further reconstruction is required, the pericranial flap is placed along the skull base. The anterior table bone is then replaced, with a small inferior gap to prevent strangulation of the pericranial flap.

Nasal Bone

ANATOMY

See section on nose in Management of Facial Soft Tissue Trauma.

EVALUATION

History should be obtained about the mechanism of trauma, and necessary trauma workup should be initiated for suspected concomitant injuries. Patients should be asked about perceived changes to the appearance of their nose. History of prior trauma and nasal surgeries should be obtained. Pictures can help differentiate prior deformities from acute changes. Clear rhinorrhea or salty taste should elevate concern of associated skull base injury and CSF leak.

Physical examination includes palpating for any bony step-offs or mobile bony segments. Nasal examination with anterior rhinoscopy or endoscopy can identify septal deviation, mucosal lacerations, and septal hematoma. Palpation of the nasal septum is a critical component in diagnosing septal hematomas.

MANAGEMENT

The goal of treating nasal bone fractures is to restore premorbid appearance and nasal airway. Patient factors play a large role in the decision making for intervention, including age, aesthetic expectations, and medical comorbidities. Mild or minimally displaced nasal bone fractures may not result in nasal obstruction or noticeable deformity. If the patient has significant edema at the time of presentation, reevaluation after 3 to 5 days (but before 2 weeks) to allow the edema to subside may unmask deformities.[56] Options for patients

with nasal deformity and anatomic nasal airway compromise include closed reduction or open fracture treatment via septorhinoplasty approach.

Closed reduction techniques can be successful in select patients and fractures. The procedure can be performed under local or general anesthesia[57]; 1% lidocaine with 1:100,000 epinephrine is injected along the lateral aspect of the nasal bones, premaxilla, and septum. Additional nerve blocks are performed, including the infraorbital, external nasal, and infratrochlear nerves.[56] Pledgets soaked in 4% cocaine provide additional anesthesia and vasoconstriction. A Boies elevator is placed in the nasal cavity and against the nasal bone. The instrument should be marked or gripped at the distance between the external nares and medial canthus so as to protect the skull base (Fig. 24-15). The surgeon's opposite thumb and index finger should be placed externally on the nasal bones to palpate and control the reduction. Reduction begins on the side of the concavity for deviated fractures.[56] The bony pyramid is pulled anteriorly and toward the side of concavity to restore anatomic alignment. Ash forceps can be used to reduce septal fractures and are often required to obtain adequate nasal bone reduction due to the relationship between the nasal bones and septum. After reduction is complete, the bony pyramid should be splinted with a Denver or thermoplastic splint and the septum with a silastic splint.

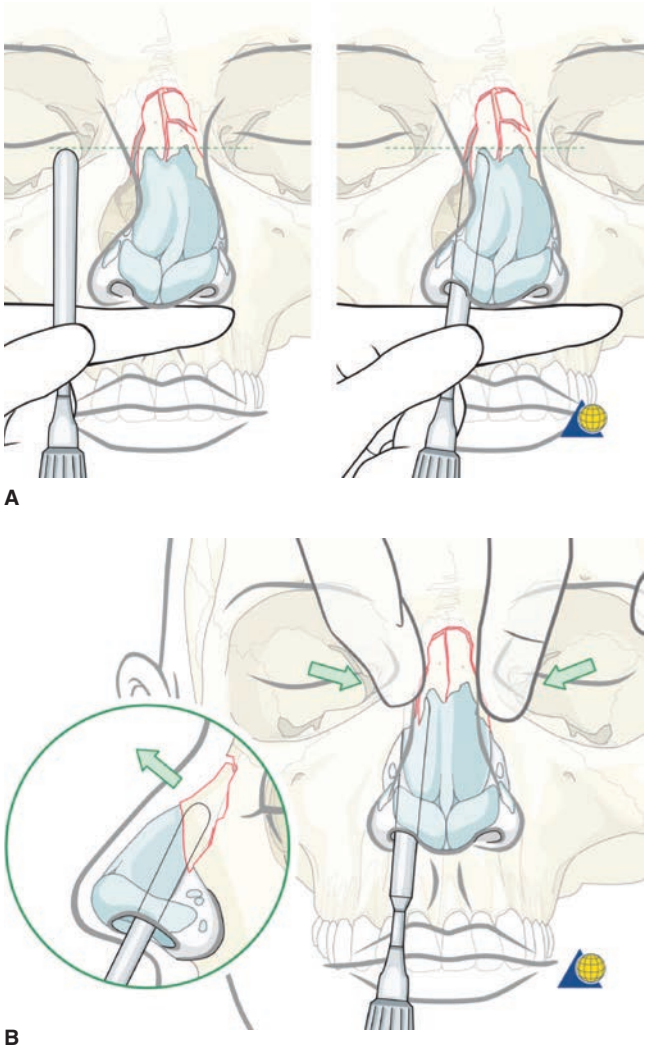

FIGURE 24-15 Closed reduction of nasal bone fractures. (**A**) The Boies elevator should be placed below the level of the skull base to prevent iatrogenic injury. (**B**) The surgeon's opposite thumb and index finger should be placed externally on the nasal bones to palpate and control the reduction. (Reproduced with permission from AO Surgery Reference. www.aosurgery.org. Copyright by AO Foundation, Switzerland.)

In complex fractures with septal involvement, severe skeletal comminution, and pyramidal instability, closed reduction techniques may result in poor outcomes and high revision rates.[58] In a detailed literature review, Staffel[59] found that surgeons were dissatisfied 37% of the time with closed reduction techniques alone. Multiple series have also demonstrated revision rates as high as 50%.[58] With the evolution of contemporary rhinoplasty techniques, there has been a shift toward early open fracture treatment. Staffel[59] demonstrated improved satisfaction from 40% with closed reduction techniques to 71% with rhinoplasty techniques including septoplasty, osteotomies, upper lateral cartilage release, anterior perpendicular plate fracture, and camouflage grafting.

Septal hematomas should be drained to prevent septal abscess, cartilage necrosis, and saddle nose deformity. After local anesthesia is injected into the septum, the mucoperichondrium overlying the hematoma should be incised bilaterally, but in nonopposing locations to prevent perforation. Once the hematoma is drained, nasal packing should be placed for 7 days to prevent reaccumulation of blood. Prophylactic antibiotics are suggested to prevent toxic shock syndrome while packing is in place.

Midface Fractures

ANATOMY

The structure of the midface is tightly related to its adaptation to masticatory forces. The shape of the midface is also related to paranasal sinus pneumatization, which is involved in vocal resonance, lightening the weight of the skull, and energy absorption.[60] The resulting structure of the midface can be thought of as a lattice-like structure of vertical and horizontal buttresses,[61] where the buttresses represent areas of stronger bone.

The four vertical buttresses are as follows: (1) nasomaxillary (also known as the medial or frontonasomaxillary) buttress, (2) zygomaticomaxillary (also known as the lateral or frontozygomaticomaxillary) buttress, (3) pterygomaxillary buttress, and (4) ethmoid-vomerian (or bony septal) buttress. The horizontal buttresses include the following: (1) superior orbital rim, (2) inferior orbital rim with extension to the zygomatic arch, and (3) maxillary alveolus/palate.

Common fracture patterns of the midface include nasal bone, NOE, ZMC, orbital, and Le Fort fractures.

EVALUATION

A thorough head and neck examination is required for every facial fracture. For the midface, examination of any

asymmetry, decreased malar projection, or gross deformities may indicate an underlying fracture. Patient pictures prior to the injury can help provide a baseline for assessment. The face should be palpated for bony step-offs or mobile segments. Bimanual examination with stabilization of the head at various levels can assess for palatal or midface mobility suggestive of dentoalveolar, palatal, or Le Fort fractures. Trismus may indicate fracture of the zygomatic arch and impingement or spasm of the underlying temporalis muscle. Oral examination should include quality of dentition (which has implications on method of intermaxillary fixation), loose dentition, and malocclusion. History of prior dental or orthognathic procedures and records should be obtained, particularly when the fracture pattern does not match the degree of malocclusion. A thorough cranial nerve and ophthalmologic examination should be performed.

ORBIT MANAGEMENT

Orbital fractures can be classified as trap door (greenstick), floor, medial wall, two wall, roof, or complex fractures. These fractures can occur in isolation or in the setting of concomitant midface fractures. Orbital "blowout" fractures occur from a combination of increased orbital pressure ("hydraulic" mechanism) and direct impact to the infraorbital rim ("buckling" theory).[62]

Although most orbital fractures can be treated within the first 2 weeks, there are certain circumstances under which emergent intervention is indicated. The oculocardiac reflex is a vagally mediated reflex with afferent signaling from the ophthalmic division of the trigeminal nerve, resulting in nausea, bradycardia, and potentially asystole. The stimulus is thought to be secondary to orbital pressure or entrapment of orbital contents.[63]

Extraocular muscle entrapment is another indication for immediate repair and is most commonly described in a greenstick or "trap door" fracture of the orbital floor. Orbital contents, including the inferior rectus muscle, displace into the maxillary sinus at the time of impact and are then entrapped as the hinged bone segment retracts into its original position. Prolonged entrapment can lead to ischemia and fibrosis of the muscle and therefore requires emergent intervention.

The goal of routine orbital fracture management is restoration of orbital volume to prevent delayed enophthalmos, hypoglobus, and diplopia. Not all blowout fractures require intervention. Some have suggested that 2 cm^2 or 50% of the area of the orbital floor is predictive of delayed enophthalmos and diplopia.[63] Distortion of the shape of the inferior rectus from a horizontally flat structure to a more rounded or vertically elongated structure is predictive of enophthalmos.[63]

The orbit can be accessed via a transconjunctival, subciliary, or subtarsal approach. Because the subciliary approach has a higher risk of cicatricial ectropion and the subtarsal approach results in visible scarring, the transconjunctival approach is favored[64] (Fig. 24-16). While autologous bone is the gold standard for orbital reconstruction, titanium and porous polyethylene are now the most commonly used materials.[62]

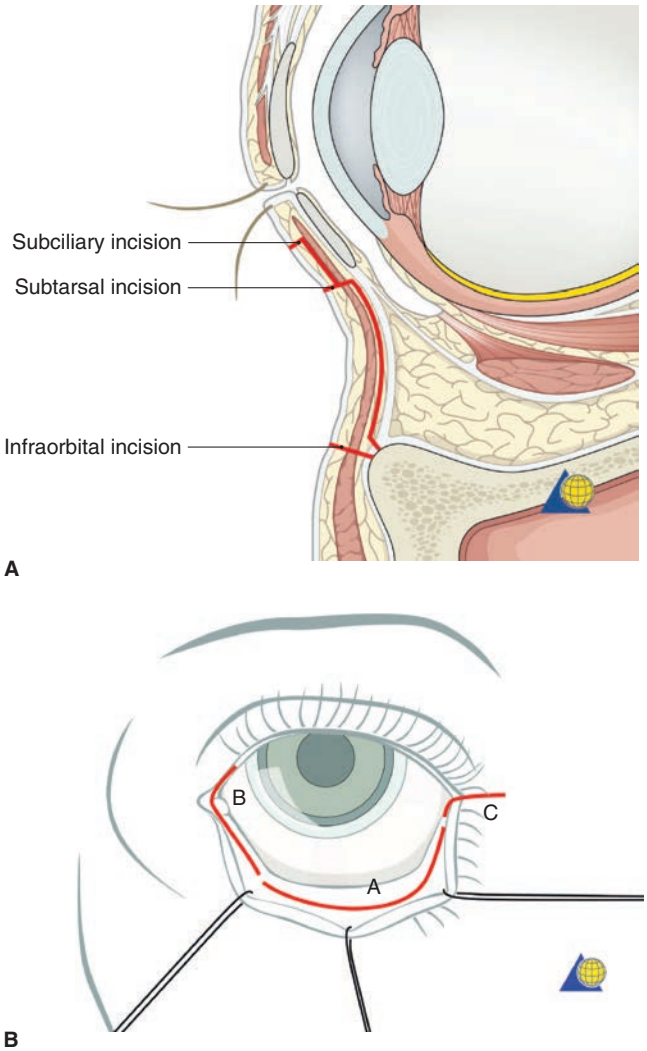

FIGURE 24-16 Incisions to approach the orbit. (**A**) Cutaneous orbital approaches via subciliary, subtarsal, and infraorbital incisions. (**B**) Transconjunctival approaches with medial and lateral extension. Incision A demonstrates the standard transconjunctival approach, with incision B representing a transcaruncular approach for medial extension and incision C representing a lateral canthotomy for lateral extension. ZMC MANAGEMENT

The ZMC describes fractures of the zygoma and its surrounding articulations. The zygoma has four articulation sites: zygomaticomaxillary suture, frontozygomatic suture, zygomaticosphenoid suture, and temporal process of the zygoma. The temporal process of the zygoma forms the anterior portion of the zygomatic arch. The zygoma contributes to the lateral orbital wall, orbital rim, and orbital floor, and therefore concomitant orbital fractures also need to be taken into consideration in the management of ZMC fractures.

The goals in repair of ZMC fractures include reestablishing facial width, malar projection, and orbital volume. Exposure

of a given articulation of the ZMC allows for confirmation of reduction and opportunity for internal fixation. This must be balanced with the morbidity of the exposure. Preexisting lacerations can provide direct exposure with minimal extension.

The best site for evaluation of reduction is the zygomaticosphenoid suture given the long segment and multiplanar articulation with the sphenoid bone.[65] The best sites for internal fixation include the (1) zygomaticomaxillary fracture line due to thicker bone and vector of fixation counteracting the pull of the masseter (2) and frontozygomatic suture due to thicker bone.

Management of ZMC fractures can range from observation with soft diet to four-point fixation, with fixation sites including the zygomaticomaxillary, frontozygomatic, zygomaticotemporal, and infraorbital rim. Minimally displaced, noncomminuted, and stable fractures with low risk for malar depression are appropriately managed with observation and a soft diet.

Manipulation of the ZMC for reduction can be performed via a percutaneous Carroll-Girard screw, sublabial Keen approach, or temporal Gilles approach. Closed reduction alone can be performed for mildly displaced fractures without comminution. Areas of comminution or significant displacement require open reduction with internal fixation.

The sublabial approach is performed with an incision in the gingivobuccal sulcus. A mucosal incision is made with care to leave an adequate cuff of mucosa for closure with care to protect the papilla of the parotid duct. Cautery is used to enter a subperiosteal plane. A periosteal elevator is used to elevate over the face of the maxilla, laterally over the zygoma, medially toward the pyriform aperture, and superiorly to the orbital rim, with care to dissect around the infraorbital neurovascular pedicle. This approach would allow plating at the zygomaticomaxillary buttress with a midface L-plate (0.7 mm thick, or 1.5/2.0 mm plates using older nomenclature). Infraorbital rim plates with curved midface plates can be accessed using this approach,[66] although orbital approaches may provide easier access to this area (as described in the orbit section).

The frontozygomatic suture can be accessed via an upper blepharoplasty approach. The incision is planned in the lateral aspect of the natural supratarsal skin crease. An incision is made through the skin, and dissection is carried through the orbital part of the orbicular oculi muscle. Dissection continues laterally to the superolateral orbital rim, where subperiosteal dissection reveals the frontozygomatic suture. Curved midface plates (0.5 mm thickness, or 1.3 mm by older nomenclature) can be used for internal fixation.

Exposure of the zygomatic arch for internal fixation requires a coronal approach and carries the morbidity of a large incision, alopecia, scarring, and risk of damage to the temporal branch of the facial nerve. Generally, this approach is reserved for significant comminution, displacement, and telescoping of the zygomatic arch.[65] The approach begins as described in the frontal sinus fracture section. Laterally, as the TPF is elevated, the intermediate temporal fat pad is identified, and the superficial layer of the deep temporal fascia is incised to enter the fat pad above the level of the zygoma. Dissection is performed through the fat pad onto the superficial aspect of the arch, followed by subperiosteal dissection from the superficial to lateral aspect of the zygomatic arch. This dissection plane protects the temporal branch of the facial nerve as it crosses over the lateral surface of the zygomatic arch. The introduction of intraoperative CT has allowed for confirmation of reduction without requiring the coronal incision and arch approaches in many patients.

NOE MANAGEMENT

The NOE region is a confluence of the nose, frontal process of the maxilla, orbit, ethmoid, lacrimal bone, and anterior skull base.[52] The hallmark clinical finding of an NOE fracture is telecanthus due to displacement of the bony segment attached to the medial canthal tendon, termed the *central fragment*, or disruption of the medial canthal tendon itself.

Markowitz et al[67] classified NOE injuries into three subtypes depending on the degree of comminution around the central fragment and integrity of the medical canthal tendon (Fig. 24-17).[67] Type I fractures have a single, intact central segment. Type II fractures have comminution of the central fragment with intact medial canthal tendon attachment. Type III fractures have comminution of the central fragment with detachment or tear in the medial canthal tendon. CT imaging can help distinguish between type I and type II/III fractures. Physical examination for integrity of the medial canthal tendon (eg, bowstring test) can help distinguish between a type II and III fracture.

Nondisplaced or minimally displaced type I fractures may not require surgical intervention if the fragment is stable and not resulting in any deformity. Displaced or unstable type I fractures typically require miniplate fixation that can be achieved via a sublabial, gingivobuccal sulcus approach combined with transconjunctival approach or existing laceration.[52]

Type II and III fractures typically require a coronal approach for adequate reduction of comminuted segments, transnasal wiring, or other canthopexy techniques to restore medial canthal position.[52] Another consideration is the degree of comminution of the nasal root and dorsum, as cantilevered bone or cartilage grafts may be required to restore dorsal projection.

MAXILLARY (LE FORT) MANAGEMENT

Rene Le Fort described lines of weakness along the midface where fractures formed from high-energy impact[68,69] (Fig. 24-18). A Le Fort I fracture results from trauma to the lower midface and results in separation of the alveolar ridge and palate unit from the upper midface. Trauma to the upper midface can result in a Le Fort II fracture, which crosses from the nasal dorsum, frontal process of the maxilla, and lacrimal bones into the orbit and ultimately posteriorly through the pterygoid plates. A downward impact on the upper midface can result in craniofacial separation, or a Le Fort III fracture, where the fracture spans the nasofrontal suture, lacrimal and ethmoid bones, and orbital floor and then across the zygomaticofrontal suture, zygomatic arch, and pterygoid plates. A uniform finding in these fractures is involvement of the pterygoid plates in the fracture line.

For displaced or unstable Le Fort fractures, open reduction with internal fixation is required. Establishing occlusion with maxillomandibular fixation in patients with dentition is critical to restore function. Reduction of the midface can be performed with Rowe disimpaction forceps (Fig. 24-19). For Le Fort I fractures, miniplate fixation is performed along the medial and lateral buttresses via a gingivobuccal sulcus approach. For Le Fort II and III fractures, additional orbital (eg, transconjunctival, upper blepharoplasty) or even coronal approaches are required for access to the frontal process of maxilla, orbital rim, and frontozygomatic suture.

Mandible

The mandible can be divided into its subsites: symphysis and parasymphysis, body, angle and ramus, condylar

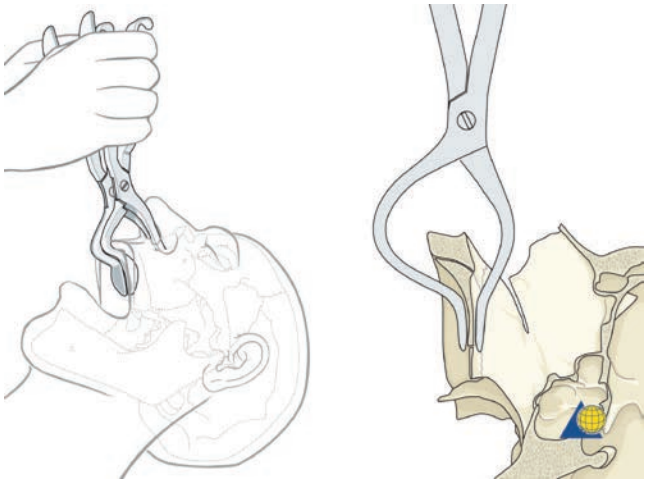

FIGURE 24-19 Use of Rowe disimpaction forceps in reduction of Le Fort fractures. (Reproduced with permission from AO Surgery Reference. www.aosurgery.org. Copyright by AO Foundation, Switzerland.)

process and head, and coronoid process. Fracture management for the mandible is dependent on the patient's dentition, fracture subsite, degree of comminution, and medical comorbidities. There are two major categories of fixation for mandible fractures: load-bearing and load-sharing. Load-bearing osteosynthesis involves fixation such that the plate construct bears 100% of the load placed at the fracture site.[70] This is accomplished with heavier reconstruction plates and bicortical screws. Load-sharing osteosynthesis denotes a construct where the plate and bone share the forces placed at the fracture site, requiring adequate bone stability to buttress to load. Load-bearing fixation is indicated for comminuted fractures, atrophic mandibles, and reconstruction of mandibular defects.[70]

Maxillomandibular fixation is performed if the patient has adequate dentition to restore occlusion. Once rigid fixation is achieved, maxillomandibular fixation can be removed prior to awakening the patient.

Mandibular body fractures can be approached through a transoral gingivobuccal sulcus approach or externally via a transcervical or Risdon incision. Internal fixation with a load-bearing inferior border plate (with or without miniplate tension band just below the tooth roots) is favored over two-miniplate internal fixation due to the higher risk of wound infections and hardware failure in the latter technique.[71]

Parasymphyseal and symphyseal fractures are treated similarly, with the preferred internal fixation approach for unstable and displaced fractures being a load-bearing inferior border plate with or without miniplate or arch bar tension band superiorly.[70] The key to reduction of fractures in this region is to avoid splay of the fracture along the lingual cortex. Lag screw techniques can be used in this region but are technically challenging.[72] These fractures can be exposed via a gingivobuccal sulcus incision, with care to preserve the mental nerve. Existing submental lacerations can be used, but care must be taken if extending these, as the marginal mandibular branch of the facial nerve lies in close proximity.

Angle fractures are the most common isolated mandible fracture. Repair can be challenging and is associated with a high complication rate.[73] Although nondisplaced and stable fractures can be observed with soft diet or short course of antibiotics, most fractures require open reduction, internal fixation due to displacement.[70] For simple fractures, multiple techniques have been described including open reduction, internal fixation with single miniplate along external oblique ridge (Champy technique), single miniplate along the lateral surface of the mandible, two miniplates, or geometric plates. Ellis[73] found that a single miniplate had fewer complications than two-miniplate techniques and that a lateral border miniplate had fewer complications than one placed on the external oblique ridge. Moreover, geometric box miniplates were associated with fewer postoperative complications than conventional miniplates. Comminuted fractures of the angle require load-bearing fixation.

The management of subcondylar fractures is perhaps the most controversial of the subtypes of the mandible. A variety of approaches are used and take into consideration the patient's dentition, age, and comorbid conditions precluding maxillomandibular fixation. In edentulous patients or in minimally displaced fractures with no malocclusion, soft diet and close observation can be performed. Closed treatment with a short course of maxillomandibular fixation with early mobilization was the mainstay of therapy for most fractures, with few absolute and relative indications for open reduction, internal fixation as described by Zide and Kent.[74] Since that time, there has been a paradigm shift toward open reduction, internal fixation, with increasing reports of improved outcomes, including pain, chin deviation, protrusion, and mobility.[75]

Panfacial Trauma

Panfacial fractures involve at least two of the three horizontal thirds of the facial skeleton: cranial vault, midface, and mandible. The principles of management remain the same for each individual fracture. However, panfacial fractures are more complex than a collection of independent fractures. The unique challenge to panfacial trauma is establishing the ideal sequence of repair. Although multiple sequencing strategies have been described, including "bottom-up," "top-down," "outside-in," and "inside-out,"[76,77] the general method of starting from stable areas and proceeding to less stable areas remains key.[78]

SUMMARY

The management of facial trauma requires a comprehensive patient and injury evaluation including careful physical examination and imaging. Careful attention to the extent and location of soft tissue injuries can optimize functional and aesthetic outcomes. Special care should be taken in critical areas such as the facial nerve, orbit, eyelid, parotid duct, nose, and lips. Skeletal deformities should be managed to restore premorbid form and function with care to protect the central nervous system, orbit, and critical adjacent soft tissues. Meticulous attention to scar placement and wound care postoperatively can minimize the aesthetic impacts of surgical repair. Long-term follow-up and postoperative imaging are often required to confirm correct skeletal repair and to watch for skeletal or soft tissue complications that would benefit from revision surgery. These patients are best managed by well-trained experts who are skilled in the nuances of the management of craniofacial soft tissue and skeletal injuries.

Neck and Larynx

Jason L. Sperry • Elizabeth Guardiani • Grace Snow • Kirsten Meenan • David V. Feliciano

KEY POINTS

- Penetrating wounds to the neck, particularly those that might involve cervical vascular structures, are grouped into three separate vertical zones with different operative exposures.
- In zone I, a vascular injury from a penetrating wound or blunt trauma may cause a mediastinal or extrapleural hematoma seen on a chest x-ray or computed tomography (CT) scan of the chest, external hemorrhage from the thoracic outlet, or intrapleural exsanguination.
- In zone II, a large lateral hematoma compressing or deviating the trachea mandates endotracheal intubation over a fiberoptic bronchoscope; failure of intubation mandates a cricothyroidotomy.
- In zone III, exsanguinating hemorrhage from the base of the skull after a penetrating wound mandates insertion of a Fogarty balloon catheter for rapid tamponade.
- When all patients with penetrating wounds through the platysma muscle in zone II of the neck are managed with a mandatory operative exploration, nearly 50% will have an unnecessary operation.
- Diagnostic options in patients with vascular "soft" signs after a penetrating wound of the neck are CT arteriography or duplex ultrasonography/color flow Doppler in the modern era.
- A fracture-dislocation of the cervical spine has a 30% or greater incidence of an associated blunt cerebrovascular injury.
- Thirty to 40% of patients with blunt injury to the carotid artery and 10% to 15% of those with blunt injury to the vertebral artery will suffer a stroke without treatment.
- Hyoid bone fractures are rare, and most can be managed conservatively.
- Mild laryngeal trauma can be managed with supportive care, whereas more severe trauma will require surgical intervention.
- Large laryngeal lacerations with exposed cartilage, disruption of the anterior commissure, cartilage fracture, injury to the recurrent laryngeal nerve, and cricotracheal separation are indications for operative repair.
- Laryngeal stents are used in the presence of significant mucosal injuries, injury to the anterior commissure, or when there are multiple cartilaginous fracture lines that cannot be adequately stabilized.

INTRODUCTION

One of the first reported cases of cervical trauma was in Homer's *Iliad* when Achilles delivered a fatal lance blow to Hector's neck, "where the clavicle marks the boundary between the neck and thorax." This was portrayed by Peter Paul Rubens in about 1631 and hangs in the Museum Boymans-van Beuningen in Rotterdam, the Netherlands.[1] Treatment was first described by Ambrose Pare in the mid-16th century when he ligated the right carotid artery and jugular vein of a soldier who had suffered a bayonet wound.[2] The patient survived, but was aphasic and developed a dense, left-sided hemiplegia.[3] The first successful treatment of a major cervical vascular injury did not occur until 1803 when Fleming, aboard the *HMS Tonnant*, ligated the common carotid artery of a sailor after a suicide attempt while at sea. The sailor made a prolonged but complete recovery.[4,5] A similar case was reported by Eves of Cheltenham, England, in 1849.[6]

ANATOMY (SEE ATLAS FIGURES 6 AND 7)

Knowledge of the surface landmarks of the neck is essential for optimal evaluation and management of cervical injuries.[7] The defining borders of the neck encompass the area between

the lower margin of the mandible and the superior nuchal line of the occipital bone and the suprasternal notch and the upper borders of the clavicles.

The first palpable structure from the upper to lower border of the neck is the symphysis menti, which is where the two halves of the body of the mandible unite in the midline. The submental triangle, located between the symphysis menti and the body of the hyoid bone, is bounded anteriorly by the midline of the neck. Laterally, it is bounded by the anterior belly of the digastric muscle, and the mylohyoid muscle forms the floor. The body of the hyoid bone lies opposite the third cervical vertebra. The area between the hyoid bone and the thyroid cartilage is the thyrohyoid membrane, while the notched upper border of the thyroid cartilage is at the level of the fourth cervical vertebra. The cricothyroid ligament or membrane occupies the space between the thyroid cartilage and the cricoid cartilage, which lies at the level of the sixth cervical vertebra and the junction of the pharynx with the esophagus. The interval between the cricoid cartilage and the first tracheal ring is filled by the cricotracheal ligament. Moving inferiorly, the isthmus of the thyroid gland is at the level of the second, third, and fourth tracheal rings. The suprasternal notch can be palpated between the clavicular heads and lies opposite the lower border of the body of the second thoracic vertebra. The sternocleidomastoid muscles, which divide the sides of the neck into anterior and posterior triangles, can be palpated from sternum and clavicle to the mastoid process. The borders of the posterior triangle are the body of the mandible, the sternocleidomastoid muscle anteriorly, and the border of the trapezius muscle posteriorly along with the clavicle inferiorly.

Posteriorly, the structures of the neck that can be palpated in the midline are the external occipital protuberance, the nuchal groove, and the spinous process of the seventh cervical vertebra (cervical spines 1–6 are covered by the ligamentum nuchae).

The platysma, a thin muscular sheet, is enclosed by the superficial fascia. Its origin is from the deep fascia that covers the upper part of the pectoralis major and deltoid muscles, and it inserts into the lower margin of the body of the mandible. It is the anatomic landmark that is often cited when determining whether a penetrating wound of the neck is superficial or deep. The potential for injury to a vital structure exists when this structure is penetrated.

Because it is the crossroads of the brain and corpus, the neck is dense in structure. Beneath the superficial sternocleidomastoid, strap, and trapezius muscles that envelop much of the neck, there are eight body systems that lie within or pass through the neck. Included among these are the following: (1) skeletal system (cervical vertebrae, hyoid bone); (2) nervous system (spinal cord and the facial [VII], glossopharyngeal [IX], vagus [X], spinal accessory [XI], and hypoglossal [XII] cranial nerves); (3) respiratory system (oropharynx, larynx, cervical trachea); (4) gastrointestinal system (oropharynx, cervical esophagus); (5) vascular system (common, internal, and external carotid arteries, vertebral arteries, internal and external jugular veins); (6) lymphatic system (thoracic duct); (7) endocrine system (thyroid and parathyroid glands); and (8) immune system (cervical extensions of the thymus).

ZONES

Penetrating wounds to the neck, particularly those that might involve cervical vascular structures, have been grouped into three separate zones since the original description by Monson et al[8] in 1969 (Fig. 25-1). A minor modification suggested by Roon and Christensen in 1979 is not of clinical significance.[9] Zone I is inferior to the clavicles and manubrium sterni and encompasses all structures in the thoracic outlet. Structures in this zone include the proximal common carotid arteries, vertebral arteries, right and left extrapleural subclavian arteries, jugulo-subclavian venous junctions, crossover left innominate vein, thoracic duct, trachea, esophagus, spinal cord, proximal brachial plexus, and the vagus nerve. Operative exposure for injuries in zone I mandates a median sternotomy with cervical extension, high anterolateral thoracotomy, or a supraclavicular incision with claviculotomy or partial excision of the clavicle, so strong clinical evidence of vascular or visceral injury must be present prior to operation. Zone II is between the thoracic outlet and the angle of the mandible. Structures in this zone include the common carotid arteries and bifurcations, vertebral arteries, internal jugular veins, larynx and cervical trachea, cervical esophagus, spinal cord, and the vagus, spinal accessory, and hypoglossal nerves. Operative exposure for injuries in zone II mandates an ipsilateral oblique incision along the anterior border of the sternocleidomastoid muscle or a high anterior cervical (collar) incision with oblique extensions for possible bilateral injuries. Zone III is between the angle of the mandible and the base of the skull. Structures in this zone include the internal carotid arteries, vertebral arteries, internal jugular veins, pharynx, spinal cord, and the facial, glossopharyngeal, vagus, spinal accessory, and hypoglossal nerves. Operative exposure for injuries in zone III mandates subluxation of the temporomandibular joint with interdental wiring or a vertical ramus mandibulotomy. Again, as exposure in this zone is difficult, strong clinical evidence of hemorrhage not responsive to catheter-based therapy should be present prior to operation.

PRESENTATION

Patients with penetrating or blunt trauma to the neck present with *overt* symptoms and/or signs, present with *modest* or *moderate* symptoms and/or signs, or are *asymptomatic* without signs of aerodigestive or vascular injury. The presentation of a patient with *overt* symptoms or signs will vary depending on the zone of the neck involved. In zone I, a vascular injury from a penetrating wound may cause a mediastinal or extrapleural hematoma on a chest x-ray or computed tomography (CT) scan of the chest, external hemorrhage from the thoracic outlet, or intrapleural exsanguination. A penetrating wound in zone II or blunt disruption of the cricotracheal junction secondary to a "clothesline" injury may lead to loss of the airway and early asphyxiation. Loss of the airway can occur secondary to the presence of a large hematoma from an injury to the carotid artery as well. Active hemorrhage from either the carotid artery or internal jugular vein in zone II can be external and lead to exsanguination or internal into an associated injury to the trachea, leading to aspiration and asphyxiation. Although injures in zone III are uncommon, exsanguination can occur from an injury to the internal carotid artery at the base of the skull.

Patients with *modest* or *moderate* symptoms or signs may present with complaints of hoarseness, dysphagia, or odynophagia and palpable crepitus suggestive of injury to the larynx, trachea, or esophagus. The other presentations in this group are proximity of penetrating wound or blunt contusion to the carotid sheath and/or a stable hematoma suggestive of injury to the carotid artery or internal jugular vein.

An *asymptomatic* patient will have penetration of the platysma muscle by a gunshot or knife wound or bruising or contusion after blunt trauma but have no symptoms or signs of injury to the aerodigestive tracts, cervical vessels, the spine, or the spinal cord.

Management of the patient depends on presentation. Overtly symptomatic patients have "A, B, or C" problems on the primary survey as taught in the American College of Surgeons' Advanced Trauma Life Support (ATLS) course, and immediate resuscitation is performed in the emergency center or operating room. Patients with modest or moderate symptoms or signs undergo a diagnostic evaluation referable to the suspected system injured or one that encompasses the aerodigestive and arterial systems. Asymptomatic patients can be admitted for observation, can undergo radiologic evaluation such as cervical and/or chest CT or CT arteriography (CTA), or can be discharged in some instances.

MANAGEMENT OF PATIENTS WITH OVERT SYMPTOMS OR SIGNS

Zone I and Inferior Zone II

In patients with exsanguinating external hemorrhage from the thoracic outlet or the lower anterior neck, usually from a penetrating wound, blind finger compression of the bleeding vessel through the skin defect is appropriate in the trauma bay (Fig. 25-2). Another trauma bay option is to insert a Foley balloon catheter and see if inflation of the balloon will temporarily tamponade the bleeding. If this is unsuccessful, rapid enlargement of the skin defect with or without local anesthesia is performed. Once again, an attempt is made to compress the bleeding vessel with two or three fingers inserted through the enlarged skin defect. An unsuccessful attempt is followed by tight packing of the area using 3- or 4-in gauze and rapid transport to the operating room. Of interest, a wound compression device has been tested and has been shown to control cervical hemorrhage in a perfused cadaver model.[10] The operative incision will depend on the track of the wound, whether or not manual compression or packing has controlled the bleeding, the patient's hemodynamic status, and the experience of the surgeon. For example, a wound thought to involve the proximal common carotid artery at the base of the neck rather than more proximally in the mediastinum is exposed with the standard anterior oblique incision on the side of injury. An unstable patient with continuing hemorrhage from the outlet or presumed intrapleural exsanguination should undergo a high anterolateral thoracotomy (third or fourth intercostal space above the male nipple) on the side of the injury to allow for direct proximal clamping or pack compression of the injured vessel in the thoracic outlet. If the wound is on the right side of the thoracic outlet and the patient is profoundly hypotensive, the high right anterolateral thoracotomy is performed, the sternum is divided transversely, and a standard (below the nipple) left anterolateral thoracotomy is performed, as well. This will allow for cross-clamping of the descending thoracic aorta to increase perfusion to the coronary and carotid arteries as resuscitation and vascular repair or ligation are accomplished on the right side.

Zone II

In zone II, a penetrating wound may cause impending asphyxiation from a major injury to the trachea, which is suggested by a continuing air leak from the entrance site. The skin defect is rapidly enlarged with or without local anesthesia, and a tracheostomy tube or an endotracheal tube is inserted through the enlarged track following the air bubbles into the distal end of the trachea once it is visualized. The aforementioned "clothesline" injury from blunt trauma may cause cricotracheal separation. Even with impending asphyxiation, there should only be one attempt at standard rapid sequence endotracheal intubation.[11,12] If this is unsuccessful, a rapid standard tracheostomy using a midline (vertical) incision to avoid unnecessary bleeding is performed between the second and third tracheal rings below the area of injury. Should there be bruising and palpable crepitus over the thyroid cartilage suggestive of an injury to the larynx itself, once again there should only be one attempt at standard endotracheal intubation. Failure to complete this is followed by a rapid tracheostomy much as with cricotracheal separation.

Loss of the airway in zone II may occur secondary to tracheal deviation or compression from a hematoma resulting from an injury to the carotid artery or internal jugular vein,

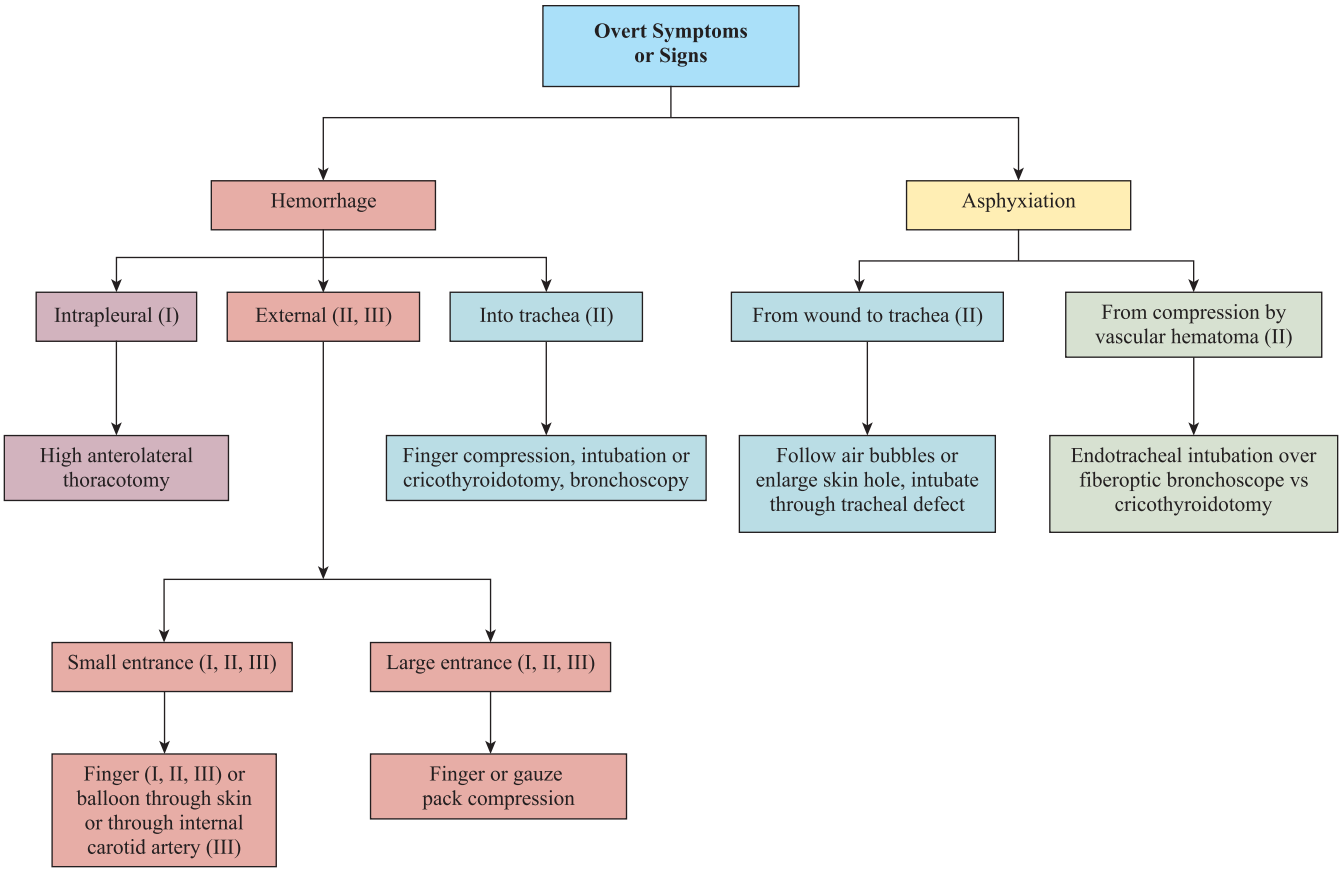

FIGURE 25-2 Algorithm for the management of patients with overt symptoms or signs.

also (Fig. 25-3). With impending asphyxiation, the patient is rapidly moved to the operating room for an attempt at endotracheal intubation over a fiberoptic bronchoscope. If this fails or if the patient is unable to move air when first seen, a cricothyroidotomy is performed rapidly because its high limited central incision (as compared to a standard tracheostomy) avoids the lateral hematoma from the vascular injury.

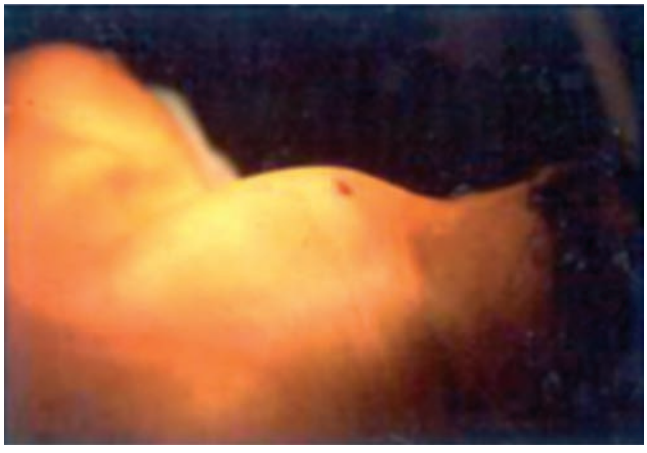

FIGURE 25-3 Significant zone II hematoma secondary to gunshot wound of carotid artery. (From Brown MF, Graham JM, Feliciano DV, et al. Carotid artery injuries. *Am J Surg*. 1982;144:748-753. Used with permission. Copyright © Elsevier.)

With external hemorrhage from a penetrating wound in zone II, direct compression with a finger or fist on the entrance site is performed in the emergency department or trauma bay and en route to the operating room. The decision on where to make the incision can be made in the operating room after endotracheal intubation has been performed.

On rare occasions, there may be internal hemorrhage into the airway when there are adjacent injuries to the carotid artery and trachea. If a single attempt at endotracheal intubation is successful, temporary but relatively tight inflation of the endotracheal balloon may prevent further aspiration of blood while exposure and repair of the artery are accomplished. If a single attempt at intubation is unsuccessful, compression is placed on the carotid artery at the entrance site or at the base of the neck, and a cricothyroidotomy is performed. Because aspiration will have occurred, fiberoptic bronchoscopy is performed once the injury to the carotid artery has been repaired. Tracheal repair should then follow.

Zone III

There are two options when exsanguinating hemorrhage occurs from a penetrating wound to the internal carotid artery at the base of the skull in zone III.[13] Finger compression is

often only partially successful in this location as the internal carotid artery is deep to the mandible. The quickest option is to maintain manual compression as the patient is moved rapidly to the operating room. Once the patient is intubated and the neck is draped, a #3 or #4 Fogarty balloon catheter is inserted into the wound and advanced 2 cm, and the balloon is inflated.[14,15] If hemorrhage continues, the balloon is deflated and advanced 1 cm at a time and inflated until balloon tamponade controls the hemorrhage. The catheter is then sutured to the skin, and endovascular control of hemorrhage can be sought. When external passage of the Fogarty balloon catheter is only partially successful or unsuccessful, a Foley balloon catheter is passed because it has a larger balloon. If this is unsuccessful as well, the catheter is removed and manual compression is applied once again. A standard oblique cervical incision on the anterior border of the sternocleidomastoid muscle is made, the internal carotid artery is exposed, and a small arteriotomy is made in the middle of a 6-0 polypropylene purse-string suture. Once again, a #3 or #4 Fogarty balloon catheter is passed through the arteriotomy and inflated sequentially until balloon tamponade is successful. On rare occasions, it may be necessary to pass balloon catheters through the entrance site and through the internal carotid artery simultaneously (Fig. 25-4).

In addition to operative techniques including balloon tamponade and temporary manual compression, endovascular/angiography techniques when hemodynamic stability allows can be beneficial. These typically can be performed at most Level I and II trauma centers in the operating room, in a hybrid operating room, or in an angiographic suite and can provide information on contralateral carotid flow and allow for ipsilateral proximal and distal control. This type of management assumes that endovascular expertise is readily available, and the patient is temporized, allowing possible transport if needed. Every attempt should be made to keep the patient normotensive with a 100% oxygen saturation level during the case. Intracranial pressure monitoring may be appropriate so that treatment can be initiated when ischemic edema occurs. If the contralateral CT carotid arteriogram documents inadequate crossover flow and a baseline electroencephalogram is abnormal, cerebral ischemia is occurring. This is expected in patients who have had a period of significant hypotension secondary to exsanguination prior to inflation of the balloon. In the past, it was recommended that a patient with ipsilateral cerebral ischemia undergo a saphenous vein bypass from the cervical internal carotid artery to the petrous portion through a small temporal craniotomy.[16] Currently, deflation of temporary occlusive balloon(s) and rapid insertion of an endovascular stent into the high internal carotid artery would be the procedure of choice.[17,18]

FIGURE 25-4 Patient with stab wound through left eardrum into left internal carotid artery behind left mandible. Hemorrhage was controlled by passing Foley balloon catheter through left ear and #3 Fogarty balloon catheter through the left internal carotid artery. (Reproduced with permission from Ball CG, Wyrzykoski AD, Nicholas JM, et al. A decade's experience with balloon catheter tamponade for the emergency control of hemorrhage. *J Trauma*. 2011;70:330.)

EVALUATION OF PATIENTS WITH MODEST OR MODERATE SYMPTOMS OR SIGNS OR ASYMPTOMATIC PATIENTS (FIG. 25-5)

Zone I

Hemodynamically stable patients with penetrating wounds in proximity to the thoracic outlet should undergo surgeon-performed ultrasound and a chest x-ray. The ultrasound (looking for hemopericardium) will rule out an associated cardiac injury and document the presence of a hemothorax or pneumothorax. The chest x-ray will aid in tracking the course of the missile and in documenting the presence of a hematoma in the superior mediastinum, base of the neck, or supraclavicular area. There have been several retrospective studies documenting that a normal physical examination and chest x-ray virtually exclude a vascular injury at the thoracic outlet.[19,20] Even so, certain trauma centers will use a screening CT as an added study to determine the track of a penetrating wound in this area.[21] When the track of a missile or knife wound is in proximity to vessels at the thoracic outlet and there is an adjacent hematoma on the chest x-ray, a CTA of the carotid, vertebral, and subclavian arteries is performed. This will document the presence and location of a vascular injury and allow for the choice of an appropriate operative incision or endovascular management plan depending on the hemodynamic status and the symptoms demonstrated by the patient. A CTA that is inadequate to make a diagnosis should be followed by a standard arteriogram with the potential for endovascular management/intervention.

There are symptoms (hoarseness, dysphagia, odynophagia), signs (palpable crepitus, continuing air leak through the wound), or findings on imaging (cervical or mediastinal air) that suggest a possible injury to the trachea or esophagus. The diagnostic workup is described in the following "Zone II" section and can then be followed by appropriate operative management if required.

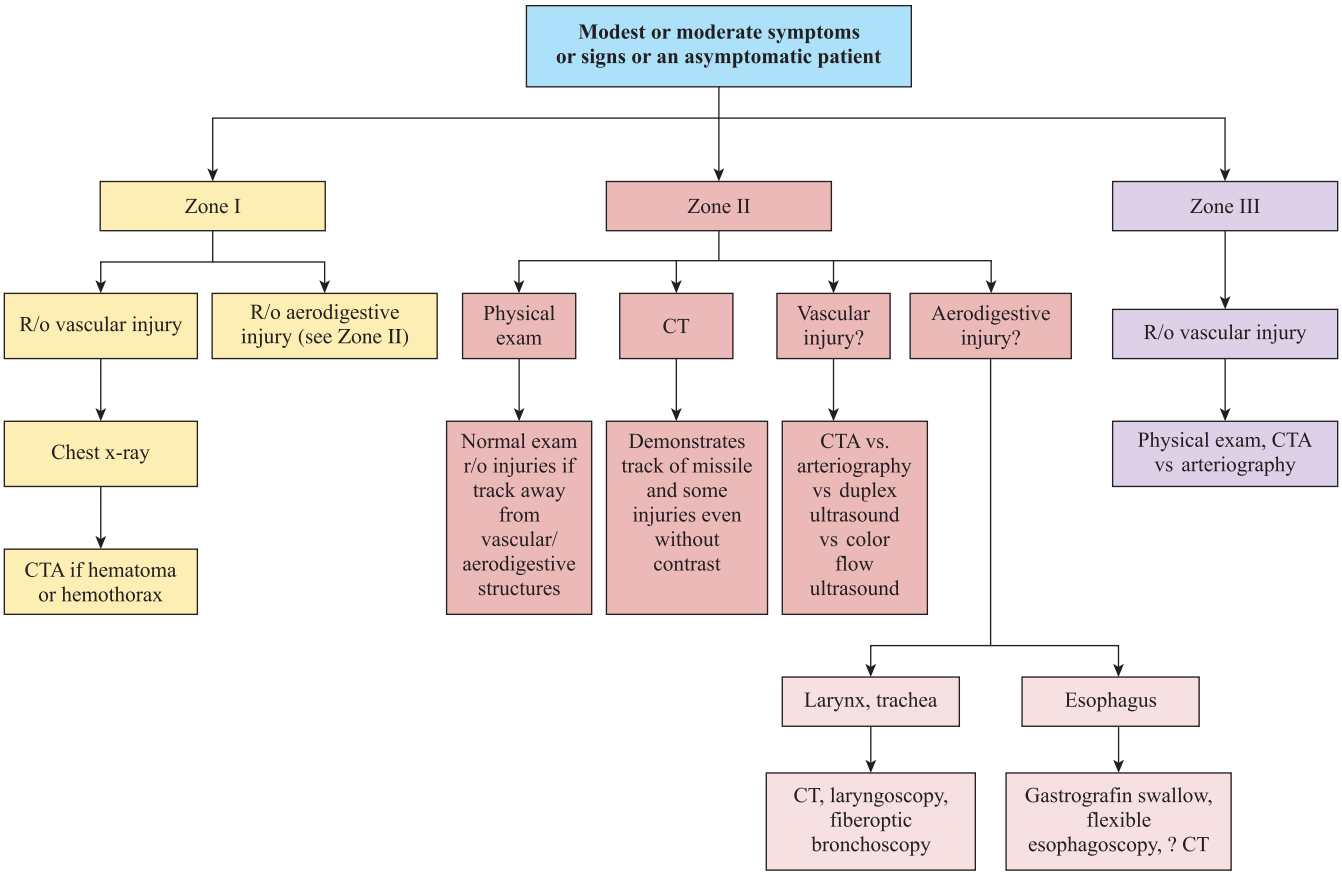

FIGURE 25-5 Algorithm for evaluation of patients with modest or moderate symptoms or signs or an asymptomatic patient. CT, computed tomography; CTA, computed tomography arteriography; r/o, rule out.

Zone II

The approach to possible injuries in this zone has varied considerably over the past 60 years. Based on the report by Fogelman and Stewart[22] at Parkland Memorial Hospital in 1956, mandatory exploration for wounds penetrating the platysma muscle was recommended. This historic recommendation was based on a mortality rate of 6% in patients undergoing early operation versus 35% in those undergoing delayed operation.

It quickly became obvious, however, that cervical explorations in all patients (overtly symptomatic, modestly or moderately symptomatic, or asymptomatic) with penetration of the platysma muscle in zone II resulted in a "negative" exploration rate of approximately 50%.[23] A more selective approach to operation based on symptoms and signs, as described earlier, was then adopted by many centers. One review article in 1991 comparing the two approaches noted that mandatory cervical exploration for platysma penetration had a mortality rate of 5.8% versus 3.7% for a selective approach.[24] Of interest, a negative or nontherapeutic cervical operation occurred in 46.2% of patients treated with mandatory exploration. When patients with modest or moderate symptoms or signs or those who are asymptomatic are managed with a selective approach, only 55% to 65% eventually come to operation. Numerous large studies subsequently verified the safety of a selective approach in the 1980s and 1990s.[25-35]

PHYSICAL EXAMINATION

Physical examination alone is highly accurate in evaluating an asymptomatic patient with a penetrating (through the platysma muscle) stab wound in zone II. This is true for patients with gunshot wounds in zone II as well, as long as the track is tangential or away from the major vessels (lateral) or aerodigestive tract (central).[35-37] With platysma penetration, but without further evaluation by CT, CTA, duplex ultrasonography, or endoscopy, serial examinations of the patient's neck every 6 to 8 hours for 24 to 36 hours are appropriate.

COMPUTED TOMOGRAPHY

Over the past two decades, the evaluation and management of penetrating neck injuries have significantly evolved. Practice has moved from mandatory neck exploration of zone II injuries and the high negative exploration rate toward expectant and selective operative management

with assessment based on increased utilization of CT imaging.[21,22,38-44] When patients have no "hard signs" of vascular injury in zone II, but are "at risk for injury to vital structures within the neck," CT can demonstrate a trajectory away from these structures.[21] With such a trajectory, "invasive studies can often be eliminated from the diagnostic algorithm."[20] Studies using multislice helical CT angiography in the past 15 years have documented a 100% sensitivity and 95.5% specificity in detecting all cervical vascular and aerodigestive injuries.[44,45]

ARTERIOGRAPHY, DUPLEX ULTRASONOGRAPHY, COLOR FLOW DOPPLER, AND CTA

Patients with "hard" signs of a vascular injury in zone II present with external bleeding, bleeding into the trachea or esophagus, an expanding or stable large hematoma, and/or an audible bruit/palpable thrill. Patients with bleeding or an expanding or large stable hematoma undergo an emergency cervical exploration. A patient with a likely arteriovenous fistula should have some type of vascular diagnostic study performed for localization. Should a fistula between the internal carotid artery and jugular vein be present, an endovascular stent rather than cervical exploration may be chosen.

In patients with "soft" signs (modest or moderate signs) of a vascular injury in zone II, such as a history of bleeding at the scene; proximity of a stab, missile, or pellet track; or a small nonexpanding hematoma, the role of arterial diagnostic studies remains controversial. As noted earlier, physical examination alone is highly accurate in ruling out an arterial injury in the asymptomatic patient. Much as in evaluating possible peripheral arterial injuries, however, there is at least a 3% to 5% chance of a surgically reparable arterial lesion in a patient who presents with a cervical vascular "soft sign." In addition, it is likely that a combination of "soft signs" (ie, proximity of wound and small hematoma) will increase the need for surgical intervention. Therefore, some type of diagnostic study is performed in patients with "soft signs" in the majority of centers (Fig. 25-6).

Four-vessel cerebral arteriography was the longtime gold standard of care for evaluating the carotid and vertebral arteries. The technique is highly accurate in diagnosing arterial injuries, eliminating nontherapeutic explorations, and allowing for transcatheter embolization when indicated.[46,47] The disadvantages include the time required to allow the interventional radiology team to return to the hospital at night, the dye load required, the potential for an iatrogenic pseudoaneurysm, and the low yield when all asymptomatic or modestly symptomatic patients are studied.[48]

Duplex ultrasonography, a combination of real-time brightness (B)–mode imaging and pulsed Doppler velocimetry, has been used in the diagnosis of atherosclerotic occlusive decrease of the carotid artery for 40 years.[49,50] Basically, the technology produces images that define anatomy and a spectral profile that documents flow through the vessel. Numerous reports during the 1990s documented the ease and accuracy of the technique when applied to patients with penetrating

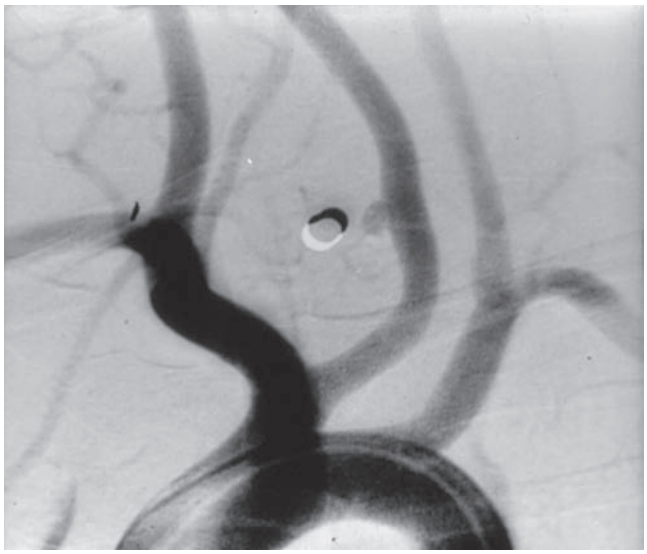

FIGURE 25-6 Pellet wound in an asymptomatic child caused 30% transection of left common carotid artery in zone II. Arteriogram performed secondary to traverse of missile through zone II.

wounds in zone II.[51-54] It was suggested that duplex replace conventional arteriography because of ease of performance and the significant cost savings that would result.[53-55] This did not happen over time in most trauma centers because the technique can be performed only by a registered vascular technologist or experienced vascular surgeon trained in duplex.

A related technique of color flow Doppler has also been used to evaluate the carotid arteries after penetrating trauma to zone II.[56,57] In this technique, flow to and from the point of the Doppler examination is represented on a color scale. Several studies in the 1990s documented that the combination of a careful physical examination and color flow Doppler was a safe alternative to routine contrast angiography.[56,57] It should be noted that Doppler imaging should not be used for the diagnosis of suspected vascular injuries in zone I or zone III or at their borders because imaging will be obscured beneath the clavicle or the angle of the mandible and may lead to a false-negative study.

For the past two decades, there have been ongoing studies to determine the accuracy of CTA, particularly in patients with possible blunt cerebrovascular injuries (BCVIs). Penetrating cervical injuries have been studied as well, with reports demonstrating high sensitivity and specificity.[44,58-62] Based on the ease and speed of obtaining accurate images reconstructed at 1-mm intervals, helical CT can replace conventional angiography in the initial screening setting in most cases.[53] CTA is able to significantly decrease the number of conventional arteriograms required and negative cervical explorations performed.[60-63] The early enthusiasm for using CTA was tempered by early concerns about its accuracy in evaluating possible BCVIs.[64] Subsequent prospective multicenter studies in evaluating patients with penetrating cervical wounds were reassuring.[44,45] Based on currently available data, it appears that multidetector helical CTA has replaced

conventional arteriography as a rapid and noninvasive screening modality to evaluate possible arterial injuries in all zones after *penetrating* trauma. An equivocal screening study or one in which the anatomic area of interest is obscured by scatter or artifact created by adjacent metallic fragments should still, however, be followed by a conventional arteriogram.

ESOPHAGOGRAM, ESOPHAGOSCOPY, AND CT

Patients with modest or moderate symptoms of an esophageal injury present with complaints of deep cervical pain, dysphagia, odynophagia, or hematemesis. On examination, palpable crepitus and deep cervical tenderness may be present. Imaging of the neck will usually demonstrate retropharyngeal or retroesophageal air in the soft tissues, whereas a pneumomediastinum will be present on a chest x-ray if there has been a delay in the patient's arrival to the trauma center.

Historically, the time-honored "sip test" was performed in such patients in centers with limited resources.[32] A patient who was able to swallow a mouthful of water without severe discomfort was felt to have at most only a small injury or no injury of the cervical esophagus and was admitted for observation. The patient who had severe pain with swallowing would then undergo standard diagnostic testing to evaluate for the presence of an esophageal injury.

Although CT has now been widely applied in the diagnostic evaluation of patients with penetrating and blunt cervical trauma as previously noted, its accuracy in detecting an injury of the cervical esophagus has not been studied extensively. This is because several of the reports in which CT has been evaluated do not include any patients with esophageal injuries.[38,44,45] For this reason, asymptomatic patients with air in the soft tissues of the neck after trauma, or a concerning trajectory or proximity, or a combination of modest/moderate symptoms and signs of an esophageal injury should undergo the standard diagnostic evaluation using a contrast esophagogram and endoscopy.[65-67]

Although there is a risk of secondary necrotizing pneumonitis and pulmonary edema if the contrast agent Gastrografin (meglumine sodium) is aspirated, it remains the initial contrast agent of choice for esophagograms in most centers.[66] The accuracy of detecting an injury to the cervical esophagus with this agent is 57% to 80%.[67-70] A "thin" barium study follows a negative Gastrografin swallow or has been used as the primary contrast agent in some centers.[66,67] There should be no concern for mediastinitis after contrast esophagogram because patients with positive esophagograms will go to surgery immediately for washout, drainage, and/or repair.

Because contrast esophagograms with either Gastrografin or thin barium have a less than 100% sensitivity in diagnosis, flexible esophagoscopy is next performed in the at-risk patient with a negative contrast study. It has long been known that the combination of a contrast study and esophagoscopy has an accuracy of nearly 100% in patients with esophageal injuries in zone II.[71,72] In two studies describing the results of flexible esophagoscopy specifically over 16 years, sensitivity was 98.5% to 100%, specificity was 96% to 100%, and accuracy was 97% to 99.3%.[73,74]

LARYNGOSCOPY, FIBEROPTIC BRONCHOSCOPY, AND CT

Patients with modest or moderate symptoms of an injury to the larynx or cervical trachea present with hoarseness, stridor, or hemoptysis.[75] On examination, contusions over the larynx or cervical trachea, palpable crepitus, deep cervical tenderness and bubbling, or an ongoing leak of air from a penetrating wound may be present. As with injuries of the cervical esophagus, paratracheal air or a pneumomediastinum will usually be present on cervical plain films, a chest x-ray, or CT imaging if performed.

In asymptomatic patients with air in the soft tissues of the neck or those with a combination of modest/moderate symptoms and signs of a tracheal injury, the traditional diagnostic evaluation includes laryngoscopy, fiberoptic tracheoscopy, and bronchoscopy. Laryngoscopy will diagnose and localize an injury to the supraglottic, glottic, or subglottic larynx[7,76] (see section on injuries to the larynx).

Fiberoptic tracheoscopy and bronchoscopy continue to be used to evaluate stable patients with suspected injuries to the trachea and major bronchi as well.[77-79]

Zone III

Historically, conventional arteriography was recommended for all stable patients with penetrating wounds in zone III.[80] Much as with mandatory diagnostic studies and/or operation in all patients with penetrating wounds of the neck, the approach to wounds in zone III is now more selective.[72,81] As with the other zones of the neck, patients with hard signs of an arterial injury in zone III have a greater than 90% chance of having a positive cervical exploration. Patients without hard signs, however, rarely have an arterial injury on CTA or conventional arteriography that will require surgical intervention.[81-84] Of course, CTA or arteriography will be of value in a select number of stable patients with hard signs not including bleeding or a combination of soft signs such as a history of bleeding, proximity of wound, and/or a nonexpanding hematoma in this location. When a limited arterial injury is diagnosed on one of these studies, observation or endovascular therapy would be appropriate.

EVALUATION AND TREATMENT OF PATIENTS WITH POSSIBLE BLUNT CEREBROVASCULAR INJURIES

Although BCVIs were first described in 1872, knowledge about pathophysiology, screening, diagnosis, and treatment has mainly accumulated over the past 35 years.[85-88]

The unique relationship of the carotid and vertebral arteries and the skull and cervical vertebrae is a causative factor for these injuries. The common carotid artery bifurcates into the internal and external carotid arteries at the level of the fourth cervical vertebra. The internal carotid artery passes upward and is then fixated in the carotid canal of the petrous portion of the temporal bone until it reaches the foramen lacerum.

Most blunt injuries occur in the internal carotid artery below this fixed area in the skull. In a similar fashion, the second portion of the vertebral artery passes through the transverse foramina (foramina transversaria) of the cervical vertebrae C2–C6 before curving behind the lateral mass of the atlas.

Blunt injury to the neck that results in an intimal tear in the carotid or vertebral artery may lead to stenosis, occlusion, pseudoaneurysm, or embolization. One would suspect that the circle of Willis would compensate for most lesions. However, because 80% of individuals have an anatomic variation (hypoplastic segments or missing components) leading functionally to an incomplete circle, there is less capacity for collateral flow around a lesion, leading to an increased incidence of stroke.[89]

The mechanism of blunt injury to the internal carotid artery can be a direct cervical blow, a basilar skull fracture involving the carotid canal, or a fracture of the petrous portion of the temporal bone. Most authors, however, feel that the most common mechanism is a cervical hyperflexion/hyperextension injury with stretching of the vessel over the bodies of cervical vertebrae C1–C3.[90] The hyperflexion/hyperextension injury is a presumed sequela of the use of shoulder harness restraints in the modern car. Prior to the use of these, many front-seat victims of head-on motor vehicle crashes sustained hyperextension injuries only on impact with the windshield. The hyperflexion/hyperextension injury to the internal carotid artery may be compounded by lateral rotation of the neck away from the side of the shoulder restraint.[90,91]

The mechanism of blunt injury to the vertebral artery may be a fracture of one of the foramina transversaria or a subluxation-type injury in the cervical spine with a locked facet, destroyed facet, or dislocation with instability. Depending on the cause, direct trauma to the vertebral artery (ie, a fracture) or distraction of the foramina with secondary stretching of the artery (ie, dislocated facet) will result.

Incidence and Screening

Most recent series place the incidence of BCVI at approximately 1% to 2% of all admissions for blunt trauma, which is a significant rise from earlier reports with incidences of 0.58% and 1.03%.[89,92] As such, there has been long-term interest in developing and analyzing screening criteria to increase the yield of diagnostic studies.[64,93-100] The group at Denver Health Medical Center/University of Colorado has described liberal screening criteria that include symptoms and signs of BCVI and associated injuries from a high-energy mechanism[93] (Table 25-1). The revised screening criteria added to their screening triggers include mandible fractures, complex skull fractures or cranial injuries, and upper thoracic injuries with traumatic brain injury. These additions have resulted in a significant increase in identification of BCVI at screening.[101,102]

When evaluating the yield of individual criteria, the Memphis group noted that the incidence of BCVI when only one criterion was present ranged from 6% to 17%.[64] When similar criteria were analyzed at the University of Cincinnati in 2009, the respective incidences of BCVI varied widely. For example, skull base fractures through or near the carotid canal had a BCVI incidence of 16.9%; midface fracture or fracture-dislocation of the cervical spine had an incidence of 38.8% and 30.7%, respectively; and Raeder or Horner syndrome had an incidence of 80%.[98] Of interest, a 1987 report based on an analysis of 1,398,310 patients with blunt trauma in the National Trauma Data Bank of the American College of Surgeons (BCVI incidence, 0.15%) noted that BCVI was "poorly predicted by modeling with other injuries."[100]

Imaging for Screening

With the availability of CTA over the past 20 years, there has been increasing enthusiasm for using this modality rather than digital subtraction cerebral arteriography to screen for BCVI. CTA screening has become significantly more common around the globe due to the extent of the screening literature and attention paid to this injury complex.[103,104]

There have been numerous studies suggesting that 16-slice and higher multidetector CTA is a very accurate modality when screening for BCVI. In one study by Berne et al[105] in which four-vessel cerebral arteriography was performed if a 16-slice CTA was positive or equivocal for BCVI, no patient with a negative CTA subsequently developed neurologic symptoms. Eastman et al[106] described 146 patients who had both a 16-slice CTA and cerebral arteriography and noted a 97.7% sensitivity, 100% specificity, and 99.3% accuracy for CTA. In the study by Biffl et al[107] in which 331 patients had a 16-slice CTA and abnormal studies were followed by a conventional arteriogram, no patient with a negative CTA developed a BCVI.

In the not too distant past, much as with the lack of consensus regarding screening criteria, there were numerous studies that questioned the accuracy of CTA in detecting BCVI.[108,109] In 2014, data from the University of Tennessee, Memphis, documented a 68% sensitivity using 64-channel CTA versus 51% sensitivity with older 32-slice scanners, and 62% of

the false-negative studies occurred in low-grade injuries that would likely remain clinically silent.[110] There remains significant variation in the reported sensitivity of CTA despite 64-channel technology, with some series missing up to 20% of carotid injuries.[111] In an attempt to increase the accuracy of diagnosis of BCVI, the Memphis group added CTA to the workup of any patient with potential head, neck, or facial injuries. By adding these injuries to their screening criteria, they were able to find a significant number of carotid and vertebral injuries that were missed by screening criteria alone.[112] When used to help screen patients with a history of blunt head, face, or cervical trauma, 64-slice or higher multidetector CTA has the sensitivity to detect clinically relevant BCVI and has supplanted conventional angiography as an accurate and noninvasive test in the majority of circumstances.

Only a limited number of patients with possible BCVI have been appropriately characterized and studied with magnetic resonance angiography.[113] The most recent literature would suggest that magnetic resonance angiography can "potentially accurately identify and evaluate BCVI."[114] Improvements in technology and vessel wall imaging, however, hold promise to supplement current MRI practices and improve diagnostic specificity for these injuries.[115]

Types of Injuries

Most centers use the grading scale for blunt carotid arterial injury developed at Denver Health Medical Center by Biffl et al[116] in 1999. This grading scale is described as follows: grade I, luminal irregularity or dissection with less than 25% narrowing; grade II, dissection or intraluminal hematoma with 25% or greater luminal narrowing, intraluminal thrombus, or raised intimal flap; grade III, pseudoaneurysm; grade IV, occlusion; and grade V, transection with free extravasation.

Management

As a group, 30% to 40% of patients with blunt injury to the carotid artery and 10% to 15% of those with blunt injury to the vertebral artery will suffer a stroke without treatment.[117-119] The anatomy of the circle of Willis may be an important factor in determining which patients do have a stroke.[120] In the current era of screening, evidence demonstrates that 37% of strokes attributable to BCVI will be apparent upon admission, with the majority of the remainder being diagnosed in the initial 72 hours and only a small percentage (11%) beyond 72 hours.[121] It is evident that, if detected, there is a therapeutic window for treatment with anticoagulation or antiplatelet agents in the majority of patients. Studies have shown that they are both safe and equivalent in asymptomatic patients with carotid or vertebral lesions.[122] The goals of anticoagulation and antiplatelet therapy are to prevent thrombosis, stop embolization, and prevent the propagation of a thrombus that has formed prior to the initiation of treatment.

Early heparinization with a continuous dosage of 10 U/kg/h to a target partial thromboplastin time of 40 to 50 seconds is appropriate for patients with BCVI grade III or IV injuries.[123,124] Antiplatelet therapy may be substituted when heparin is contraindicated.[122] Depending on the rate of hemorrhage, a grade V injury can be treated with insertion of an endovascular stent with insertion of extraluminal coils as needed or, on the rarest of occasions, surgery after subluxation of the temporomandibular joint with interdental wiring or vertical ramus osteotomy as previously noted.

Observation only without the administration of anticoagulants is appropriate temporarily in patients with a grade I to IV injury and an associated traumatic brain or solid organ injury, although the risk of an early stroke is significant with the grade IV injuries.[125] The timing of initiation of anticoagulant therapy in the described patient groups remains controversial at this time, but an early therapeutic window exists to reduce the risk of stroke.[126,127] Treatment should be based on the presence or absence of neurologic findings, the magnitude of the BCVI, and the magnitude of the associated injuries and associated risks of anticoagulation.

The early enthusiasm for endovascular stenting for primarily grade III injuries in the internal carotid artery[128-131] was tempered somewhat by the follow-up report from the Denver group in 2005 in which carotid stents had an occlusion rate of 45%.[132] Subsequent reports, however, have demonstrated a significant decrease in the occlusion rate.[133-137] This difference may be due to strict adherence to the use of antiplatelet agents during the time in which it takes endothelialization of the stent to occur. When endovascular and operative therapies were compared in 842 patients with blunt injuries of the carotid arteries in the National Trauma Data Bank, there was no functional or survival advantage for either group.[138] The development of a postinjury stroke and significant injury severity originally result in the worse outcomes after BCVI.[139]

OPERATIVE MANAGEMENT

General Principles, Incisions, and Emergency Control of Hemorrhage

Once an airway has been established using the emergency techniques previously described or with standard endotracheal intubation, a rolled sheet is placed transversely under the shoulders to hyperextend the neck. The patient is then placed in a sitting position to bring the operative field closer to the surgical team.

With a unilateral track of a penetrating wound or with any aerodigestive injury below the larynx in zone II, an ipsilateral oblique incision is made along the anterior border of the sternocleidomastoid muscle. The length depends on the location of the known or presumed injury, the likelihood of a significant vascular injury, and the experience of the surgeon. For example, a patient with a large unilateral hematoma in zone II overlying a presumed injury to the carotid artery or internal jugular vein should have an incision extending from the sternum inferiorly to the mastoid process superiorly. Such an extensive incision will allow for proximal and distal vascular control around the injury before entering the hematoma. In contrast, a patient without symptoms and signs of

a vascular injury despite a deep stab wound in zone II may be explored through a more limited oblique incision by an experienced surgeon.

When the track of a missile is through zone II bilaterally, a high anterior collar incision at the level of the track of the missile is appropriate. Depending on the patient's hemodynamic status, superior and inferior subplatysma flaps are raised, the midline raphe of the sternohyoid muscles is opened longitudinally, and the sternohyoid muscles are separated from the sternocleidomastoid muscles laterally. An injury on either side of the neck that is higher than expected can be exposed through an oblique extension of one side of the collar incision.

The appropriate incision for probable or documented injury in zone I will depend on the likely injury, the patient's hemodynamic status, and the experience of the surgeon (see Atlas Figures 15 and 16). A profoundly hypotensive patient with active intrapleural hemorrhage from an injury to a great vessel in the superior mediastinum or a subclavian vessel behind the clavicle should have an ipsilateral high (above the nipple) anterolateral thoracotomy. If the injury is on the right side, a trans-sternal extension and left anterolateral thoracotomy (below the nipple) is added to allow for cross-clamping of the descending thoracic aorta as part of resuscitation as previously noted. Vascular control is then obtained with pack compression or direct clamping. When the patient is modestly hypotensive (systolic blood pressure 90–120 mm Hg) and there is a hematoma in the superior mediastinum, a median sternotomy with a cervical or supraclavicular extension is appropriate. In the stable patient with a localized vascular injury on a CTA or conventional arteriogram, a median sternotomy or supraclavicular incision is chosen depending on which vessel is injured.

In the rare patient with hemorrhage from a penetrating wound to the internal carotid artery at the base of the skull in zone III, a balloon catheter is passed through the entrance site on the skin, as previously noted. Inadequate vascular control with the balloon inflated should prompt an ipsilateral oblique cervical incision to allow for exposure of the internal carotid artery and transarterial passage of a Fogarty balloon catheter for internal tamponade. This would then be followed by endovascular stenting, grafting, or angiographic embolization as appropriate.[140]

Injury to the Carotid Artery (See Atlas Figure 8)

Patients with "hard" signs of an arterial injury such as external hemorrhage from zone II, internal hemorrhage into the trachea or esophagus, or the presence of a pulsating/expanding hematoma in the anterior triangle of the neck should undergo immediate cervical exploration. In patients with loss of the carotid pulse but no neurologic deficit, many centers choose to perform a CTA to verify thrombosis of the internal carotid artery. Management of a documented thrombosis from a penetrating wound in the asymptomatic patient (observation vs revascularization) is controversial. The presence of a suspected carotid artery–internal jugular vein fistula, particularly in high zone II or in zone III, should prompt a CTA as well. Depending on local expertise, a documented arteriovenous fistula may be treated with an endovascular stent graft or an open repair.

As previously noted, patients with "soft" signs of an arterial injury still undergo a diagnostic workup in many centers. Included would be patients with a history of bleeding at the scene or in transit, a gunshot wound passing through zone II, a stable hematoma, or a neurologic deficit such as hoarseness from an injury to the vagus nerve proximal to the origin of the recurrent laryngeal nerve. Management will vary depending on the magnitude of any injury to the carotid artery documented on a CTA, conventional arteriogram, duplex ultrasonography, or color flow Doppler examination. In general, extravasation, the presence of an early, pulsatile pseudoaneurysm, significant disruption of the intima, or significant disruption of flow to the brain mandates ipsilateral cervical exploration and repair of the common or internal carotid artery.

PATIENT WITH AN ASSOCIATED NEUROLOGIC DEFICIT

A neurologic deficit in a patient with a penetrating wound to the common or internal carotid artery may be due to cerebral ischemia from the injury itself, hypotension from hemorrhage, acute alcoholic intoxication, or the use of illicit drugs. In patients with any neurologic deficit short of coma (Glasgow Coma Scale score <8), immediate repair of the carotid artery is indicated as the etiology of the deficit is unknown.[141-146] The often-quoted review article by Liekweg and Greenfield[147] in 1978 documented that a "favorable outcome" occurred in only 27% of patients undergoing carotid revascularization versus 25% undergoing ligation when "coma" was the presentation.

In the patient with a carotid thrombosis documented on CTA with a neurologic deficit and a significant (several hours) delay in diagnosis, repair should not be attempted due to the significant possibility of converting an ischemic to a hemorrhagic stroke.

EXPOSURE OF INJURIES IN ZONE III

When an endovascular repair is not appropriate for an injury to the internal carotid artery in zone III (ie, active hemorrhage, pseudoaneurysm has failed stenting with trans-stent coil, the internal carotid artery is very small), an operative approach is indicated. Exposure of the distal internal carotid artery at the base of the skull is obtained by a "stepladder" mandibulotomy,[148] subluxation of the temporomandibular joint with interdental wiring[149-151] or with monocortical screws and steel wiring,[152] or a vertical ramus osteotomy.[153]

REPAIR

In the absence of other significant injuries, systematic heparinization (100 U/kg) is used when any repair more complex

TABLE 25-2: Principles of Repair of the Carotid Artery

- Systemic heparinization (100 U/kg) if complex repair (resection with end-to-end anastomosis or interposition graft) or repair at base of skull will be necessary
- No intraluminal shunt unless inadequate back-bleeding or prolonged repair at base of skull will be necessary
- Interrupted 6-0 polypropylene suture repair in children or in internal carotid artery in all patients
- Flushing sequence after verifying back-bleeding is externally, and then into external carotid artery, and, finally, flow is reestablished into internal carotid artery

than lateral arteriorrhaphy is needed (Table 25-2). Repairs of the carotid artery are accomplished using standard techniques including the following: (1) minimal debridement and lateral arteriorrhaphy with interrupted 6-0 polypropylene sutures for a lateral defect; (2) patch angioplasty with saphenous vein, thin-walled polytetrafluoroethylene, or bovine pericardium for loss of one wall; (3) segmental resection and end-to-end anastomosis for through-and-through injuries or segmental disruption; and (4) segmental resection and insertion of a saphenous vein or polytetrafluoroethylene interposition graft[13,142-144] (see Atlas Figure 9). On rare occasions, an injury to the proximal internal carotid artery may be repaired by ligating and dividing the distal external carotid artery and using the proximal segment as a transposition graft (see Atlas Figure 10).

In a young patient with excellent back-bleeding from the internal carotid or common carotid artery after vascular control has been attained, an intraluminal shunt is *not* indicated as the repair is completed. With a rare distal injury in the internal carotid artery in upper zone II or in zone III, insertion of a graft may take longer than 30 minutes. In this situation, a temporary intraluminal shunt should be considered as the repair is completed.

Because cross-clamping of the common or internal carotid artery after a period of hypotension and during the period of repair may result in ipsilateral cerebral ischemia, postoperative care is critical.[154] The possibility of an ischemia–reperfusion injury with secondary ipsilateral cerebral edema mandates avoiding hypotension and hypoxemia as well as performing serial careful postoperative neurologic examinations.

Should the patient have no improvement of preoperative neurologic symptoms or develop neurologic deterioration in the early postoperative period, emergent CT of the brain is performed. Ipsilateral cerebral edema is treated with the insertion of an intracranial pressure monitor as well as standard drainage and medications such as hypertonic saline and/or mannitol.

In one older series, the survival rate for all 129 patients undergoing operation on an injured carotid artery was 75%. When patients failing resuscitation were excluded, the survival rate was 85%.[142]

Injury to the Vertebral Artery (See Atlas Figure 12)

An injury to the vertebral artery such as dissection from blunt trauma or intimal disruption, a pseudoaneurysm, arteriovenous fistula, or active hemorrhage tamponaded by packs or bone wax at operation is often diagnosed or confirmed on a CTA or other imaging study in the hemodynamically stable patient. Appropriate treatment is the placement of an endovascular stent for a pseudoaneurysm or intimal lesion and acute balloon occlusion, if needed, followed by coil embolization of an arteriovenous fistula or active hemorrhage.[155,156]

In patients undergoing a cervical exploration for hemorrhage or a suspected injury to the aerodigestive systems, active hemorrhage originating from the posterolateral neck adjacent to the spinal transverse processes is likely from an injured vertebral artery. Although detailed descriptions of operative approaches to the different levels of the vertebral artery are available, they are used infrequently in the modern era.[157-159] As proximal ligation of the ipsilateral vertebral artery originating from the second portion of the subclavian artery is unlikely to stop the hemorrhage, packing with bone wax or gauze is commonly used and is nearly always successful (see Atlas Figure 13). Many surgeons leave the bone wax in place, whereas the gauze pack will need to be removed at a reoperation. After packing, an ipsilateral vertebral CTA followed by proximal embolization is appropriate.

With occlusion of the vertebral artery by the trauma itself or by operative ligation or coil embolization, antegrade thrombosis is a risk in the postoperative/postprocedure period. For this reason, anticoagulation with heparin and/or antiplatelet therapy is appropriate before discharge. Whether long-term anticoagulation is necessary is still unclear at this time.

When unilateral vertebral artery ligation, packing, or coil occlusion is performed, a mortality rate of 5% to 15% is expected.[157,160] Deaths are invariably due to prehospital exsanguination or an associated traumatic brain injury.

Injury to the Internal Jugular Vein

Selective nonoperative management is now used in several centers around the world.[161,162] When an operation is necessary, lateral venorrhaphy is appropriate for wall defects, whereas more extensive injuries are treated with ligation. Because bilateral ligation of the internal jugular veins may result in pseudotumor cerebri, every effort should be made to repair one internal jugular vein when bilateral injuries are present.

Injury to the Esophagus

The simplest technique to expose the cervical esophagus is to dissect down to the cervical vertebral bodies and then lift the posterior wall of the esophagus off them by stripping with a finger (Table 25-3). Exposure of the anterior esophagus requires some care, as the recurrent laryngeal nerves are

TABLE 25-3: Principles of Repair of the Esophagus

- Either one- or two-layer repair with absorbable sutures is acceptable, preferably in a transverse direction.
- Loss of a portion of the wall in zone II and some patients with a delayed diagnosis of perforation should be treated with a loop esophagostomy over a rod rather than an acute tenuous repair that is likely to dehisce.
- Combined injuries with the trachea or carotid artery mandate a vascularized muscle buttress/separator such as the sternocleidomastoid muscle.

located in the tracheoesophageal groove at the lower cervical level. Once the esophagus has been dissected circumferentially, it can be looped with a finger or Penrose drain and carefully inspected by pulling it toward the operating surgeon. Any area of hematoma staining should be gently explored with a scissor to see if the mucosa underneath has been perforated. If the mucosa is intact, the esophageal muscle is reapproximated with several simple interrupted sutures of 3-0 absorbable material.

On occasion, it may be necessary to have the anesthesiologist help make the diagnosis of a small occult perforation in the cervical esophagus. One technique is to compress the distal esophagus at the thoracic inlet with a finger or noncrushing clamp and to fill the proximal esophagus with 30 to 50 mL of methylene blue dye in saline (one ampule in 200 mL). Full-thickness staining of dye at any location suggests that a perforation is present. Another technique is to place the tip of a nasogastric tube in the midcervical esophagus, compress the distal esophagus, and have the anesthesiologist inject 30 to 50 mL of air into the proximal esophagus through the nasogastric tube. By filling the operative field with saline solution, any air leak from an occult perforation would be seen as bubbling into the saline. On-table endoscopy can similarly provide air and result in bubbling at the site of injury.

With a limited injury from a stab or gunshot wound, minimal debridement is performed. A two-layer repair starts with a continuous 3-0 absorbable suture closure of the mucosa, preferably in a transverse direction. The repair is completed by placing interrupted 3-0 absorbable sutures through the muscularis layer of the esophagus. Because there is a 5% to 25% leak from repairs of the cervical esophagus historically, a small Penrose drain or closed suction drain is placed adjacent to the repair before closure of the incision.[163-166] This drain is brought anteriorly so as not to cause erosion of the carotid artery laterally.

When there has been a loss of tissue from one wall or the diagnosis of a perforated cervical esophagus has been delayed, a simple lateral suture repair or end-to-end anastomosis is not appropriate. A lateral loop esophagostomy at the site of the defect should be placed over a red Robinson catheter (much like a rod under a loop colostomy) located in the incision or lateral to it.[167,168] Whether a tie of absorbable suture material should be placed around the distal side of the elevated loop remains controversial.[168] Keeping the esophagus in continuity, even with a large defect, will preserve esophageal length and avoid the need for a colon interposition or free jejunal graft in the future. Conversion to a loop esophagostomy rather than performing a tenuous repair avoids the complication of a large esophagocutaneous fistula with secondary problems such as tracheoesophageal fistula, carotid artery blowout, or wound infection in the postoperative period. The esophagostomy has a tendency to shrink and to pull to the posterior midline over time, and delayed closure is often much easier than expected.

Although primary repair when feasible is preferred, newer options also include esophageal stenting. This can be performed safely as an adjunct to appropriate drainage when minimal contamination at the time of diagnosis exists or when primary repair would be less than adequate. The temporary stent reduces contamination and spillage from a documented esophageal injury and avoids complications from a "forced" or tenuous repair.[169-171]

Injury to the Trachea

Anterior or lateral perforations are not debrided and are closed with interrupted full-thickness 3-0 absorbable sutures to create an airtight seal (Table 25-4).[78,172] When there is tissue loss in the anterior or lateral trachea, a tracheostomy tube can be placed into the defect until a decision is reached on use of a vascularized muscle patch or formal reconstruction. Should the large defect be in the proximal trachea, the sternal head of the sternocleidomastoid muscle is detached, rotated medially, and sewn directly to the defect to create an airtight seal after removal of the tracheostomy tube. Resection of a large defect, mobilization of both ends of the trachea, and an end-to-end anastomosis can be performed electively but have never been performed at a first operation after trauma in the senior author's experience.

When there is a large defect in the membranous portion of the cervical trachea, a three-sided longitudinal anterior pericardial flap based superiorly is created after a median sternotomy is performed. The pericardial flap is then sewn to the defect in the membranous trachea to create an airtight seal.

TABLE 25-4: Principles of Repair of the Trachea

- No debridement is necessary.
- One-layer repair with absorbable suture if small or moderate-sized hole.
- When there is loss of a portion of the anterior or lateral wall, a tracheostomy tube is inserted into the defect. The sternocleidomastoid muscle is then detached inferiorly, mobilized, and sewn in an airtight fashion to the defect after the tracheostomy tube is removed.
- When there is loss of a portion of the membranous trachea, a three-sided rectangular longitudinal flap of pericardium based superiorly is sewn to the defect to create an airtight seal.

Late reconstruction of a previously injured trachea with a segmental partial loss of tissue is best performed by a thoracic surgeon with experience in tracheal resection and reconstruction. Dissection should be limited at the 3 and 9 o'clock areas of the trachea to avoid devascularizing the ends. Both laryngeal lowering and bilateral lung elevating procedures may be necessary with gaps in the trachea exceeding 5 to 6 cm.[173] Repair is accomplished with interrupted 3-0 absorbable sutures, no protective tracheostomy is performed, and a sternocleidomastoid muscle flap may be used to buttress the suture line.

Combined Injuries to the Trachea–Esophagus, Trachea–Carotid Artery, or Esophagus–Carotid Artery

A postoperative complication rate of 74% was reported in one older series of 23 combined tracheoesophageal injuries.[174] Analysis of the complications documented that the majority were due to leaks from the esophageal repair. This led to wound infections, tracheoesophageal fistulas, secondary pneumonias, and blowouts of adjacent repairs of the carotid artery. With adjacent repairs of the trachea and esophagus, trachea and carotid artery, or esophagus and carotid artery, a vascularized sternocleidomastoid muscle flap should be used to cover the visceral repair[175] (see Atlas Figure 11). This should lower the incidence of a leak from the visceral repair and, if a leak occurs, protect the adjacent arterial repair.

The sternocleidomastoid muscle has a tripartite blood supply that includes the thyrocervical trunk, superior thyroid artery, and occipital artery. Therefore, it can be detached from the sternum and clavicle inferiorly or the mastoid process superiorly and rotated to cover the repair of the trachea or esophagus and act as a vascularized buttress. With combined injuries of the trachea, esophagus, and/or carotid artery at the upper or mid-area of zone II, the first step is detaching the sternal head of the sternocleidomastoid muscle from the sternum if the muscle is bulky. If it is not, both the sternal and clavicular attachments are divided. Either the detached sternal end or the entire muscle is then mobilized and rotated medially to buttress the tracheal or esophageal repair and separate it from the repair in the carotid artery. The mobilized muscle is sewn in place with multiple interrupted sutures of 3-0 absorbable material. Any esophageal repair is drained anteriorly with the drain track away from the repair in the carotid artery.

SUMMARY OF TRAUMA TO THE NECK (NOT INCLUDING INJURIES TO THE HYOID BONE AND LARYNX)

Patients with penetrating or blunt injuries to the three zones of the neck present with overt symptoms or signs, present with modest and moderate symptoms or signs, or are asymptomatic without signs of aerodigestive or vascular injury. When overt symptoms and/or signs are present, standard "ABC" resuscitation as described in the ATLS manual is performed and early intervention should occur. With moderate or modest symptoms or signs, a variety of diagnostic tests including cervical CT, conventional arteriography, duplex ultrasonography, color flow Doppler, CTA, esophagography, and fiberoptic esophagoscopy, tracheoscopy, and bronchoscopy are used to determine whether an injury to the carotid artery system, vertebral arteries, esophagus, or trachea is present.

When a BCVI is diagnosed, heparinization or antiplatelet treatment for grade I to IV injuries and endovascular stenting, balloon occlusion, or operation for grade V injuries are indicated. Prior to repeat imaging (CTA) in patients with grade I to III injuries, aspirin and clopidogrel bisulfate are administered in anticipation of the need for an endovascular stent.

Basic principles and techniques of arterial repair are used when a penetrating injury to the carotid artery is present. Temporary intraluminal shunts are only indicated if distal backflow is poor or if a prolonged complex repair is anticipated in high zone II or in zone III. Penetrating unilateral vertebral artery injuries with hemorrhage are managed with packing, temporary balloon occlusion, proximal and distal ligation, or embolization.

Simple esophageal perforations are repaired with one or two layers of absorbable sutures. When there is a loss of esophageal tissue from one wall or a delay in diagnosis of an esophageal injury, a cervical loop esophagostomy is occasionally necessary.

Tracheal repairs for routine perforations are performed with one layer of absorbable sutures. A more significant anterior defect is managed with a tracheostomy at the first operation. When there is loss of the membranous trachea, a three-sided pericardial flap that is rotated superiorly will be necessary.

Diagnostic approaches and operative techniques have been refined significantly over the past 70 years, and this has resulted in a significant decrease in unnecessary operations and better outcomes after indicated operations.

INJURY TO THE HYOID BONE

The hyoid bone is a U-shaped bone in the anterior neck. Given its relative anatomic protection by the mandible anteriorly as well as its mobility in all directions, fractures of the hyoid bone are rare occurrences.[176] These typically occur as a result of blunt trauma to the anterior neck and are particularly associated with asphyxiation-type injuries, although motor vehicle accidents are the most common cause of hyoid fractures currently.[177,178] Hyoid fractures may occur in isolation, but often occur simultaneously with fractures to the midface and mandible, injuries to the cervical spine, and laryngotracheal injuries.[177,178] Because of its position relative to the pharynx, fracture of the hyoid bone can result in significant airway edema, which can be delayed in presentation. There may also be concurrent pharyngeal lacerations, which can result in bleeding and contribute to airway obstruction.[179]

Diagnosis

Patients may complain of anterior neck pain, dysphagia, dysphonia, painful coughing, gagging, and/or dyspnea.[178] In more severe cases, patients may present with hemoptysis and respiratory distress; however, patients may be also be asymptomatic initially, and there may be other more obvious injuries.[179] Physical examination may reveal swelling or ecchymoses of the anterior neck, crepitus, and tenderness of the anterior neck on palpation.[177] A fracture of the hyoid bone may be detected by plain x-ray; however, CT of the neck has largely become the diagnostic modality of choice due to its ability to provide better detail of the fracture as well as injury to any surrounding structures. Flexible laryngoscopy is also critical in the evaluation of patients with a suspected hyoid fracture to evaluate for the presence of airway edema and pharyngeal lacerations. In addition, the performance of a nasal Valsalva maneuver (asking the patient to forcibly exhale with mouth closed) during flexible laryngoscopy may reveal instability of the hyoid bone and detect fractures that are not recognized on CT.[180]

Management

Because of the rare nature of hyoid bone fractures, no definitive management algorithm exists. The majority of these injuries can be managed conservatively with steroids, rest, analgesics, and a soft diet.[177] Because delayed airway edema can occur, inpatient observation for a period of 24 to 72 hours is recommended.[176] In patients in whom there are significant pharyngeal lacerations or severe dysphagia, nasogastric or orogastric feeding should be considered. Tracheotomy is sometimes required in the case of severe airway edema. Surgical exploration may be considered in patients in whom there are extensive pharyngeal lacerations or bone fragments entering the pharynx or impinging on other critical structures. Open reduction and internal fixation (ORIF) of the hyoid bone appears to be of limited utility. In a systematic review of 41 patients with hyoid bone fractures that were conservatively managed, all reported resolution of symptoms.[177]

INJURY TO THE LARYNX

The larynx is protected by the sternum inferiorly, the mandible superiorly, and the sternocleidomastoid muscles laterally. It is also supported by numerous muscles and tendons, which can help disperse the forces of trauma. Its protected location makes external laryngeal trauma rare. In the 1990s, the incidence was reported to be between 1 in 5000 and 1 in 30,000 emergency department visits in the United States.[181-183] A recent study in Canadian centers reported an incidence of 1 in 2478 emergency presentations, suggesting that laryngeal trauma might be more prevalent than previously described.[184] Major blunt laryngeal trauma has declined in recent years due to improvements in motor vehicle safety, but the proportion of penetrating injuries has increased secondary to an increase in violent crimes.[185]

TABLE 25-5: Classification Scheme, Characteristics, and Management of Laryngeal Trauma

Group	Characteristics of injury	Management
Group 1	Minor endolaryngeal hematoma/laceration No fracture	Observe at least 24 hours, repeat flexible laryngoscopy Conservative management
Group 2	Edema, hematoma, minor mucosal disruption No exposed cartilage May have nondisplaced fracture on computed tomography	Direct laryngoscopy and esophagoscopy to rule out more severe injury Serial exams Conservative management May require intubation or tracheotomy
Group 3	Massive edema, large mucosal lacerations Exposed cartilage Displaced fractures Vocal cord immobility	Direct laryngoscopy and esophagoscopy Often require tracheostomy Generally require surgical repair
Group 4	Same as group 3 plus: • Massive mucosal damage • Disruption of anterior commissure • Two or more fracture lines	Direct laryngoscopy and esophagoscopy Tracheostomy Surgical repair with laryngeal stent
Group 5	Complete laryngotracheal separation	Awake tracheostomy or ventilating bronchoscopy to secure airway followed by tracheotomy Laryngotracheal reconstruction

The most common cause of blunt laryngeal trauma is motor vehicle collisions, during which the neck is hyperextended, leaving the larynx exposed to injury from the dashboard or steering wheel. Other causes include violence, strangulation, and sports injuries.[181] Penetrating laryngeal injuries are often secondary to gunshot or knife wounds and projectiles from machinery and motor vehicle collisions.

The most commonly used classification system for laryngeal trauma is the Schaefer-Fuhrman system (Table 25-5).[182,186] This system was first described for blunt laryngeal injuries but can be extrapolated for penetrating injuries.

Diagnosis

The mechanism, trajectory, and force of the injury can help predict the subsite of injury in the larynx, extent of injury, and involvement of the recurrent laryngeal nerve. A thorough physical examination the is key to diagnosing laryngeal trauma. The signs and symptoms of laryngeal injury after blunt trauma to the neck may be minimal and overlooked.

The skin and muscle may be unharmed, and symptoms may progress over hours as edema, hematoma, or instability of the larynx evolves.[186] The most common symptoms are dysphonia and respiratory distress as well as neck pain, dysphagia, odynophagia, and hemoptysis.[181,185-187] Signs of laryngeal trauma include subcutaneous emphysema, ecchymoses or edema of the anterior neck, stridor, tenderness, and inability to tolerate supine positioning.[185,188,189] Patients may also present with cardiopulmonary arrest, shock/hemorrhage, and neurologic deficits, particularly after penetrating trauma.[189]

The most critical part of the initial examination is recognizing and treating an impending airway obstruction. If the patient has a stable airway, nasolaryngoscopy should be performed to assess patency of the airway, mobility of the vocal folds, and mucosal injuries. A topical anesthetic should be avoided to prevent aspiration.[186] Some authors advocate for obtaining a CT scan in all patients with laryngeal trauma after they are stabilized.[183,190,191] Others recommend not performing a CT scan if the injuries are very mild or if they are severe enough that the patient will undergo neck exploration regardless of imaging.[192-194] In intermediate cases, CT can help determine if there are displaced fractures that would benefit from repair (Fig. 25-7). In patients with type 2 to 5 laryngeal injuries, direct laryngoscopy should be performed to assess the degree of injury provided there is no injury to the cervical spine that would preclude safely extending the neck. Bronchoscopy and esophagoscopy can be performed at the same setting to evaluate for any tracheal or esophageal injury. If there is concern for a concomitant esophageal injury that cannot be assessed by esophagoscopy, an esophagogram should be obtained.[181]

Management

Maintaining a safe airway is the primary goal in the management of laryngeal trauma. Tracheostomy is the preferred method for securing the airway. Unless laryngotracheal separation has been ruled out, orotracheal intubation and cricothyrotomy should be avoided. Awake fiberoptic intubation may be a safe option in select patients when a physician experienced in this technique is available. Ideally, the airway should be evaluated by fiberoptic laryngoscopy prior to intubation to ensure that fiberoptic intubation is feasible.[183,185] A smaller endotracheal tube with a high-volume, low-pressure cuff should be used.[181] If a cricothyrotomy is performed, it should then be converted to a tracheostomy in the operating room.[185] Secondary goals of management include preservation of voice and avoidance of a long-term tracheostomy. Depending on the severity of injury, laryngeal trauma can be managed medically or surgically.[195]

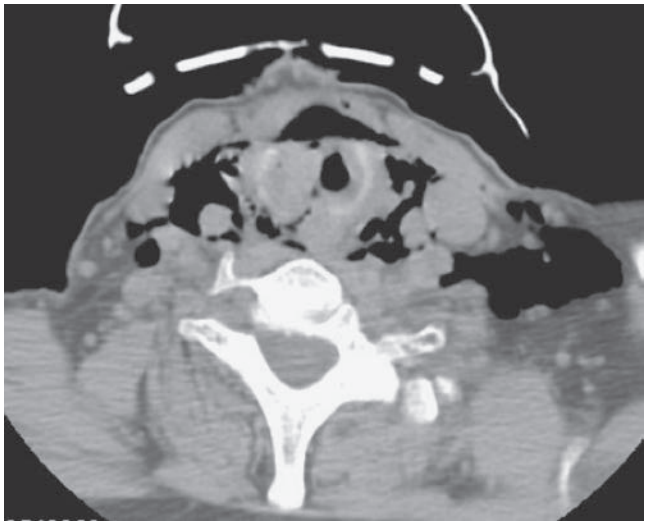

FIGURE 25-7 Computed tomography of the neck revealing a severely displaced fracture of the cricoid cartilage and extensive subcutaneous air.

MEDICAL TREATMENT

Patients in group 1 and many patients in group 2 (Table 25-5) who have injuries consisting of edema, small hematomas, minor mucosal lacerations without exposed cartilage, or a single nondisplaced fracture of the thyroid cartilage are likely to recover without surgical intervention. Patients should be observed with continuous pulse oximetry for at least 24 hours and should undergo repeat flexible laryngoscopy in order to assess for worsening of edema.[185] Supportive care measures should be employed (Table 25-6).

SURGICAL TREATMENT

Patients in groups 3, 4, and 5 typically require surgical intervention. Specific indications for surgery include large mucosal lacerations, lacerations involving the vibratory edge of the vocal fold, exposed cartilage, multiple or displaced cartilage fractures, avulsed or dislocated arytenoids, and transection of the recurrent laryngeal nerve. In general, any patient undergoing surgical management should have a tracheostomy placed at the same setting if not already performed. Fig. 25-8 illustrates the standard management algorithm for laryngeal trauma.

ARYTENOID DISLOCATION

The arytenoids are two small paired laryngeal cartilages that articulate with the cricoid cartilage and are attached to the vocal cords. Arytenoid dislocation is a rare finding associated with blunt laryngeal trauma and can be differentiated from vocal fold paralysis with a CT scan or with laryngeal

Laryngeal trauma. In: Johnson J, Rosen CA, eds. *Bailey's Head and Neck Surgery: Otolaryngology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2014:1144.)

electromyography (EMG). A CT scan will show obliteration of the cricoarytenoid joint, whereas a laryngeal EMG typically shows normal recruitment in arytenoid dislocation but signs of denervation when paralysis of a vocal cord is present.[196]

Arytenoid dislocation is treated by performing endoscopic reduction to restore the proper height of the vocal process. To reduce an anterior dislocation, an anterior commissure laryngoscope is placed against the anterior surface of the arytenoid and is rotated in a posterior-lateral direction while applying external counterpressure to the larynx. To reduce a posterior dislocation, a Miller laryngoscope blade is placed against the posterior surface of the arytenoid and cephalic pressure is applied, followed by anteromedial rotation.[197]

MUCOSAL TEARS OR EXPOSED CARTILAGE

Endolaryngeal mucosal tears or exposed cartilage can be addressed using a median thyrotomy approach. A horizontal incision is made in a skin crease at the level of the cricothyroid membrane. Subplatysmal flaps are raised superiorly to the level of the hyoid and inferiorly to the cricoid. The strap muscles are separated in the midline and retracted laterally. The cricothyroid membrane is incised horizontally. The larynx is then entered by making a vertical incision through the thyroid cartilage extending superiorly through the anterior commissure under direct visualization of the true vocal folds. If a median or paramedian vertical thyroid cartilage fracture is present within 3 mm of the anterior commissure, it can be used to gain access to the larynx. The endolarynx is examined thoroughly, and mucosal lacerations are repaired with 5-0 or 6-0 absorbable suture. Exposed cartilage should be covered primarily or with local mucosal advancement flaps. If the anterior commissure is disrupted, the anterior margin of the true vocal cord should be sutured to the external perichondrium of the thyroid cartilage to resuspend it.[198] After repair of endolaryngeal injuries, ORIF is performed of the median thyrotomy incision through the thyroid cartilage.

FRACTURE OF THE THYROID OR CRICOID CARTILAGE

Except for a single nondisplaced fracture, all thyroid or cricoid cartilage fractures should be repaired by ORIF. If there is associated injury to endolaryngeal soft tissue, the cartilage

fractures should be repaired first to provide a stable framework for the soft tissue repair. If there is no associated injury to endolaryngeal soft tissue, the cartilage fractures can be repaired without entering the larynx.

Wire, nonabsorbable suture, resorbable miniplates, or permanent miniplates can be used. Miniplate fixation is preferred because it is more likely to result in cartilaginous union rather than fibrous union and maintains better anatomic reduction of the fractures.[187,199] Resorbable plates are made of polylactic acid copolymer and absorb within 1 to 2 years.[200] If there is loss of cartilage in the anterior cricoid ring, the infrahyoid strap muscles can be sutured into the defect to help maintain patency of the airway.

LARYNGEAL STENTING

Laryngeal stents are indicated in the setting of extensive mucosal injury and lacerations involving the anterior commissure in order to prevent web formation and laryngeal stenosis. They are also indicated in the setting of multiple cartilaginous fractures that cannot be stabilized by ORIF such as in a gunshot wound to the larynx. If a laryngeal stent is placed, a tracheostomy must also be performed as the stent will obstruct the airway at the level of the larynx. It is also critical that the stent is secured such that it cannot migrate. Montgomery and Eliachar stents are two commercially available laryngeal stents that are commonly used in the setting of laryngeal trauma.[201] If preformed stents are not available, a stent can be fashioned from an endotracheal tube, or a finger can be cut from a surgical glove and filled with soft material such as Gelfoam. Stents are left in place for approximately 2 weeks and are then removed endoscopically. If left in place for a prolonged period of time, they can promote the formation of granulation tissue.

INJURY TO THE RECURRENT LARYNGEAL NERVE

Vocal cord immobility in the setting of laryngeal trauma may indicate injury to the recurrent laryngeal nerve. If this occurs as a result of blunt trauma, these injuries can typically be observed because it is unlikely that the nerve has been transected and spontaneous recovery may occur. In the case of penetrating trauma, the neck should be explored, and if the recurrent laryngeal nerve is found to be severed, it should be repaired primarily. The recurrent laryngeal nerve contains fibers that adduct and abduct the vocal cord, so normal mobility of the vocal cord will not be restored if the recurrent laryngeal nerve is repaired; however, bulk and tone of the vocal cord can be preserved. This can improve voice and swallowing.[202] If primary reanastomosis of the recurrent laryngeal nerve is not possible, the ansa hypoglossi, which innervates the infrahyoid strap muscles, can be redirected and sutured to the distal stump of the recurrent laryngeal nerve.

LARYNGOTRACHEAL SEPARATION

Laryngotracheal separation is the most severe form of laryngeal trauma (Table 25-5). Patients typically present with airway obstruction but may be less symptomatic than expected if fascial tissue anterior to the airway remains intact. The trachea will retract inferiorly, so a low tracheotomy should be performed. If the cricoid is intact, nonabsorbable suture should be placed from the superior aspect of the cricoid to the inferior aspect of the second tracheal ring, tying the knots extraluminally. If this is not possible due to the extent of injury, then thyrotracheal anastomosis can be performed.

Endovascular Commentary to Chapter 25: Neck and Larynx

Joseph J. DuBose

In this edition, Dr. Sperry and colleagues have constructed an excellent treatise on the optimal evaluation and management of injuries to the neck. In review of their work, I am struck by the emerging importance of imaging and therapeutic technologies and their evolving role in optimal care of these injuries.

As an example, while a comprehensive understanding of the neck zones remains integral to decision making in the unstable or overtly injured patient, the value of computed tomographic (CT) imaging has evolved as an increasingly valuable element of evaluation for stable patients. In the not so distant past, the zone of injury of the neck dictated the initial operative approach along with the consideration of possible extension to the other incisions. For the stable patient, however, CT and other imaging adjuncts now provide the surgeon an opportunity to more precisely guide an operative plan, a particularly valuable resource at the extremes of zones I and III, where operative intervention may require extension into the chest or advanced skull-based exposures.

The authors also outline briefly the limited data available on the utilization of endovascular adjuncts in the care of vascular injuries to the neck. Endovascular skill sets afford additional options for diagnosis, proximal control of injury with intraluminal balloons to mitigate blood loss during subsequent operative exposure, and even definitive management options. These capabilities are emerging quickly, particularly as many trauma centers incorporate endovascular practitioners and hybrid operating rooms into their trauma teams.

Among stable patients without overt signs of injury, the selection for and timing of potential endovascular therapy remain areas of needed investigation. As the authors outline, data from Denver Health Medical Center and others have blunted the initial enthusiasm for early, aggressive coverage of blunt cerebrovascular injuries (BCVIs) with endovascular stent grafts. Although traumatic pathologies are very different from those of atherosclerotic disease, the concern for higher stroke rates with endovascular versus open treatment is a concern in the wake of multicenter studies.[1]

Other endovascular adjuncts, however, would seem to represent valuable options for use. In my opinion, the hybrid pairing of endovascular capabilities with open surgical management has significant potential application for vascular injuries to the neck. I envision that there will come a time when endovascular adjuncts will more effectively supplement optimal management in ways that are just now being better appreciated. For stable patients, it would make sense that proximal balloon occlusion used for hemorrhage control should serve as a natural fit in this fashion. If successful, descriptions of Foley catheters through wounds and balloon catheters placed into vessels through open incisions that are welling with blood may become relics of the pre-endovascular era.

In particular, it is intriguing to observe the changes in management with regard to BCVIs. In my practice, most blunt injuries can be observed and treated with anticoagulation/antiplatelet therapy and medical management. Repeat imaging is then obtained at 24 to 48 hours. For BCVI injuries that improve, antiplatelet therapy is continued, and additional imaging is obtained at 1 week and monthly thereafter. During long-term follow-up, the risks and benefits of antiplatelet and anticoagulation therapy must be weighed against the potential risk of stroke that might occur without treatment. If the injury heals, medical therapy can be discontinued.

Recognizing that these data are not well established, I advise transitioning to a simple 81-mg aspirin daily after the first month for a grade I or II BCVI that does not progress, recognizing that the greatest risk of cerebrovascular accident from these injuries is likely early in the postinjury course.

For grade III BCVI/pseudoaneurysm, initial medical management is almost universally appropriate, but careful attention must be paid to the 24-/48-hour and 1-week interval imaging. If progression or increase in size occurs at this interval or in a more delayed fashion, coverage of the region with an endovascular stent graft is warranted. It must be appreciated, however, that the placement of these stents represents an inherent thromboembolic risk that requires lifelong antiplatelet therapy (often dual therapy in this regard) possibly paired with anticoagulation. The optimal regimen is not well established, because long-term data are not available. The issue is further confused by the availability of more oral anticoagulation agents with little to no data supporting their optimal use universally. Regardless of the pharmacologic agents employed, repeat imaging for these patients should probably be employed at 1-, 3-, and 6-month intervals initially. Thereafter, 6-month or annual imaging or clinical exam is advisable.

Grade IV BCVI injuries (occlusion) represent a clinical challenge and are most commonly observed. The role of antiplatelet or anticoagulation therapy for asymptomatic patients is unclear, while the potential benefit is thought to be the mitigation of propagation of clot proximal and distal to the occlusion. I do not routinely use any medical therapy for asymptomatic occlusions but do conduct 1-week and 1-month follow-ups to look for evidence of propagation of clot.

Grade V BCVI transections, particularly those that cannot be easily repaired with open intervention, are amenable to embolization for proximal control of ongoing hemorrhage. For distal injuries, such as those at high carotid or vertebral locations, sound principles often involve both proximal and distal embolization if the region cannot be covered by a stent graft to restore in-line flow. When required, distal embolization is a technically demanding procedure requiring traverse of the circle of Willis and specialized catheter/device capabilities most commonly found in the skill sets of neuro-interventional providers—a key partner in these situations.

High carotid–jugular fistulas, although uncommon, represent another unique endovascular challenge. As with other high injuries, a specific subset of skills and devices inherent to neuro-interventional training (and much less commonly to vascular surgeons) is typically required. Although some of these fistulas can be observed and followed with repeat imaging, many require treatment. Stent graft coverage of the arterial segment, if it can be achieved, is typically curative. As an alternative, if embolization does not compromise the distribution of blood flow through the circle of Willis, this approach is well tolerated.

The lack of long-term data and study in this particular area of trauma remains a dilemma. Data are sorely needed to define optimal utilization of endovascular capabilities (or any treatment modality for that matter) and study the natural history of specific lesions, particularly focal dissections of traumatic origin or small pseudoaneurysms. It is this author's hope that ongoing efforts to study vascular injury in a longitudinal way, including through the American Association for the Surgery of Trauma's PROspective Observational Vascular Injury Treatment (PROOVIT) registry,[2,3] will provide some useful answers in this regard.

The authors are to be congratulated on an excellent contribution. As one would expect from their cumulative reputations and known experience, this chapter is certainly a "must read" for any surgical provider who might be called upon to care for trauma victims with injuries to this body region.

Spinal Cord and Spine

Philip F. Stahel • Benjamin C. Dorenkamp • Michael E. Janssen

KEY POINTS

- The presence of an unstable spinal injury is presumed in all trauma patients until proven otherwise.
- Complete and thorough spinal evaluation and neurologic examination are mandatory in all critically injured patients.
- Strict log-roll precautions and cervical rigid-collar immobilization should be continued until unstable injuries are ruled out or identified and managed by early proactive surgical treatment protocols.
- Computed tomography is the standard initial diagnostic trauma workup in patients requiring imaging. Magnetic resonance imaging is indicated on a case-by-case basis after formal spine surgery consultation.
- An accurate classification of spine injuries using validated classification systems facilitates surgical decision making and serves as a basis to guide treatment.
- Early mobilization of critically injured patients with spinal injuries is essential. This requires either spinal clearance or spinal stabilization by surgical means.
- Spinal clearance should be provided within 24 hours of admission to minimize the risk of preventable immobilization-related complications.
- A standardized *spine damage control* protocol allows stabilization of unstable thoracic and lumbar spine fractures within 24 hours and subsequent mobilization of patients without restrictions.
- Unstable cervical spine injuries benefit from halo-vest application or Gardner-Wells tong traction until definitive surgical fixation is performed.
- The use of steroids is considered obsolete in the management of acute traumatic spinal cord injury.

INTRODUCTION

The scope of this chapter is to provide the trauma surgeon a pragmatic approach on how to coordinate the care of the multiply injured patient who presents with associated spinal injuries. The chapter focuses on current strategies for initial assessment and management of spinal injuries relevant to trauma surgeons with respect to the decision making for the integrated care of the critically injured patient. Pertinent issues include the conundrum of how to recognize an unstable spine injury, when and how to clear the cervical spine, the role of steroids in the management of spinal cord injury, the optimal timing of tracheostomy in spinal cord–injured patients, and the coordination of care for associated spine injuries in the multiply injured patient. Understanding these critical aspects related to the care of spinal injuries will allow optimization of the coordination of care for these highly vulnerable patients at risk of sustaining delayed "second-hit" insults and adverse outcomes.

INITIAL ASSESSMENT AND DIAGNOSTIC WORKUP

The presence of an associated spinal injury must be assumed in any multiply injured patient until proven otherwise.[1] Of note, approximately 10% to 15% of all trauma patients with severe head injuries have an associated cervical spine injury.[2] It is important to understand that most spine injuries do not present with a neurologic impairment. Pain or tenderness anywhere along the spine, from the occiput to the sacrum, should raise the concern for a spinal injury. The key imperative in the acute management of a trauma patient with a suspected spine injury consists of application of a cervical collar, exact documentation and timing of the findings, and immediate evacuation to a designated trauma center.[3] A cervical collar must be applied in all trauma patients until cervical spine injuries are either confirmed as absent (see spinal clearance protocols provided later) or identified and treated appropriately. The unstable spine is at risk for injury from

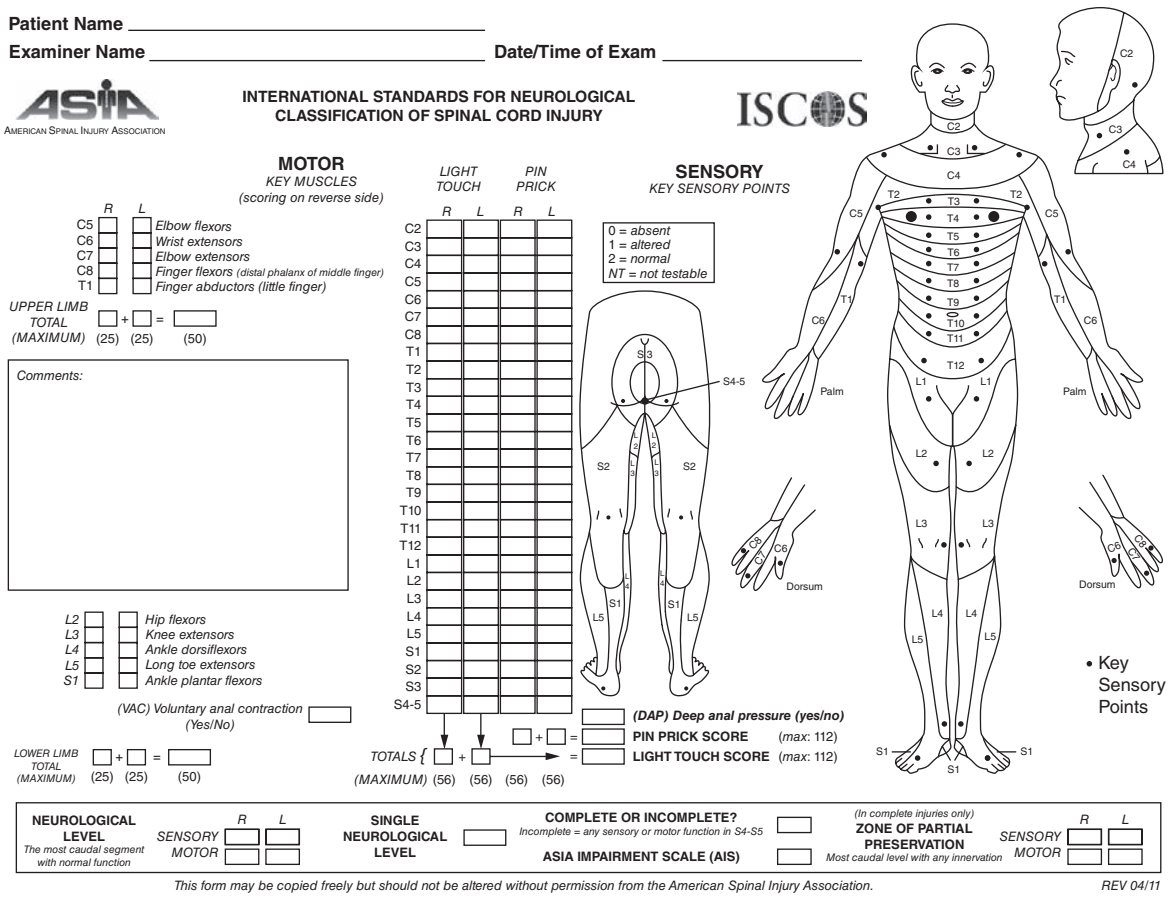
careless manipulation. Therefore, strict log-roll precautions should be maintained until spinal injuries are excluded or spinal stability is restored.[4] If a long spine board has been applied for transport, this must be removed on arrival in the emergency department in order to avoid pressure sores from prolonged immobilization.[3] The entire posterior spine should be inspected and palpated for local tenderness and deformities while adhering to log-roll precautions. This requires a team of four to five health care personnel to log-roll a patient with simultaneous in-line cervical stabilization. The paraspinal soft tissues should be inspected for evidence of swelling, malalignment, or bruising. Systematic palpation of the spinous processes of the entire spinal column can help to identify and localize a spinal injury because significant gapping between processes can occur in flexion–distraction injuries and spinal fracture–dislocations.[4] During inspection of the face and trunk, it is important to keep in mind that certain injuries can be associated with significant visceral and axial skeletal injuries. Facial trauma and head injuries should alert the examining physician to the possibility of an injury to the cervical spine.[2] An abrasion caused by a shoulder restraint in a motor vehicle occupant can be associated with significant injuries to the cervical spine and cervicothoracic junction. Similarly, lap belt contusions should heighten suspicion for flexion–distraction injuries to the thoracolumbar spine. These can also be associated with visceral injury. Calcaneal fractures from significant decelerations, including falls from heights, are associated with axial loading injuries of the thoracic and lumbar spine.[5] Subsequent to a systematic inspection, a complete neurologic examination is performed (see later). The goal of repeated assessments is to identify and provide initial treatment of potentially unstable spinal fractures from both a mechanical and a neurologic basis. This allows for a longitudinal comparison of the neurologic status and early determination of a potentially progressive neurologic deficit. Spinal injuries are identified and worked up during the secondary survey, after successful lifesaving measures. Most spine injuries do not present with a neurologic impairment. If a patient has signs of numbness, tingling sensation, or paralysis to any extremity, a serious injury to the spinal cord must be suspected. Impairment of bladder and bowel function is frequently missed on initial evaluation, which speaks to the absolute necessity of a thorough neurologic exam, as discussed later.[6]

The diagnostic workup of spinal injuries includes computed tomography (CT) scan and magnetic resonance imaging (MRI) for visualization of soft tissue injuries to ligaments and intervertebral disks, epidural bleeding, dural tears, spinal cord contusions and lacerations, and intramedullary lesion expansion over time. Importantly, an MRI should be exclusively obtained only in patients who are hemodynamically stable and adequately resuscitated. The initial workup of multiply injured patients by multislice whole-body CT scans provides thin-section images of the entire spine, along with two- and three-dimensional reconstructions. In this regard, the general availability of multislice CT scanners has eliminated the historic necessity of obtaining conventional radiographs of the entire spine to prevent missing additional vertebral fractures at a different level, which occur in approximately 10% of all cases.[7] Of note, the exclusive finding of transverse process fractures in the initial CT scan does not warrant a spine surgical consultation per se, unless there is a suspicion for associated unstable spinal column injuries based on radiographic findings or presence of neurologic symptoms.

NEUROLOGIC EVALUATION

A thorough neurologic exam is mandatory in any trauma patient with suspected spinal injury. Cranial nerve abnormalities can be suggestive of occipitocervical junction injuries. Four-extremity motor examination should focus on the C5–T1 and L2–S1 myotomes. Truncal and four-extremity sensory exams should document light-touch and pinprick sensation throughout all dermatomes. Subjective numbness or tingling sensation or paralysis to any extremity implies presence of a serious injury to the spinal cord. The level and severity of a spinal cord injury can be determined using a systematic chart published by the American Spinal Injury Association (ASIA).[8] This chart illustrates the key sensory points that correspond to specific neurologic levels in the spinal cord (Fig. 26-1).

When assessing neurologic impairment in an individual who sustained a spine injury, it is crucial to document the exact time of assessment because neurologic deterioration may occur over time.[6] The extent of neurologic injury is stratified into complete (ASIA grade A) or incomplete (ASIA grades B–D), with ASIA grade E reflecting a normal neurologic status.[9] Spinal cord injury is further stratified into paraplegia (paralysis of the lower extremities), resulting from thoracic and lumbar spine injuries, and quadriplegia (paralysis of all four extremities), which originates from cervical spine injuries. With incomplete injuries, the patient has some extent of preserved neurologic function below the level of injury, which is associated with a better outcome prediction compared to complete injuries, where the prognosis is dismal. The neurologic exam should include reflex examination with a focus on triceps, brachioradialis, and patellar and Achilles tendons. Hyperreflexivity may be indicative of a spinal cord injury, whereas areflexia is reflective of spinal shock with temporary absence of all reflexes. Testing for pathologic reflexes includes the Hoffman sign, Babinski sign, and presence of clonus in the case of impaired upper motor neuron downregulation. A rectal examination is part of the mandatory exam and should document anal resting and voluntary tone, anal and perianal sensation (light touch and pinprick), and spinal reflexes (anal wink and bulbocavernosus reflex; the latter requires Foley catheter placement in females). Obtunded patients should be observed for voluntary movements and withdrawal activity with objective assessments taken from reflex and rectal examinations. Return of the bulbocavernosus reflex is reflective of resolution of spinal shock. In contrast to spinal shock, neurogenic shock represents a hemodynamic entity characterized by hypotension and bradycardia resulting from impaired sympathetic outflow tracts in the injured spinal cord.



Muscle function grading

0 = Total paralysis

1 = Palpable or visible contraction

2 = Active movement, full range of motion (ROM) with gravity eliminated

3 = Active movement, full ROM against gravity

4 = Active movement, full ROM against gravity and moderate resistance in a muscle specific position.

5 = (Normal) active movement, full ROM against gravity and full resistance in a muscle specific position expected from an otherwise unimpaired peson.

5* = (Normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (ie, pain, disuse) were not present.

NT = Not testable (ie, due to immobilization, severe pain such that patient cannot be graded, amputation of limb, or contracture of >50% of the range of motion).

ASIA impairment (AIS) scale

- ❑ **A = Complete.** No sensory or motor function is preserved in the sacral segments S4-S5.
- ❑ **B = Sensory in complete.** Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5 (light touch, pin prick at S4-S5: or deep anal pressure [DAP]), AND no motor function is preserved more than three levels below the motor level on either side of the body.
- ❑ **C = Motor incomplete.** Motor function is preserved below the neurological level**, and more than half of key muscle functions below the single neurological level of injury (NLI) have a muscle grade less than 3 (Grades 0–2).
- ❑ **D = Motor incomplete.** Motor function is preserved below the neurological level**, and at least half (half or more) of key muscle functions below the NLI have a muscle grade ≥ 3.
- ❑ **E = Normal.** If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

**For an individual to receive a grade of C or D, ie, motor incomplete status, they must have either (1) voluntary anal sphincter contraction or (2) sacral sensory sparing with sparing of motor function more than three levels below the motor level for that side of the body. The standards at this time allows even non-key muscle function more than 3 levels below the motor level to be used in determining motor incomplete status (AIS B vs C).

NOTE: When assessing the extent of motor sparing below the level for distinguishing between AIS B and C, the *motor level* on each side is used; whereas to differentiate between AIS C and D (based on proportion of key muscle functions with strength grade 3 or greater) the *single neurological level* is used.

Steps in classification

The following order is recommended in determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
2. Determine motor levels for right and left sides.
   Note: in regions where there is no myotone to test the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.
3. Determine the single neurological level.
   This is the lowest segment where motor and sensory function is normal on both sides, and is the most cephalad of the sensory and motor levels determined in steps 1 and 2.
4. Determine whether the injury is Complete or Incomplete. (ie, absence or presence of sacral sparing)
   If voluntary anal contraction = **No** *AND all S4-5 sensory scores* = 0 *AND deep and pressure* = **No**, *then injury is COMPLETE. Otherwise, injury is incomplete.*
5. Determine ASIA impairment scale (AIS) grade:

Is injury Complete?
If **YES**, AIS=A and can record ZPP (lowest dermatome or myotome on each side with some preservation)

NO ↓

Is injury motor Incomplete?
If **NO**, AIS=B

YES ↓

(YES=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

Are at least half of the key muscles below the single neurological level graded 3 or better?

NO ↓ AIS=C

YES ↓ AIS=D

If sensation and motor function is normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

NEUROLOGIC SYNDROMES

Anterior Cord Syndrome

Anterior cord syndrome represents an entity of *incomplete* spinal cord injury resulting from vascular compromise in the anterior spinal artery distribution and subsequent ischemic injury to the anterior two-thirds of the cord, which can occur after blunt trauma mechanisms or ischemic injuries (Fig. 26-2). Clinically, patients present with loss of motor function and pain and temperature sensation below the level of injury from involvement of the ventrally located lateral corticospinal and spinothalamic tracts. Patients typically retain proprioception and the ability to sense vibration and deep pressure from preservation of the posterior columns of the spinal cord. The chance of a relevant clinical recovery in anterior cord syndromes is poor due to the irreversible ischemic neuronal tissue damage.

Central Cord Syndrome

Traumatic central cord syndrome is associated with a contusion, ischemia, or hemorrhage in the central portions of the spinal cord due to traumatic injury sustained in the cervical or upper thoracic spine. The syndrome is characterized by weakness in the arms with "burning hands" and relative sparing of lower extremity motor function, associated with variable sensory loss. Traumatic central cord syndrome typically results from a cervical hyperextension injury in patients with preexisting degenerative changes and narrowing of the spinal canal. Clinically, the upper extremities are more involved than the lower extremities due to the more central location of the upper extremity axons within the spinal cord tracts. Patients typically regain the ability to walk but have more limited return of function to the upper extremities.

Brown-Séquard Syndrome

This entity represents an *incomplete* spinal cord syndrome resulting from a hemitransection of the spinal cord frequently resulting from penetrating injuries. The syndrome is characterized by unilateral damage to the corticospinal tract, spinothalamic tract, and dorsal columns. The clinical presentation consists of loss of ipsilateral light touch sensation, proprioception, and motor function and contralateral loss of pain and temperature sensation.

Posterior Cord Syndrome

This syndrome is rare and results from involvement of the dorsal columns with subsequent loss of proprioception and vibration and preserved motor function. The prognosis is variable, with many patients experiencing difficulty walking due to the deficit in proprioceptive sensation.

Cervical Root Syndrome

This injury pattern is reflective of an isolated nerve root injury that causes a deficit in sensation and motor function secondary to an acute disk herniation or facet fracture, subluxation, or dislocation.

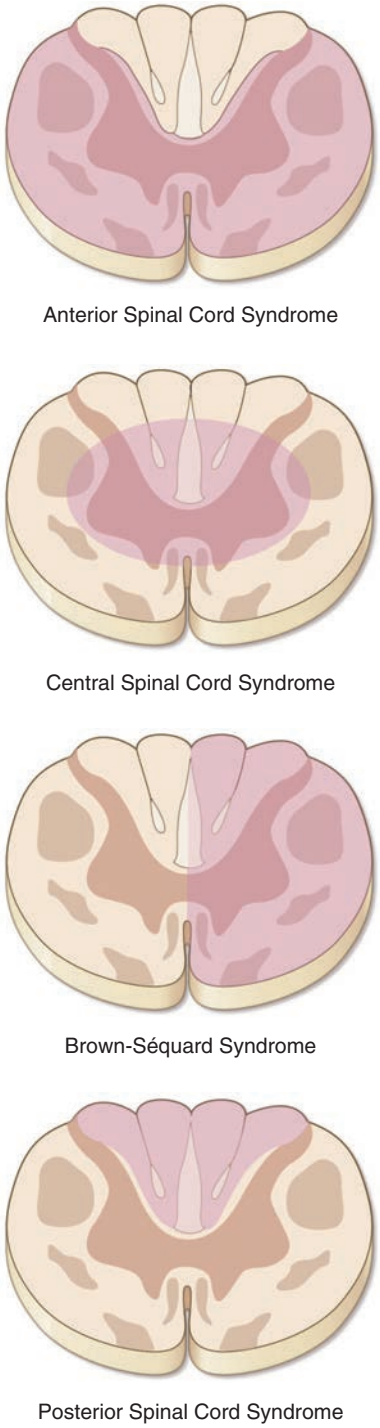

FIGURE 26-2 The most common patterns of incomplete spinal cord injury.

Conus Medullaris Syndrome

Injury to the conus medullaris, which is typically located at the level of the L1–L2 intervertebral space, can produce

mixed upper and lower motor neuron findings. Isolated injury to the conus may result in loss of bowel and bladder control without sacral sparing. Nerve roots that "escape" the injury can allow preserved lower extremity motor and sensory function despite injury to the distal tip of the spinal cord.

Cauda Equina Syndrome

The cauda equina extends distal to the conus and is composed of the lumbar and sacral nerve roots. Injury to the cauda equina results in lower motor neuron findings with sensory loss and motor dysfunction. Involvement of the lower sacral roots can result in bladder and bowel dysfunction.

ACUTE MANAGEMENT STRATEGIES

The initial management principles for trauma patients with associated spinal injuries consist of protection of airway and breathing/ventilation, ensuring adequate oxygenation, control of blood loss, and maintenance of adequate blood pressure according to the established guidelines by the Advanced Trauma Life Support (ATLS) protocol.[3,10] Presence of an unstable spinal injury must be suspected in any patient who sustains a high-energy trauma mechanism, independent of a neurologic impairment. A cervical collar is kept in place until formal spine clearance (see protocols later), which usually requires additional radiographic workup. When securing the airway, care is required during intubation to prevent hyperextension of the neck that might cause an iatrogenic injury to the cervical spine or spinal cord. Endotracheal intubation must be performed with in-line cervical traction or by fiberoptic assistance. Maintenance of oxygenation and avoiding hypotension are key to minimizing the potential for second-hit insults to the vulnerable spinal cord. In a selected subset of patients with spinal cord injuries, hypotension may result from neurogenic shock due to disruption of sympathetic output to the cardiovascular system.[11] Neurogenic shock is characterized by bradycardia in the presence of hypotension. These patients typically require the use of a vasopressor (eg, Neo-Synephrine or Levophed) to maintain systolic blood pressure. Occasionally in some patients with profound bradycardia, chronotropic support (eg, dopamine) or even temporary pacing is necessary to maintain an acceptable heart rate. Patients with spinal cord injuries above the level of C5 are more likely to require intubation and mechanical ventilation.[11]

HOW TO RECOGNIZE AN UNSTABLE SPINE INJURY

One of the most important tasks for the treating spine surgeon is to determine the presence or absence of spinal stability. Most spine surgeons agree with the general definition that spinal stability refers to the ability of the spine to maintain its alignment and protect the neural structures during normal physiologic loads.[12] Biomechanically, spinal instability refers to an abnormal response to applied loads and can be characterized by motion in spinal segments beyond the normal constraints. In a clinical scenario, defining *spinal stability* remains challenging and a topic of ongoing debate. The working definition of spinal stability takes into consideration that under physiologic loads (the influence of gravity on body mass) the spine will not experience increasing deformity, onset of neurologic impairment, or a drastic increase in patients' subjective level of pain.[12] Reciprocally, unstable spine injuries are at risk for progressive deformity and neurologic compromise (or both), which may represent the basis for considering surgical spine stabilization and decompression of the spinal cord. If spinal stability can be confirmed without the need for surgical intervention, patients should be cleared from log-roll precautions followed by early mobilization with or without adjunctive bracing. If spinal injuries are deemed unstable, early surgical treatment should be considered to prevent complications related to prolonged bed rest and immobilization (eg, pressure sores, pulmonary and thromboembolic complications).

Spinal fractures, traumatic dislocations, and fracture–dislocations are best classified by the comprehensive AO Foundation/Orthopaedic Trauma Association (AO/OTA) classification system, which is based on the alphanumeric classification published by Magerl et al[13] in 1994 (Fig. 26-3).

The AO/OTA classification codes the anatomic spine region by a number (cervical: 51; thoracic: 52; lumbar: 53) and the injury pattern/severity by an alphanumeric combination (A, B, C and 1, 2, 3).[14] The clinical implication of classifying spinal injuries by the AO/OTA system is that the alphanumeric code reflects injury severity and guides treatment (operative vs nonoperative) based on spinal stability. In brief, A-type spinal injuries represent *axial loading* trauma mechanisms leading to compression fractures (A1), vertebral split fractures (A2), or burst fractures (A3). In contrast, B-type injuries reflect unstable fractures and fracture–dislocations originating from *flexion/distraction* (B1, B2) or *hyperextension* (B3) trauma mechanisms. Finally, C-type injuries are by definition *rotationally unstable* and include rotational wedge/split/burst fractures (C1), flexion–distraction or hyperextension injuries with rotation (C2), or complete rotational shearing injuries (C3). The incidence of associated neurologic (spinal cord) injury increases with the alphanumeric fracture classification, from nearly 0% in stable A1-type compression fractures to close to 100% in C3-type injuries (Fig. 26-3).[6] The C3-type injury is representative of the worst spinal injury pattern (so-called Holdsworth injury, slice fracture, or traumatic spondyloptosis) and is associated with an almost 100% risk of spinal cord injury or spinal cord transection.[15]

The extent of vertebral displacement (spondylolisthesis) is classified by the Meyerding grading system (Fig. 26-4).[16] This classification is based on radiographic measurements on lateral views of the according spine segment. The Meyerding classification describes four grades of severity of spondylolisthesis, based on the calculated percentage of vertebral slip: 0% to 25% (grade I), 25% to 50% (grade II), 50% to 75% (grade III), and 75% to 100% (grade IV).

A traumatic dislocation of the spine (traumatic spondyloptosis) is almost exclusively related to high-energy

Fracture type (AO/OTA)	Stability	Risk of SCI	Management
A-type: Axial compression		0%	
 A1: Impaction/ compression	Stable		Nonoperative
 A2: Split	Stable		Nonoperative
 A3: Burst	Stable/unstable*		Nonoperative/operative*
B-type: Flexion/distraction or hyperextension			
 B1: Flexion/ distraction	Unstable		Operative
 B2: Chance fracture	Unstable		Operative
 B3: Hyperextension	Unstable		Operative
C-type: A or B type with rotation			
 C1: Rotational wedge	Unstable		Operative
C2: Rotational flexion/ extension	Unstable		Operative
C3: Rotational shear (Holdsworth slice fracture)	Unstable		Operative
		100%	

FIGURE 26-3 Spinal fractures, traumatic dislocations, and fracture–dislocations are best classified by the comprehensive AO Foundation/ Orthopaedic Trauma Association (AO/OTA) classification system, which is based on the alphanumeric classification published by Magerl et al[13] in 1994.

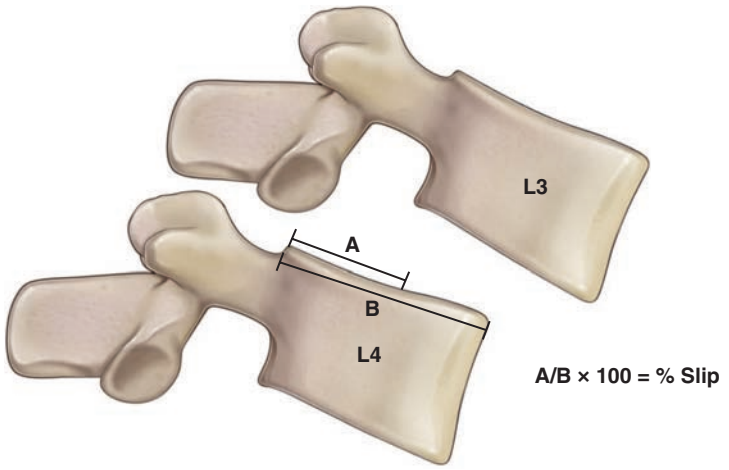

FIGURE 26-4 The extent of vertebral displacement (spondylolisthesis) is classified by the Meyerding grading system.

acceleration/deceleration trauma mechanisms. The cervical spine is particularly vulnerable due to its flexible fixation between the head and the thorax. Rigidity at these two points (the occipitocervical junction and the cervicothoracic junction) causes vulnerability to occur at the intervening cervical segment between. For the same reason, the thoracolumbar junction is particularly vulnerable to traumatic fractures and fracture–dislocations (Fig. 26-5).[16]

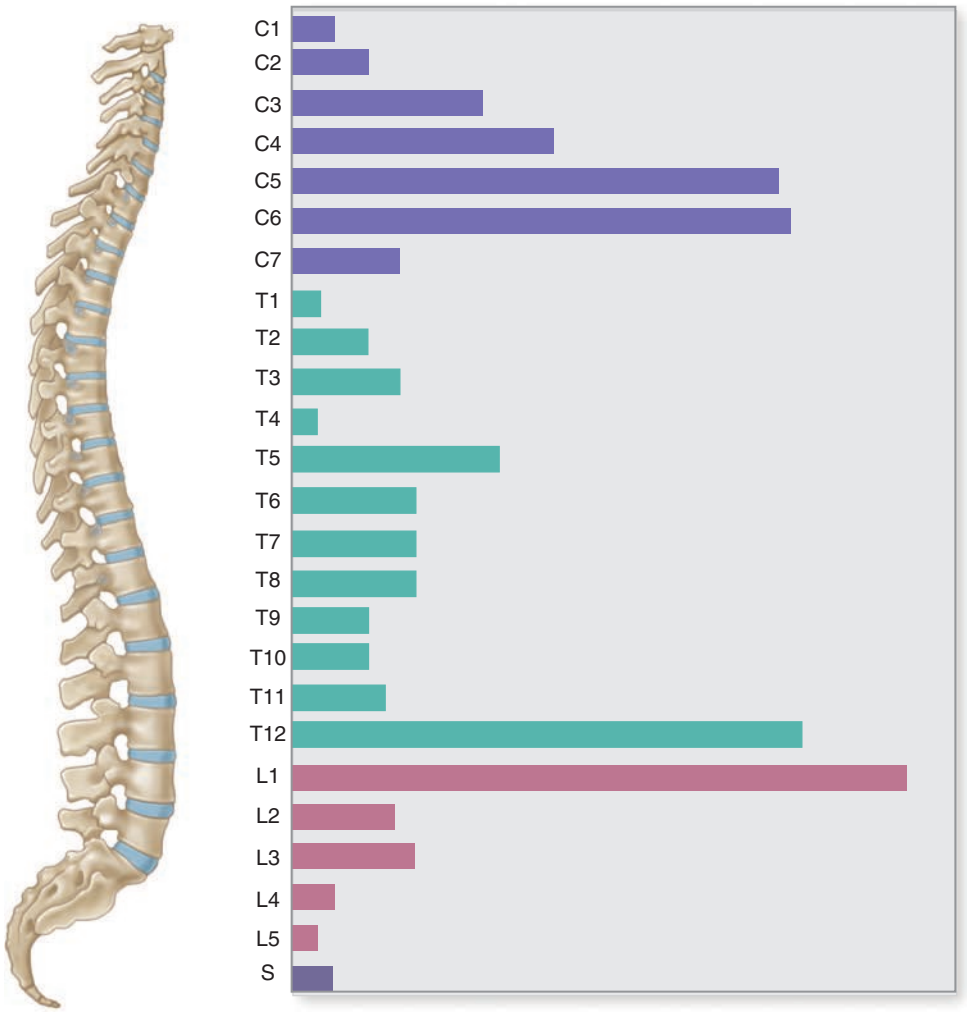

FIGURE 26-5 The thoracolumbar junction is particularly vulnerable to traumatic fractures and fracture–dislocations.

TABLE 26-1: Subaxial Injury Classification and Severity Scale (SLIC)

Injury characteristic	Points
Injury morphology	
No abnormality	0
Compression	1
Burst	+1 (=2)
Distraction (eg, facet perch, hyperextension)	3
Rotation/translation (eg, facet dislocation, unstable "tear-drop" or advanced stage flexion compression injury)	4
Discoligamentous complex (MRI)	
Intact	0
Indeterminate (eg, isolated interspinous widening, MRI signal change only)	1
Disrupted (eg, widening of anterior disk space, perched facet/dislocation, kyphotic deformity	2
Neurologic status	
Intact	0
Root injury	1
Complete cord injury	2
Incomplete cord injury	3
Ongoing cord compression in setting of neurodeficit	+1

A summarized score <4 points suggests nonoperative management as an adequate treatment strategy, whereas a score ≥4 points implies consideration of surgical management.

MRI, magnetic resonance imaging.

TABLE 26-2: Thoracolumbar Injury Classification and Severity Score (TLICS)

Injury characteristic	Qualifier	Points
Injury morphology		
Compression		1
Burst		+1 (=2)
Rotation/translation		3
Distraction		4
Neurologic status		
Intact		0
Nerve root		2
Spinal cord/conus medullaris	(incomplete)	3
Spinal cord/conus medullaris	(complete)	2
Cauda equina		3
Posterior ligamentous complex (MRI)		
Intact		0
Suspected/indeterminate		2
Disrupted		3

A summarized score <4 points suggests nonoperative management as an adequate treatment strategy, whereas a score ≥4 points implies consideration of surgical management.

MRI, magnetic resonance imaging.

Additional classification systems for vertebral fractures include the classic three-column classification by Denis, the Allen/Ferguson fracture classification, the White and Panjabi system, and the load sharing classification system for assessment of stable versus unstable burst fractures.[17-19] In addition, the Subaxial Injury Classification (SLIC) system for cervical injuries (Table 26-1) and the Thoracolumbar Injury Classification and Severity Score (TLICS) for thoracic and lumbar fractures (Table 26-2) offer guidance in the decision making for operative versus nonoperative management of spinal injuries.[20,21] Although these two widely used classification systems are helpful for guiding treatment, the respective scoring relies on availability of MRI for prediction of discoligamentous complex integrity.

WHEN TO CLEAR THE CERVICAL SPINE

The incidence of cervical spine injury is reported to be around 4% in the trauma patient.[22,23] Given the potential for catastrophic complications following a missed cervical spine injury, it is essential that patients be properly immobilized in rigid cervical collars at the time of rescue with continued immobilization until safe and protocolized cervical spine clearance.

During patient rescue, transport, and initial assessment and management, every attempt should be made to minimize the movement of the spinal column. Spinal precautions are aimed at avoiding secondary damage to the spinal cord by excessive bending or twisting in presence of potentially unstable injury patterns. The presence of neurologic symptoms must be assumed to represent a spinal cord injury with associated spinal column instability until proven otherwise.

Clearance of the cervical spine has represented a conundrum for many decades, due to the potential medical-legal implications related to missed spinal injuries and the risk of complications associated with prolonged spinal immobilization.[24] An observational cohort study from a Level I trauma center in the Netherlands revealed that more than half of all adult trauma patients admitted through the emergency department had indentation marks from their cervical collars and that the risk of developing a pressure ulcer increased by 66% per additional day of immobilization.[25] In particular, patients admitted to the intensive care unit (ICU), patients on mechanical ventilation, and patients with traumatic brain injury being monitored for intracranial pressure were noted to have increased complications associated with their cervical collars.[25] Additional risks of prolonged cervical spine immobilization in rigid collars include the following:

- Technical challenges for endotracheal intubation and airway management
- Technical challenges for central line placement

- Time delay for tracheostomies in spinal cord–injured patients
- Increased risk of aspiration and pulmonary infections
- Increased risk of skin breakdown and pressure ulcers
- Increased pain and discomfort in awake patients
- Impaired nursing care and patient experience

The published literature provides a multiplicity of protocols for clearance of the cervical spine in the trauma patient. In essence, the relevant decision-making algorithms are stratified into three main categories based on the underlying patient condition. These include (1) awake and alert patients without neurologic symptoms[26]; (2) awake and alert patients with presence of neurologic symptoms[27]; and (3) obtunded, intoxicated, or otherwise nonexaminable patients.[28]

For patients who are awake, alert, and hemodynamically stable, without any neurologic symptoms, there are standardized guidelines for cervical spine clearance guided exclusively by clinical findings. These include the National Emergency X-Radiography Utilization Study (NEXUS) low-risk criteria[29] (Fig. 26-6) and the Canadian Cervical Spine Rule (CCR) guideline[30] (Fig. 26-7).

The application of these clinical prediction tools allows for a rapid clinical clearance of the cervical spine without the need for radiographic imaging. Multiple validation studies and meta-analyses of the literature revealed a high sensitivity (98.1%) and negative predictive value (99.8%) for the NEXUS low-risk criteria and the CCR guideline to safely clear the cervical spine without radiographic imaging in alert, asymptomatic patients who are hemodynamically stable and are able to complete a functional range-of-motion examination in absence of distracting injuries or neurologic deficits.[26,27,31-33]

Symptomatic patients with neurologic symptoms and obtunded or intoxicated patients who are not amenable to a clinical evaluation require advanced imaging studies. The use of upright plain radiographs of the lateral cervical spine is outdated and obsolete, based on a low reported sensitivity of just 45.5% in detecting presence of a spinal injury.[34] In contrast, current available evidence has unequivocally demonstrated that a normal high-quality CT scan alone is sufficient to allow safe clearance of the cervical spine in the nonexaminable patient.[28] In this regard, the 2015 guidelines by the Eastern Association for the Surgery of Trauma (EAST) recommend cervical collar removal after a negative high-quality cervical spine CT scan results in obtunded adult blunt trauma patients.[35] These recommendations by the EAST study group are based on a systematic review of the literature that revealed a negative predictive value of 100% for spinal clearance by a normal high-quality CT scan alone.[35] These insights were confirmed by the 2017 Western Trauma guidelines, which are based on a prospective multicenter observational study confirming that CT alone was effective for ruling out a clinically relevant cervical spine injury with a negative predictive value of 100%.[36] Based on these data, the escalation to further advanced imaging by MRI appears exclusively indicated in patients with an abnormal neurologic examination.[36]

Despite the unequivocal available evidence from the pertinent literature, it appears that there is an ongoing unjustified overutilization of MRI studies in the current clinical practice. For example, a large-scale survey of 22 trauma centers in England reported that 52% of the respondents were using MRI for clearance of the cervical spine in obtunded patients despite the presence of a negative high-quality CT scan.[37] The authors raised a call for greater awareness about the evidence from the EAST guidelines and the British Orthopaedic Association Standards for Trauma (BOAST) recommendations regarding the reliability of a normal CT examination in clearing the cervical spine in obtunded patients in the absence of focal neurology.[37] This recommendation is supported by a recent meta-analysis that reported an extremely low rate of positive findings by MRI in obtunded patients with blunt cervical spine trauma of only 0.12% in a pooled cohort of 5286 patients.[38] In addition to the low diagnostic yield, obtaining an MRI in obtunded patients has multiple technical ramifications and potential risks. These include unnecessary transports of critically injured patients, difficult patient positioning, suboptimal monitoring and access during a prolonged examination, the unjustified delay to discontinuation of cervical spine immobilization pending MRI clearance, and the unnecessary utilization of time and resources.[39,40]

In summary, the current peer-reviewed literature and international consensus-based guidelines support the discontinuation of cervical collar immobilization in the obtunded, intoxicated, or otherwise nonexaminable patient subsequent to a negative high-quality CT scan.

Figure 26-8 provides a summarized algorithm of the current evidence-based recommendations for cervical spine clearance after blunt trauma mechanisms in adult patients.

THE ROLE OF STEROIDS REVISITED

Despite current science unequivocally demonstrating a lack of effectiveness of high-dose methylprednisolone in the acute management of patients with spinal cord injuries, the issue remains a topic of daily debate and uncertainty among the involved care providers in the trauma bay. From a historic perspective, the consideration of high-dose steroids originated from presumed benefits in patients with brain tumors and head injuries in the 1960s and 1970s. After publication of the second National Acute Spinal Cord Injury Study (NASCIS-2) in 1990, the application of high-dose methylprednisolone for patients with acute spinal cord injury became a globally accepted standard of care for more than a decade.[41,42] A critical analysis of the NASCIS data, however, placed the use of high-dose steroids under scrutiny due to questionable benefits and the potential for inflicting unintentional harm, such as placing the patients at increased risk for pulmonary infections.[43] The large-scale, prospective, randomized, multicenter trial Corticosteroid Randomization After Significant Head Injury (CRASH) confirmed the notion of the unjustified experimental nature of high-dose steroids in the acute management of neurologic injuries. The CRASH trial was unexpectedly aborted after enrollment of about 10,000 patients, based on the unexpected finding of a drastically increased mortality in patients treated with methylprednisolone, compared to the placebo control group.[44] The extrapolation of the negative results from this large-scale trial implied that the uncritical administration of corticosteroids in the 1980s and earlier may have been the cause of preventable postinjury mortality.[45] In absence of new prospective randomized trials on the role of steroids in spinal cord injury, current guidelines and clinical recommendations consider the routine use of steroids for patients with acute spinal cord injury obsolete.[3] Selected neurologic injury patterns, including spinal contusions or traumatic central cord syndrome, allow consideration for a short course of steroids at the individual treating spine surgeon's discretion.

THROMBOEMBOLISM PROPHYLAXIS

Prophylaxis against venous thromboembolism (VTE) is a crucial consideration in patients with unstable spine fractures and spinal cord injuries. The most recent and updated American College of Chest Physicians CHEST guidelines for VTE prophylaxis were published in 2016.[46] All trauma patients with associated spinal injuries should have mechanical prophylaxis instituted as soon as possible with graduated compression stockings and/or sequential compression devices. Pharmacologic prophylaxis with unfractionated heparin or low-molecular-weight heparin (LMWH) should be initiated within 24 hours of admission or as soon as the acute risk for additional bleeding in the trauma patient is adequately controlled (ie, pending adequate response to resuscitation and reversal of postinjury coagulopathy).[47] LMWH appears to be more effective for VTE prevention and is associated with fewer bleeding complications than unfractionated heparin in patients with spine injuries.

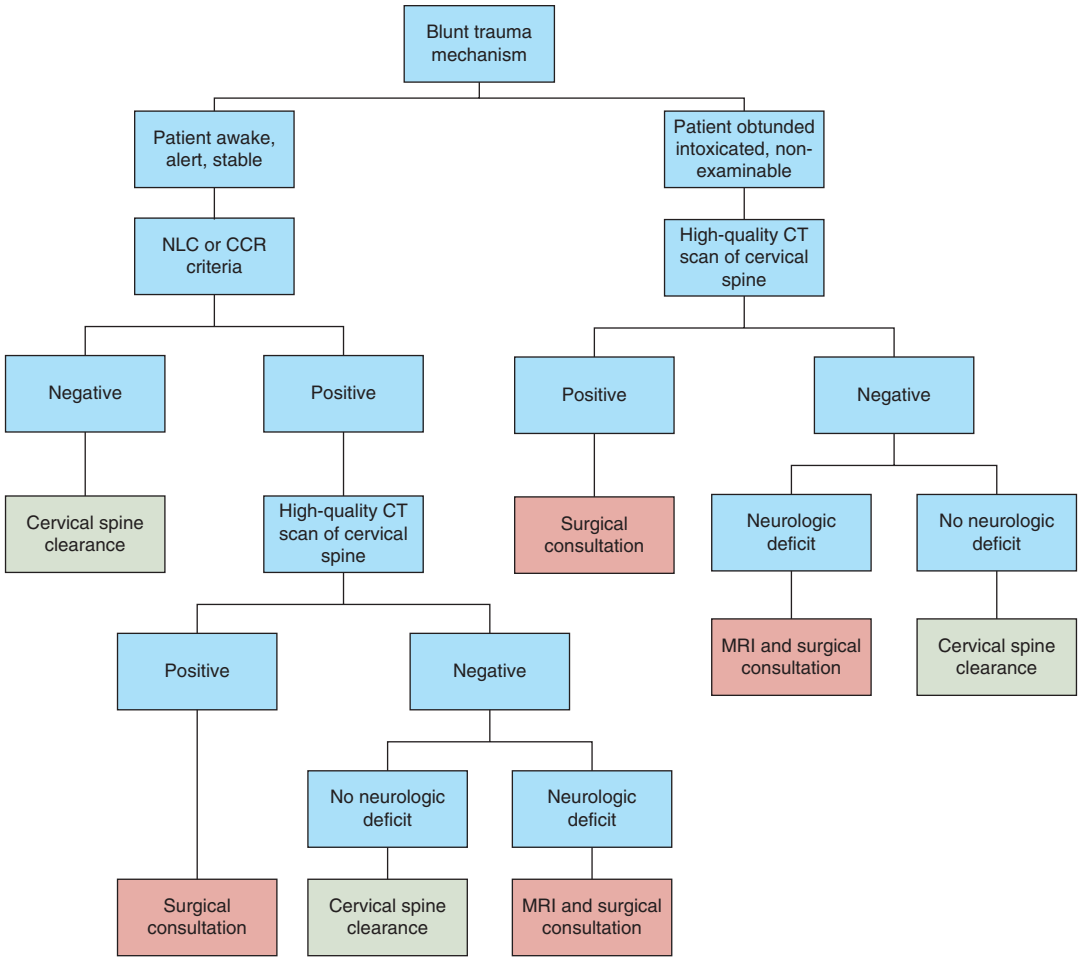

FIGURE 26-8 Algorithm for clearing the cervical spine in both awake and alert and obtunded or intoxicated patients. CCR, Canadian Cervical Spine Rule; CT, computed tomography; MRI, magnetic resonance imaging; NLC, NEXUS (National Emergency X-Radiography Utilization Study) low-risk criteria.

The duration of pharmacologic VTE prophylaxis is determined by the patient's mobility status and should be typically continued for 2 weeks in patients without neurologic injuries and for 6 to 12 weeks in the presence of spinal cord injury. If patients are poor candidates or have a contraindication to pharmacologic VTE prophylaxis due to increased risk of bleeding complications, then the early placement of a removable inferior vena cava filter should be considered as an alternative option.[47] Pharmacologic VTE prophylaxis is not indicated in low-risk situations (eg, for ambulatory patients with isolated stable A1-type thoracolumbar compression fractures).

TIMING OF TRACHEOSTOMY

One of the unresolved challenges in the management of ventilator-dependent trauma patients with associated unstable spine fractures and spinal cord injuries consists in defining the ideal timing of conversion to a tracheostomy.[48] The conundrum consists of coordinating the timing of early tracheostomy (the intent of which is to reduce the inherent risk of ventilator-associated pneumonia) and the timing of cervical spine fixation (if indicated for the management of unstable cervical injuries). Spine surgeons are generally worried that a preceding tracheostomy may increase the risk of a surgical site infection for a delayed anterior cervical discectomy and fusion (ACDF). This concern appears unjustified based on the existing literature, which demonstrates that ACDF surgery is safely performed in the presence of a prior tracheostomy, without an increased risk of a postoperative infection.[49] Because the dual incisions are typically located several centimeters apart, the tracheostomy wound can be safely draped off during the preparation for the ACDF procedure and does not appear to pose a risk of cross-contamination. In fact, these two procedures can be safely performed during the same operating room visit under the same anesthetic. At our own institution, the requirement for prolonged mechanical ventilation in patients is discussed as part of the overall surgical plan in the management of patients with spine fractures and spinal cord injuries. Our protocol attempts to coordinate the early timing of tracheostomy with the timing for the spinal fusion.

This proactive approach, tailored at decreasing the risk of preventable pulmonary infections and adverse outcomes in a highly vulnerable patient population, requires close cooperation between spine surgeons and the general surgery trauma team.[50]

TIMING OF SPINAL SURGERY

Unstable spine fractures, dislocations, and fracture-dislocations must be recognized early and treated in a timely fashion. This entails early closed reduction and application of Halo fixation for unstable cervical spine injuries and early open reduction and spinal fixation/fusion for unstable thoracic and lumbar injuries and for irreducible cervical spine dislocations. Examples of institutional protocols for the surgical management of thoracic and lumbar fractures/fracture–dislocations have been published elsewhere.[16] The widely disseminated practice of internally fixating unstable thoracic and lumbar fractures in polytrauma patients consists of either (1) a conservative approach of delayed spine fixation (after full resuscitation), or (2) a more proactive approach of early total care. Early total care often includes invasive anterior approaches, vertebral corpectomy, spinal canal decompression, and anterior spinal column stabilization/fusion. Many spine surgeons are discouraged from early spinal surgery based on the notion that multiply injured patients are frequently "too sick" to safely undergo surgical procedures within the first few days after major trauma.[51] The problem associated with this conservative philosophy is that these vulnerable patients remain bedridden on log-roll precautions, which precludes from a coherent and proactive management of severe associated injuries to the head, chest, abdomen, and pelvis. In a landmark article, Croce and colleagues[52] performed a retrospective analysis of a prospective database on 291 consecutive patients with unstable spine fractures requiring surgical fixation. Patients were matched for injury severity and stratified by level of spine injury into two distinct cohorts, depending on the timing of fracture fixation: early fixation (within 3 days, n = 142) versus late fixation (>3 days, n = 149).[52] The authors found that the early fixation of thoracic spine fractures resulted in a lower incidence of pneumonia, fewer ventilator-dependent days, a shorter ICU stay, and reduced hospital charges.[52] This notion was confirmed by a systematic review of the published literature by Rutges et al,[53] who provided a comparison between different time points of surgical stabilization of thoracic or lumbar spine fractures. The authors concluded that early intervention for fracture stabilization in the thoracolumbar spine is safe, advantageous, and associated with a significantly decreased incidence of postoperative complications.[53]

However, due to the lack of unequivocal scientific evidence from prospective randomized trials, there remains a lack of consensus regarding the "optimal" timing of spine fracture fixation in multiply injured patients.[54] Intuitive advantages of early spine fixation relate to preventing complications associated with prolonged bed rest and the inability to adequately position and mobilize severely injured patients in the ICU. Unequivocally, multiply injured patients require unrestricted options for mobilization and positioning in the ICU, such as the upright seated position for treatment of head injuries and prone positioning for the management of acute respiratory distress syndrome. Finally, unstable and unreduced spinal fractures contribute to adverse sequelae of major trauma related to stress, pain, ongoing bleeding, and sustained systemic inflammation.[55] These concepts provide a strong argument for the necessity of early spine clearance and discontinuing bed rest and log-roll precautions in multiply injured patients. Current evidence suggests that any unstable thoracic or lumbar spine fracture or dislocation should be reduced and fixated within 24 hours of admission.[54,56-58] This approach is particularly applicable in the care of multiply injured patients at risk of sustaining second-hit insults and postinjury complications, including pressure sores, pulmonary infections, and thromboembolic complications.[59]

A proactive approach of spine damage control has been described and validated in the recent literature with the intent of mitigating the risk of adverse outcomes in polytrauma patients with associated unstable thoracic or lumbar spine fractures at risk of adverse outcomes.[60-64] The concept of spine damage control entails a staged procedure of immediate posterior fracture reduction and instrumentation within 24 hours (day 1 surgery), followed by scheduled 360° completion corpectomy and fusion during a physiologic time window of opportunity (>3 days after trauma).[51] Proceeding with the second stage is done if an adjunctive anterior decompression and fusion is indicated for neurologic or biomechanical reasons. This concept differs from the more common elective strategy of staged spine fixation by initial posterior fixation and delayed anterior completion in two ways: first, by its timeliness (posterior fixation within 24 hours), and second, by its expanded applicability to all unstable thoracolumbar fractures, including exclusive anterior column burst fractures.

The analogy of management strategies for femur shaft fractures and unstable thoracolumbar spine fractures in multiply injured patients is schematically depicted in Fig. 26-9.

In a prospective validation study of the spine damage control protocol, 112 consecutive patients with unstable thoracic or lumbar spine fractures and Injury Severity Score (ISS) of greater than 15 were prospectively enrolled during a 3-year time period.[65] Early spine damage control within 24 hours was performed in 42 patients, whereas 70 matched patients in the control group underwent definitive operative spine fixation at a delayed time point. The mean time to initial spine fixation was significantly decreased in the spine damage control group (8.9 ± 1.7 hours vs 98.7 ± 22.4 hours, $P < .01$). The early spine fixation cohort also showed a reduced length of operative time (2.4 ± 0.7 hours vs 3.9 ± 1.3 hours), length of hospital stay (14.1 ± 2.9 days vs 32.6 ± 7.8 days), and number of ventilator-dependent days (2.2 ± 1.5 days vs 9.1 ± 2.4 days) compared to the delayed spine fixation control group. Most importantly, the postinjury and postoperative complication rates were significantly decreased after spine damage control, including a reduced incidence of wound complications and surgical site infections (2.4% vs 7.1%), urinary tract infections (4.8% vs 21.4%), pulmonary complications (14.3% vs 25.7%),

Advocating "spine damage control" as a safe and effective treatment modality for unstable thoracolumbar fractures in polytrauma patients: a hypothesis. *J Trauma Manag Outcomes*. 2009;3:6.)

and pressure sores (2.4% vs 8.6%). Our early experience implies that a proactive concept of early stabilization of unstable thoracic and lumbar fractures in multiply injured patients represents a safe and effective treatment strategy that should be considered for implementation in other trauma centers.[65]

SURGICAL CONSIDERATIONS

Surgery for unstable spinal injuries attempts to accomplish three main goals: (1) to decompress neurologic structures (spinal cord, spinal nerve roots, cauda equina, conus medullaris), as indicated; (2) to restore and maintain the sagittal alignment of the spine; and (3) to restore and maintain stability of the spine.

Cervical Injuries

The preferred treatment modality for unstable cervical spine fractures consists of an anterior decompression (including corpectomy) and fusion with anterior plating (ACDF) in conjunction with a bone graft substitute or cage. Unstable three-column fractures and fracture–dislocations with posterior facet dislocations may require a posterior approach

or combined posterior/anterior approach with 360° fusion. Posterior cervical spine fixation is typically accomplished by placement of multilevel lateral mass screws with or without adjunctive bone grafting for spinal fusion.

Thoracic and Lumbar Injuries

Unstable vertebral fractures with or without neurologic injuries are generally managed by anterior decompression with corpectomy and fusion using expandable cages and graft constructs, with or without adjunctive anterior column instrumentation with plates and screws or rods and screws. As described earlier, a standardized spine damage control approach may be considered in multiply injured patients by initial posterior fracture reduction, fixation, and decompression by laminectomy. This modality allows early mobilization and positioning of multiply injured patients as needed for intensive care. Definitive treatment consists of a delayed, staged anterior corpectomy and anterior column fusion (360°), if indicated. Chance fractures of the B2 type (Fig. 26-3) are managed exclusively by a posterior approach with definitive internal fixation using pedicle screws, with instrumentation two levels above and two levels below the fracture site. Three-column injuries frequently require a combined posterior/anterior 360° fusion, as outlined earlier. Of note, the placement of surgical drains is rarely indicated in the acute surgical management of spinal injuries. Exceptions where drains are beneficial include placement of retroperitoneal drains after extensive anterior approaches and chest tubes for transthoracic approaches. In contrast, the prophylactic placement of drains around the cervical spine for anterior or posterior approaches and for posterior thoracic or lumbar approaches does not appear to convey any benefit. While the perceived benefits include the theoretical decreased risk of postoperative hematoma formation, this must be weighed against the risk that keeping drains increases the risk of surgical site infections. Furthermore, side effects from prolonged antibiotic therapy can occur if the surgeon requests antibiotics be continued while surgical drains remain in place. Thus, on balance, the use of drains does not appear to be justified from a quality of care or patient safety perspective.

Trauma Thoracotomy: Principles and Techniques

Ravi K. Ghanta • Matthew J. Wall Jr • Kenneth L. Mattox

KEY POINTS

- Despite frequent emphasis on devastating injuries, the most common thoracic injury is a chest wall contusion or rib fracture.
- History, physical examination, and chest x-ray remain fundamental to the diagnosis of thoracic injury. Additional imaging, including extended focused ultrasonography assessment for trauma, computed tomography (CT) scanning, and CT angiography are frequently used.
- A thoracostomy tube output of 1500 mL of blood on insertion or 200 mL of blood per hour usually warrants an urgent thoracotomy.
- A left anterolateral thoracotomy through the third or fourth interspace allows exposure for opening the pericardium, open cardiac massage, clamping of the descending thoracic aorta, and treatment of a large percentage of cardiac and left lung injuries.
- A retained hemothorax should be evacuated by video-assisted thoracoscopy or thoracotomy as soon as diagnosed.
- New technologies, such as retrograde endovascular balloon occlusion of the aorta and extracorporeal cardiopulmonary resuscitation, have the potential to further change the philosophy of prehospital management for thoracic injuries.

INTRODUCTION

Thoracic injury occurs in 20% to 25% of trauma patients, resulting in 16,000 deaths annually in the United States.[1,2] Because the chest accounts for 25% of the total body mass, it is susceptible to injury from virtually any etiology or mechanism. Injury to the chest and its organs may be caused by penetration (missiles, fragments, knives, needles, and other objects), blunt forces, sudden deceleration, iatrogenic misadventure, blasts, and ingestion of toxic substances. Each of these etiologies has differing initial manifestations as well as evaluation and treatment approaches.[3-5] These differences are more specifically discussed in other chapters of this textbook.

Despite frequent emphasis on devastating injuries, such as cardiac or great vessel injury, the most common thoracic injury is a chest wall contusion or rib fracture.[2] Injuries to the heart or lungs frequently present with obvious signs that require prompt intervention. Some injuries, however, are less apparent and present with delayed manifestations requiring ongoing clinical suspicion and management. Consequently, patients with thoracic trauma require logical and sequential evaluation, followed by focused therapy, which involves an operation less than 20% of the time. Notably, the most common operation in a patient with a chest injury is an exploratory laparotomy, with formal thoracotomy a rare intervention. The objective of this chapter is to review the diagnostic process and judgment decisions leading to performing a thoracotomy in the trauma patient.

INITIAL EVALUATION

Initial evaluation follows the standard Advanced Trauma Life Support (ATLS) protocols. Physical examination should carefully evaluate for presence or absence of breath sounds or diminished breath sounds, presence of chest wall contusions, penetrating injuries, flail chest segments, and evidence of prior thoracic surgery (ie, sternotomy or thoracotomy incision scars). Upper and lower extremity pulse examination is essential and may be a marker of injury to the thoracic aorta or subclavian artery. Finally, the presence of cardiac murmurs or diminished heart sounds may be indicative of a traumatic cardiac injury.

The chest x-ray is a fundamental diagnostic tool in evaluating chest trauma. It is used to determine the position of the trachea and evaluate the lung parenchyma, mediastinal silhouette, aortic knob, and pleural cavities. In addition, it can

diagnose a hemopneumothorax, pneumomediastinum, rib fractures, spinal or other skeletal fractures, and foreign bodies. Ideally, the chest x-ray is obtained in an upright position to minimize mediastinal widening that accompanies supine positioning and to accentuate air-fluid levels.[6] An electrocardiogram (ECG) should be performed on all trauma patients, especially those with blunt thoracic injury.[7] The presence of an arrhythmia, frequent premature ventricular contractions, bundle branch blocks, or ST-segment depressions may be indicative of a blunt cardiac injury.

Focused Ultrasonography Assessment for Trauma (FAST) and Extended FAST

Focused ultrasonography assessment for trauma (FAST) allows for a rapid bedside evaluation of the pericardial and abdominal cavities that can be performed by trauma surgeons and emergency department physicians. FAST allows for identification of fluid or blood in the pericardial space via a subxiphoid view. Although operator dependent, focused echocardiography can be used to confirm tamponade physiology, cardiac filling status, and cardiac function. The presence of hemopericardium, however, is exceedingly rare in blunt trauma and often diagnosed from other acute clinical signs.[8] FAST has been extended (so-called E-FAST) to evaluate the thoracic cavity for the presence of a traumatic hemothorax and pneumothorax. In one recent large series including 756 patients, the sensitivity of E-FAST for identifying pneumothorax (69% vs 37%) and hemothorax (48% vs 29%) was favorable compared to chest x-ray.[9] As with FAST, however, a learning curve and operator expertise must be developed, as other studies have shown poor sensitivity (43%) when performed by some practitioners.[10] The decision to pursue E-FAST in lieu of a chest-x-ray should be approached with caution, taking into account the expertise of the operators at each trauma center.

Additional Diagnostic Maneuvers

A variety of diagnostic studies may be required to delineate intrathoracic injury. Additional imaging includes computed tomography (CT), CT angiography, angiography, cardiac catheterization, and echocardiogram, as mentioned earlier. Endoscopic evaluation of the trachea and esophagus, as well as contrast esophagrams, may be required. In deciding which diagnostic evaluation to perform, the first consideration is what the test is expected to demonstrate, whereas the second consideration is how the results will alter decision making or treatment. Frequently, additional tests, when needed, are initiated based on findings from the physical examination, chest x-ray, and/or FAST. Although CT scanning has become ubiquitous in the evaluation of trauma patients, it may be overused and result in a delay of necessary surgical therapy and in excessive radiation exposure.[11-13] In general, especially for suspected vascular injury, CT scanner detectors with greater than 64 slices are recommended. Older scanners with fewer slices produce inconsistent results and often create unnecessary confusion. Using these newer CT scanners with multidetectors, ECG gating, and multiplanar reconstruction, CT aortography (CTA) for aortic injury can have a sensitivity of 98% and specificity of 100%. In addition, it can provide valuable insight in surgical planning, particularly if endovascular treatment is planned.[14] Although CTA has largely supplanted angiography in clinical practice, angiography remains valuable in the diagnostic and potential therapeutic management of thoracic trauma, especially at centers without access to ECG-gated CT scanning. With the advent of hybrid operating rooms, intraoperative angiography may lead to more rapid diagnosis and treatment of thoracic vascular injuries in polytrauma patients.[15]

TUBE THORACOSTOMY

Tube thoracostomy is the most common therapeutic procedure performed following thoracic trauma, and it is also one of the most misunderstood and underrated procedures in medicine. Of patients with thoracic injuries who do need surgical intervention, tube thoracostomy is the only invasive procedure that 85% will require. Unfortunately, more than 25% of patients with thoracostomy tubes will encounter some difficulty with malposition, drainage problems, and various complications. One of the most common problems encountered is incomplete evacuation of a hemothorax, resulting in a clotted hemothorax or an empyema. Second and multiple thoracostomy tubes are then frequently inserted as a result of misunderstanding the function of the chest tube and/or improper technique for insertion.

Tube thoracostomy following trauma should be accomplished with adequate anesthesia and analgesia. Trocar-tipped chest tubes should be avoided. Chest tubes are best inserted in the area of the auscultatory triangle in the mid-axillary line in the fourth or fifth intercostal space. Using clamps or dissecting scissors, subcutaneous tissue and muscular dissection is performed to create a track directed posteriorly. The pleura is anesthetized with local anesthetic injection, and the pleural cavity is entered with an exploring finger and not a sharp instrument. Care is taken to avoid injury to the intercostal vessels and nerve on the undersurface of each rib, as this can lead to iatrogenic bleeding and significant pain. Following a gentle, digital exploratory thoracotomy, an appropriately sized thoracostomy tube (32–36F) is directed toward the back and apex of the pleural space and attached to an appropriate collection device. Because this insertion site overlies the major pulmonary fissure, care must be taken to ensure that the tube is not placed in this fissure. On occasion, the location can be determined by preinsertion digital exploration. Autotransfusion of fresh blood from a hemothorax may be considered if preprocedural chest x-ray demonstrates a complete whiteout suggestive of a massive hemothorax—800 to 1500 mL of volume can be recycled this way. Up to 25% of the population has some element of visceral and parietal pleural symphysis, and this can contribute to subcutaneous emphysema in the absence of a pneumothorax. In such

TABLE 27-1: Acute Indications for Thoracotomy

Acute hemodynamic deterioration and cardiac arrest in the trauma center
Penetrating truncal trauma and need for proximal vascular control
Cardiac tamponade
Ultrasound demonstration of hemopericardium
Vascular injury at the thoracic outlet
Massive air leak from chest tube
Endoscopic or radiographic demonstration of tracheal or bronchial injury
Endoscopic or radiographic evidence of esophageal injury
Radiographic evidence of great vessel injury
Missile embolism to heart or pulmonary artery
Traumatic thoracotomy (loss of chest wall substance)

instances, the thoracostomy tube may be inserted into the substance of the lung, rather than the pleural space. Should a pneumothorax or hemothorax actually exist, care must be taken to insert the chest tube into the space containing the blood or air, rather than at a point of pleural symphysis.

INDICATIONS FOR THORACOTOMY FOLLOWING TRAUMA

Approximately 15% of patients with thoracic trauma will eventually require a formal thoracotomy. The classic indications for emergency department or operating thoracotomy after trauma are listed in Table 27-1.[16-25]

TIMING OF THORACOTOMY

Timing of an acute thoracotomy is a function of the immediacy of the life-threatening condition.[26,27] Potentially life-threatening conditions include acute pericardial tamponade, acute and massive blood loss, disruption of ventilation, and decreased cardiac output. Infection, sepsis, pulmonary insufficiency, and other functional impairments may occur secondarily, and any or all contribute to the timing and decision to operate.

Immediate and Emergent

For an acute injury to the heart and immediate loss of cardiac output from reversible conditions such as pericardial tamponade or cardiac perforation or rupture, immediate thoracotomy is indicated. Intubated patients with posttraumatic prehospital external cardiac massage for more than 5 to 10 minutes are unlikely to be resuscitated in the hospital, even with emergency department (ED) thoracotomy (see Chapter 17). Most trauma surgeons and trauma societies agree, however, that resuscitative thoracotomy by qualified personnel is indicated for patients with penetrating thoracic trauma who have less than 15 minutes of prehospital cardiopulmonary resuscitation (CPR).[28,29] ED thoracotomy for patients with blunt injury, especially those with greater than 10 minutes of prehospital CPR and without signs of life upon arrival, has had very limited success. One recent study from the National Trauma Data Bank revealed a 100% mortality rate in 2519 patients over the age of 57 years who underwent ED thoracotomy from 2008 to 2012 for penetrating or blunt trauma.[30] When the team determines a need for an ED thoracotomy, however, such procedures can be individualized and tracked by the hospital's trauma quality review process.

Urgent

An urgent or operating room thoracotomy is performed within 6 hours after injury to control and manage a newly developed life-threatening condition or prevent the development of further deterioration, injury, or infection.

Delayed

In a patient with multisystem trauma, delayed repair of an injured hemidiaphragm or stable injury of the thoracic aorta is appropriate to allow time for stabilization or treatment of a severe injury to the brain and intra-abdominal organs or pelvis.

PATIENT POSITIONS/INCISIONS (SEE ATLAS FIGURE 27)

Most patients undergoing an emergency thoracotomy are positioned supine. This allows for a median sternotomy, right and/or left anterolateral thoracotomy, trans-sternal bilateral anterolateral thoracotomy (clamshell for a wound to the right side of the heart), and partial anterior incisions (see Atlas Figure 28). Furthermore, this positioning allows for concomitant endovascular intervention, laparotomy, and access to the extremities. As previously noted, a left anterolateral thoracotomy through the third or fourth interspace allows exposure for opening the pericardium, open cardiac massage, clamping of the descending thoracic aorta, and treatment of a large percentage of injuries to the heart and left lung. Pitfalls include making the incision too small, injury to the intercostal arteries, and injury to the esophagus or aorta during aortic cross-clamping (see Atlas Figure 35).

For an urgent or delayed thoracotomy, a more targeted thoracotomy may be considered. Approaches to the posterior mediastinum and, at times, the hilum of the lung are via either a right or left posterolateral thoracotomy through the fifth intercostal space. This position and these incisions are best suited for injury to the descending thoracic aorta, esophagus, azygous vein, and the mediastinal trachea and bronchi. If, for whatever reason, the initial approach was via an anterior incision but a predominately posterior injury is found, the anterior incision should be closed. The patient is then reopened in a lateral decubitus position and posterolateral

incision that optimizes exposure and management of the injury, provided that patient is hemodynamically stable. In a hemodynamically unstable patient who is already in a supine position, extension to a clamshell incision will still allow for limited access to the previously mentioned structures.

In the past, one indication for a thoracotomy was the presence of a thoracoabdominal injury, in which a laparotomy incision was extended across the costal margin. In the modern era, thoracoabdominal incisions are rarely used. It is more appropriate to approach injuries in multiple cavities by entering the cavity with the most apparent life-threatening injury first.

THORACIC DAMAGE CONTROL

Damage control operations in the abdomen were among the most important advances in trauma management during the 1990s. These techniques have been applied subsequently to thoracic trauma, although packing an area inside the chest does not have the same damage control utility as when used in the abdomen.[26] Thoracic damage control techniques are, philosophically, a simple approach to a complex problem. Damage control tactics for the patient with thoracic trauma are cited in other chapters of this book and include the following:

1. ED thoracotomy and resuscitation[18-21,23]
2. Pulmonary tractotomy[31]
3. Pulmonary hilar twist[32]
4. Temporary damage control thoracic closure[26]
5. Endovascular treatment of injury to thoracic aortic or great vessel[33]

COMPLICATIONS OF THORACIC TRAUMA

Many of the complications after thoracic trauma will be discussed in the organ-specific injury chapters. For completeness, a few of these complications are briefly discussed here.

Retained Hemothorax and/or Empyema

When a clotted hemothorax persists, video-assisted thoracoscopic surgery or thoracotomy should be used to evacuate it as soon as possible, because this reduces the incidence of posttraumatic empyema.

Fluid Overload and Adult Respiratory Distress Syndrome

Recognized for decades but specifically codified during the Vietnam War, fluid overload and the resultant adult respiratory distress syndrome (ARDS) have become better understood over the past 20 years. The fact that various crystalloids activate inflammatory mediators, as well as contribute to ARDS, is now well described. In addition, it is well recognized that the contused lung is more prone to barotrauma, pneumonia, and fluid overload than the uninjured lung.

Barotrauma

Although higher positive end-expiratory pressure was used for patients with posttraumatic respiratory insufficiency during the 1970s, it is now recognized that high inspiratory pressures and other ventilator forces cause volutrauma/barotrauma to both the bronchial lining and the interstitium of the lung.

Systemic Air Embolism

Vascular air embolism can affect venous return to the heart and the right cardiac circulation. Trauma with injuries to bronchi or bronchioles and pulmonary vein branches can also cause pulmonary venous air embolism, which becomes systemic air embolism. Both are most often iatrogenic, with systemic air embolism being secondary to a pulmonary injury under conditions of increased endobronchial pressures greater than 40 torr. Air embolizing into pulmonary venules moves to the left atrium, producing systemic air embolism, seizures, and ventricular fibrillation secondary to air in the coronary (mostly right coronary given its anterior location when patient lays supine) and cerebral arteries. When it does occur, it is almost always fatal.

Aspiration

Resuscitative efforts in injured patients may contribute to aspiration and some of its more undesirable effects. The insertion of a nasogastric or feeding tube into the pharynx of a fully awake patient with a stomach full of food is conducive to aspiration of vomited gastric contents. Aspiration of water-soluble contrast material (eg, diatrizoate meglumine) into the lungs produces a chemical pneumonitis much more severe than that produced by aspiration of a barium-based contrast material. The insertion of a feeding tube into the bronchus, lung substance, or even the pleural cavity and then subsequent introduction of enteral feedings obviously produces devastating results. Aspiration is best treated by immediate bronchoscopy and lavage to remove solid particles.

Radiation Exposure

Overutilization of chest x-rays, CT scanning, and injections of vascular contrast material has resulted in significant doses of radiation to providers. Controversy persists on the short- and long-term radiologic damage from the many radiologic studies, often unnecessary and duplicative, during the initial evaluation of a trauma patient. Unfortunately, quality review of medical records rarely reveals a preimaging progress note indicating why the test was ordered, what the clinician wanted to learn from the study, or how results might alter decision making. Such progress notes undoubtedly would be beneficial in defending excessive radiation that might be associated with development of lymphoma or leukemia many years later.[11-13]

CONTROVERSIES IN THORACIC TRAUMA

In evaluating and treating patients with thoracic trauma, it is important to recognize that some of the historic approaches are both controversial and lacking in scientific evidence, despite wide popular use.

Resuscitative Endovascular Balloon Occlusion of the Aorta

Resuscitative endovascular balloon occlusion of the aorta (REBOA) is an emerging tool for management of noncompressible torso hemorrhage in patients with traumatic injury below the diaphragm.[34] REBOA is less invasive than resuscitative thoracotomy, may be performed rapidly, and may be performed by a wider variety of trained trauma physicians. Although high-grade evidence is limited for this newer technique, REBOA in skilled hands of trained personnel was shown to offer survival benefit as compared to resuscitative thoracotomy in one recent study of a REBOA registry.[35] The use of REBOA in patients with penetrating thoracic trauma is highly controversial, but some centers are expanding REBOA in this patient population.[36] As with all emerging technologies, high-grade data are limited and deployment should be approached cautiously by appropriately trained personnel, along with rigorous hospital quality review.

Prehospital Resuscitative Thoracotomy

Prehospital resuscitative thoracotomy for patients with penetrating thoracic trauma in extremis can be lifesaving.[37] In some countries, emergency medical services (EMS) have trained personnel to perform resuscitative thoracotomy in patients with penetrating and blunt trauma. In a 15-year database review of the London EMS system, 18% of 71 patients who underwent prehospital thoracotomy survived to discharge.[38] Because many EMS systems do not integrate physicians, such as in the United States, performance of this procedure requires significant resources and training. In addition, the benefit of in-the-field treatment versus rapid transfer to a trauma center must be weighed. New technologies such as REBOA and extracorporeal CPR have the potential to further change the philosophy of prehospital management.[39]

Pericardiocentesis

Resuscitation courses have historically recommended the technique of pericardiocentesis to relieve hemopericardium and cardiac tamponade following cardiac injury. However, trauma surgeons have routinely described clotted blood between the pericardium and heart at emergency thoracotomy for hemopericardium for over a century, and an acutely clotted hemopericardium is not amenable to acute removal via pericardiocentesis. Additionally, surgeons often describe iatrogenic cardiac perforation following an attempted pericardiocentesis for acute trauma. Therefore, pericardiocentesis for acute hemopericardium after trauma is rarely indicated, and emergency thoracotomy, pericardiotomy, and cardiorrhaphy are indicated.

Subxiphoid Pericardiotomy

A subxiphoid pericardiotomy, often performed in the operating room (and sometimes performed in the emergency department) to detect hemopericardium, was introduced as a technique prior to the wide adoption of the FAST examination. The small upper abdominal incision allows for direct drainage of hemopericardium but does not allow for focused cardiorrhaphy. With more precise diagnostic techniques for pericardial fluid, a directed thoracic incision should be used to relieve pericardial tamponade and treat any cardiac injury.

Needle Decompression of Pleural Cavity

Historically, a tension pneumothorax following thoracic trauma was believed to account for significant numbers of deaths in the prehospital and emergency department phases. Insertion of a "decompressing" needle into the pleural cavity has been recommended in many resuscitation courses, despite controlled studies to demonstrate the exact frequency of tension pneumothorax or the specific benefit or utility of needle decompression. Furthermore, tension pneumothorax is undoubtedly more difficult to determine than has been presumed, particularly in a moving ambulance. In agonal or arrested trauma patients, blind thoracentesis is acceptable; unfortunately, actual entrance of available needles into the pleural cavity occurs less than 5% to 10% of the time.

Pledgets in Cardiorrhaphy

Cardiorrhaphy is routinely accomplished during cardiac surgery without the use of adjunctive pledgets in the suture line. Although often used during posttraumatic cardiorrhaphy, this practice is not supported by experience and introduces an unnecessary added step for the surgeon and operating room nurse. Pledgets are only recommended on the rare occasion of significantly bruised myocardium that will not hold sutures or when pressors have created significant intraoperative hypertension during cardiac repair. In elderly patients or those with frail tissue, a tissue reinforcement or patch repair with autologous tissue, such as pericardium, may be beneficial.

Trapdoor Thoracotomy

This combined anterolateral thoracotomy, partial sternotomy, and supraclavicular ("trapdoor" or "book") incision that was popular in the 1970s for injuries to the left thoracic outlet offers little exposure advantage. In addition, it can cause causalgia in the left upper extremity secondary to stretching of the cervical nerve roots. In the current endovascular era, proximal vascular control of the left subclavian artery can be obtained with an intravascular balloon, followed by either endovascular or open repair via a supraclavicular incision.

CONCLUSIONS

1. Improvements in imaging for patients with thoracic trauma have included the E-FAST examination, contrast CT, and CT angiography.
2. The indications for and techniques of thoracotomy have not changed significantly over the past three decades.
3. Early video-assisted thoracoscopy has replaced delayed thoracotomy for the evacuation of a retained hemothorax and has significantly lowered the incidence of posttraumatic empyema.
4. The role of REBOA and extracorporeal CPR in patients with thoracic injuries remains to be defined.

Chest Wall and Lung

Jamie J. Coleman • Fredric M. Pieracci • Joseph J. DuBose • Thomas M. Scalea • James V. O'Connor

KEY POINTS

- Only 7% (blunt trauma) to 15% (penetrating trauma) of patients with thoracic trauma will require a thoracotomy.
- The ribs are flexible, the sharpest angle of the rib occurs posteriorly at the tubercle, and the ribs are furthest apart from one another anteriorly.
- Currently available classification systems for rib fractures include the Organ Injury Scale–Chest, Rib Fracture Score, Chest Trauma Score, and RibScore.
- Both acetaminophen and nonsteroidal anti-inflammatory drugs have been shown to provide comparable analgesia to oral narcotics in trauma patients and should be given routinely to patients with injury to the chest wall.
- Surgical stabilization of rib fractures is currently recommended for patients with a flail segment and a poor response to nonoperative therapy or associated respiratory failure, patients with multiple displaced rib fractures, and patients with multiple nondisplaced fractures that undergo interval displacement and worsening clinical status.
- Prolonged (ie, 7–10 days) trials of nonoperative management in patients with multiple displaced rib fractures increase the risk of pulmonary compromise.
- A large pneumothorax seen on computed tomography, but not detected on a chest x-ray, is most often anterior.
- Indications for a thoracotomy for a hemothorax include initial chest tube drainage (15–30 minutes) of 1200 to 1500 mL or 200 mL/h for 2 to 4 hours.
- Significant injuries to the lung, particularly those from gunshot wounds and away from the hilum, are often best treated with pulmonotomy and selective vascular ligation.
- A "persistent" air leak after 5 to 7 days of drainage of the pleural cavity can be treated with autologous blood pleurodesis, a commercially available sealant, an endobronchial one-way valve, a Heimlich valve, or a thoracotomy.

INTRODUCTION

Injuries to the chest wall and lung are common following both blunt and penetrating trauma. Blunt thoracic injuries are responsible for approximately 8% of all trauma admissions and contribute to 25% of trauma deaths in the United States, with motor vehicle crashes as the most common mechanism.[1-4] The most common injury following blunt chest trauma is rib fractures.[5] In comparison, penetrating chest trauma accounts for 7% of all trauma admissions and 16% of penetrating trauma admissions overall.[6]

The first task in managing patients with injuries to the chest wall and lung is determining the need for emergency intervention. Conditions typically needing emergency intervention are related to either bleeding or a pneumothorax. The majority of patients continue to be successfully managed nonoperatively or with minor procedures. Between 18% and 40% of patients sustaining thoracic trauma can be effectively managed with tube thoracostomy alone, and thoracotomy will be required for only 7% to 15% of patients. Even among those with penetrating chest trauma, only 14% of patients with stab wounds and 20% of patients with gunshot wounds to the chest require emergent thoracotomy.[6]

When emergent operation is required, approximately 30% of patients undergoing thoracotomy require a pulmonary resection. Mortality varies between 5% and 45%.[3] This wide variability is related to differences in mechanism of injury, the inclusion of cardiac and major thoracic vascular injury in some of the datasets, the extent of pulmonary resection performed, and the contribution of concomitant extrathoracic injuries to outcome.[3,7-9]

Although the likelihood of emergency intervention following trauma to the chest wall and lung is relatively low, prompt recognition is imperative to achieve optimal outcomes. In an

era of nonoperative management for many injuries, clinicians caring for trauma patients must appreciate the indications for operation and understand the treatment options in the emergency department as well as in the operating room. Sophisticated judgment is essential when evaluating these injuries in the context of a trauma victim with multiple injuries.

When emergent interventions are not necessary, management is focused on supportive care, specifically in the form of both multimodal analgesia and pulmonary toilet. Fractures of both the ribs and sternum are unique because their involvement in respiration renders them unable to be effectively immobilized following fracture in any way other than surgically. Moreover, painful motion at sternal and rib fracture sites impairs respiration, increasing the risk of splinting, accumulation of secretions, pneumonia, and respiratory failure. Beyond these acute complications, patients with severe chest wall injuries are at high risk of chronic pain, dyspnea, and narcotic dependence.[10]

The traditional treatment of both rib and sternal fractures has been limited to pain control with narcotics and internal pneumatic stabilization with mechanical ventilation in selected patients.[11] The shortcomings of these strategies have been well documented, and contemporary management of chest wall injuries now ideally involves a multidisciplinary, protocolized approach, with selective use of locoregional anesthesia, nonnarcotic oral and intravenous adjuncts, and surgical stabilization.

The field of chest wall injury, and surgical stabilization of rib fractures (SSRF) specifically, has received much interest over the past two decades. At the turn of the century, most trauma surgeons did not recommend SSRF for any rib fracture pattern, nor had they ever been involved in either a rib or sternal repair.[12] More recent data suggest that approximately 7% of patients with three or more rib fractures undergo SSRF[13] and that the incidence of this operation is increasing exponentially.[14] This increase has been accompanied by, and is partially due to, the introduction of several rib-specific fixation systems, as well as SSRF-specific current procedural terminology codes. Finally, multidisciplinary surgical societies devoted specifically to the treatment of chest wall injuries have emerged.[15]

Although the increased interest in chest wall injuries is ultimately beneficial to patients, the trauma community needs to objectively delineate which patients derive the most benefit from each therapy. The vast majority of injuries to the chest wall and lung do not require surgery, underscoring the continuing need for expertise in nonoperative management.

INJURY TO THE CHEST WALL

Anatomy and Taxonomy

The ribs are 12 paired, curved bones that articulate with both the transverse and costal facets of the thoracic vertebral bodies posteriorly. Anteriorly, the first six ribs (true ribs) articulate directly with the sternum via independent costal cartilages, ribs 6 through 10 (false ribs) fuse costal cartilages to articulate with the lower sternum, and ribs 11 and 12 (floating ribs) do not articulate with the sternum. The ribs are bicortical, cancellous bone with a medullary canal, and the thickness of a human rib typically measures 6 to 12 mm.

As opposed to other cancellous bone, ribs possess several unique properties that must be taken into consideration when selecting implants to stabilize fractures, as well as exposing rib fractures surgically.[16] The rib surface is twisted and conical, the extent of which varies from rib to rib. The sharpest angle of the rib occurs posteriorly at the tubercle, and the ribs are furthest apart from one another anteriorly. The ribs are uniquely flexible, a property that is essential to their role in chest wall expansion and retraction during respiration. Rib flexibility is maximal during childhood, and rib fractures in children signify a large amount of force transferred during injury. The ribs are also subject to osteoporosis and fracture most easily in elderly patients. Finally, many chest wall muscles, including the intercostal, scalene, subclavius, and serratus, and the abdominal muscle, the rectus abdominus, either originate from or insert onto the ribs.

The sternum consists of the upper manubrium, manubriosternal joint (a secondary cartilaginous as opposed to a synovial joint), body, and xiphoid process. In addition to the ribs, the sternum articulates with the clavicle at the sternoclavicular joint, an atypical synovial joint. Due to the unique properties of both the manubriosternal and sternoclavicular joints (as opposed to true synovial joints), dislocations have been treated successfully via reduction and fixation.[17,18]

Finally, the scapula represents an oblong bone that articulates with both the clavicle at the acromioclavicular joint and the humerus at the glenohumeral joint. The thin scapular body covers, and is intimately associated with, the first seven ribs posteriorly. The migration of the scapula from lateral to posterior throughout evolution is believed to reflect the importance of the use of the upper limb to wield a spear for hunting.[19] Displaced upper, posterior rib fractures, particularly in conjunction with a scapular body fracture, may cause painful grinding that substantially impairs shoulder mobility (Fig. 28-1).

Organization of the complexity of rib fractures into a unified taxonomy, as has been developed for most other organs, has only recently been undertaken. Most chest wall scoring systems are limited to the number of ribs fractured and the presence of bilaterality. Recently, the Chest Wall Injury Society conducted a Delphi consensus exercise that addressed multiple rib taxonomic issues, including fracture location, degree of displacement, associated fractures in neighboring ribs, and the definition of flail chest.[20] Displacement was divided into three categories based on the degree visualized on axial computed tomography (CT) imaging (Table 28-1). Furthermore, three anatomic sectors were selected to describe the location of rib fractures including anterior, lateral, and posterior. Fractures themselves were further categorized as simple, wedge, or complex. Finally, fractures on consecutive ribs were termed a series of fractures. Although future validation is warranted, this framework represents a starting point to assist in communication among providers regarding chest

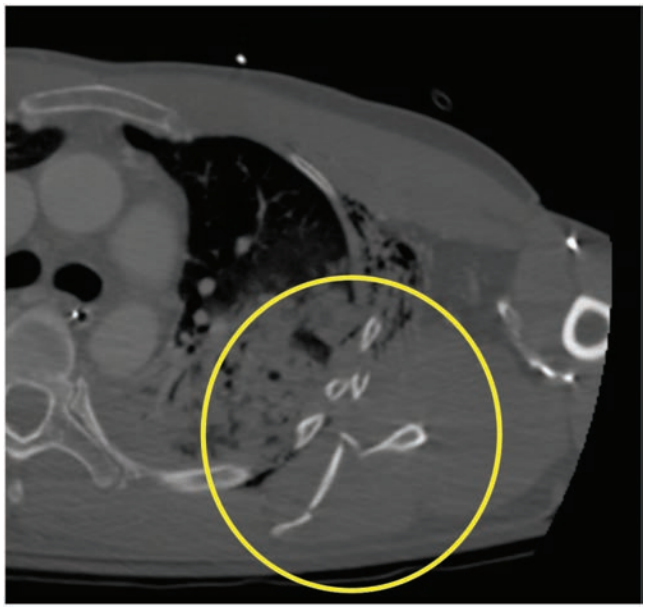

FIGURE 28-1 Displaced, subscapular rib fractures in conjunction with a comminuted scapular body fracture. This injury pattern is particularly morbid with respect to shoulder mobility.

wall injuries, as well as select patients for both invasive therapies and research.

The term *flail chest* was used originally to describe paradoxical motion of a portion of the chest wall with respiration due to multiple, consecutive ribs fractured in more than one location.[21] Respiratory compromise was due to the flail segment moving in opposition to the remainder of the chest wall. When diagnosed clinically, flail chest has had a particularly high mortality historically.[22] More recently, the diagnosis of flail chest has evolved into one that is used most commonly based upon a CT finding of two or more consecutive ribs fractured in two or more places. This ambiguity in definition has hindered research into both the prognosis and management of flail chest, as patients grouped together as having flail chest may in reality range from having clinically insignificant to devastating fractures. To address this dilemma, Edwards et al[20] suggested use of the term *flail segment* to describe the radiologic findings of three or more ribs fractured in two or more places, and the term *flail chest* to describe the paradoxical motion seen on clinical examination.

Initial Evaluation and Stratification of Risk

The initial evaluation of the patient with a suspected injury to the chest wall involves the primary and secondary surveys. Findings on physical examination concerning for rib fractures include tenderness over the chest wall, crepitus, bruising, and deformity, typically with a depressed segment of the chest wall. Rib and sternal fractures are commonly associated with pulmonary and cardiac contusions, respectively, as well as pneumothorax and hemothorax.

The initial imaging modality in patients with suspected chest wall injury is the chest x-ray. Chest x-ray is useful in terms of ruling out life-threatening injuries that require immediate attention in the trauma bay, such as a pneumothorax or hemothorax. Unfortunately, the sensitivity of chest x-ray for detecting both rib and sternal fractures is low when compared to CT.[23] Multiple studies have documented that CT identifies significantly more rib fractures, as well as both pleural and mediastinal pathology, as compared to a chest x-ray[24-26]; however, the clinical significance of these injuries remains uncertain. Many of these studies were performed prior to widespread use of both locoregional anesthesia and SSRF. Chapman et al[27] found that over half of patients with rib fractures had at least three additional rib fractures discovered on CT, as compared to a chest x-ray. Furthermore, these patients were more likely to undergo admission to an intensive care unit, locoregional anesthesia, or SSRF. Currently, it seems reasonable to perform CT of the chest in patients with three or more rib fractures visualized on chest x-ray after blunt trauma, those who require a CT chest for another reason, or those with physical exam findings discordant with the chest x-ray. Three-dimensional reconstructions of the CT chest are now routinely available; however, their routine use has not been shown to alter decision making or improve outcomes.

Even when radiologic data are made available, risk stratification of patients with rib fractures by clinicians is highly variable, as previously noted.[28] Several injury scoring systems for the chest wall have been developed in order to assist in clinical decision making. Challenges in the development of a scoring system for chest wall injury involve capture of the

large number of injury permutations, as well as the patient's pulmonary physiologic response to them, in a single, reproducible score. Scoring of patients with rib fracture at the most basic level involves summing the number of ribs fractured. A direct relationship has been observed by multiple authors between the total number of ribs fractured and adverse pulmonary outcomes, with a specific number of six ribs fractured suggested to serve as a threshold above which mortality is significantly increased.[29-32] More recently, the degree of displacement of rib fracture has also been correlated with adverse outcomes.[33]

A number of scoring systems for chest wall injury, summarized in Table 28-2, have been published, each incorporating a unique set of demographic, physiologic, and radiographic parameters.[34-39] Of these scores, the RibScore[38] includes the most detailed information on rib fracture pattern and has been validated most extensively.[40] In practice, these static scores are limited by subjectivity in data abstraction, as well as failure to incorporate the patient's physiologic response to injuries. Because of these limitations, their utility in guiding invasive therapies is relatively limited. These scores do, however, serve as a common language for communication among providers as to the degree of anatomic injury.

Dynamic assessments of a patient's physiologic response to a chest wall injury are required to guide invasive therapies, as well as address the common observation that two patients with similar demographic and radiographic findings may demonstrate vastly different phenotypic responses to injury. One commonly used dynamic measurement is the pulmonary vital capacity, which is relatively easy to perform at the patient's bedside and has been found to be associated with pulmonary complications.[41,42] Recently, the vital capacity, in addition to the numeric pain score, cough quality, and respiratory rare, were combined to create a Sequential Clinical Assessment of Respiratory Function (SCARF) score, a dynamic score that, when measured daily, correlates with adverse pulmonary outcomes.[43] Additional dynamic, pulmonary physiologic scores have since been reported and represent an important next step in real-time risk stratification of patients with injuries to the chest wall.[44]

Regardless of the scoring system used, an objective, reproducible metric should be employed consistently when assessing the patient with chest wall injury. Furthermore, it is recommended that trauma centers caring for such patients protocolize management. One such admission protocol is shown in Fig. 28-2. In general, admission algorithms have been shown to minimize variability in practice, decrease length of stay in the emergency department, and improve outcomes of patients with chest wall injuries.[39,45] Protocol details will be dictated by both the institution's patient population and available resources. One common aspect, however, should be that the protocol is reevaluated at regular intervals and modified to include contemporary evidence.

Nonoperative Management

The cornerstones of nonoperative management of patients with chest wall injury are analgesia and pulmonary toilet. Pain may be secondary to irritation of the pleura and pericardium with blood; fractures of the ribs, sternum, clavicle, and scapula; contusion of the chest wall muscles; or cutaneous lacerations, burns, and road rash. The chest wall cannot be effectively immobilized due to respiration, so nonoperative analgesia is thus centered on interrupting its sensory innervation.

Analgesics may be categorized broadly into systemic and locoregional. The term *multimodal analgesia* refers to the use of different classes of analgesics simultaneously to manage pain. Multimodal analgesia should be employed routinely in the management of patients with chest wall injuries in order to target multiple pathways involved in pain sensation. In general, a tiered approach, in which potency is escalated sequentially and based on objective measurements of response to therapy (eg, the vital capacity), should be employed. It is also important to standardize analgesia to minimize variability and allow for optimal data collection and outcomes analyses. One such example of a standardized, tiered analgesic practice management guideline is shown in Fig. 28-3.

Unfortunately, narcotics continue to be used indiscriminately for analgesia in patients with chest wall injuries. This is due to a perceived lack of effective alternatives and a well-intentioned but misguided focus on pain as the "fifth vital sign." The United States consumes a disproportionate amount of opioids, and in many centers, opioid overdose has now surpassed trauma as a reason for visits to the emergency department.[46] In addition, narcotics have unfavorable side effects such as somnolence, constipation, and respiratory depression, which are particularly disadvantageous in patients with injury to the chest wall. Although many patients with rib fractures will require narcotics to control pain, these medications should be used in a protocolized fashion and only after nonnarcotic alternatives have been exhausted.

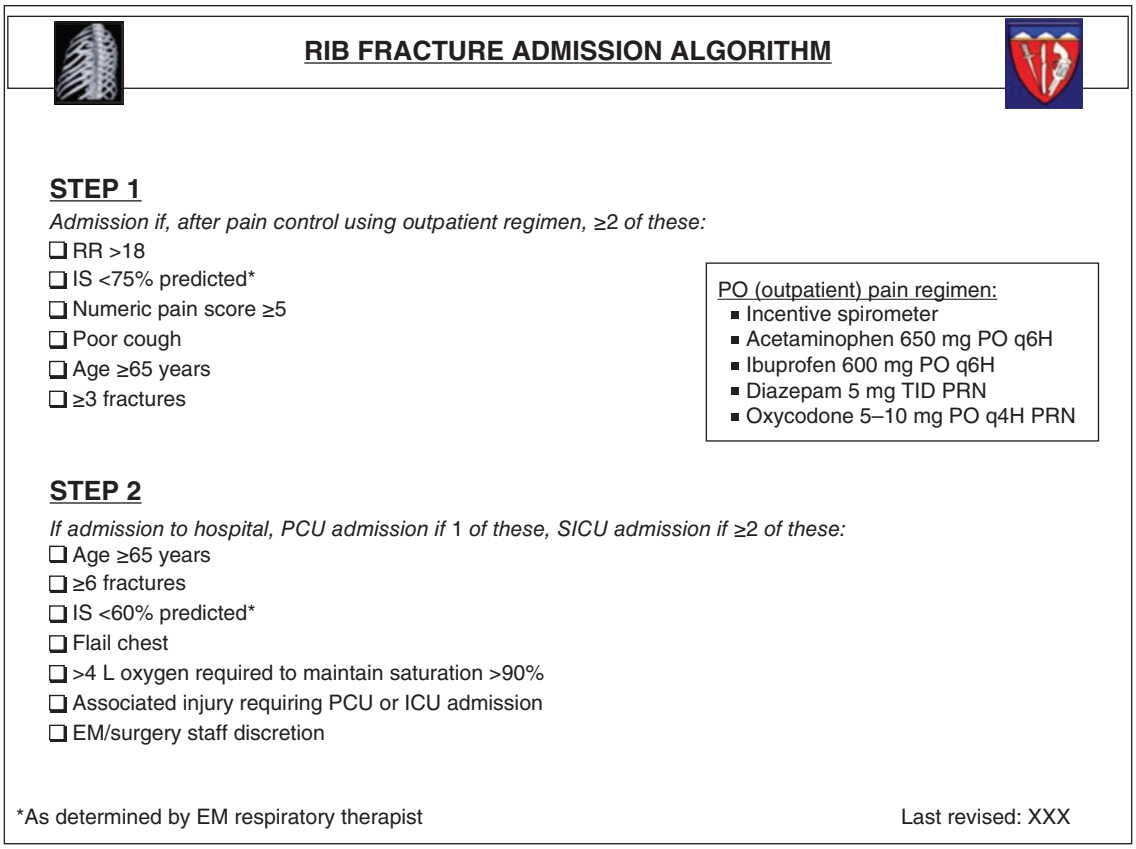

FIGURE 28-2 Denver Health Medical Center admission algorithm for patients with rib fractures. Both acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) have been shown to provide comparable analgesia to oral narcotics in trauma patients and should be given routinely to patients with chest wall injury.[47] The contention that NSAIDs either increase bleeding risk or impair bone healing has been disproven.[48,49] Muscle relaxants, such as diazepam and cyclobenzaprine, may provide additional relief, although their efficacy in patients with rib fractures is largely unproven. Recently, novel narcotic alternatives such as oral gabapentin,[50] ketamine infusion,[51] and lidocaine infusion[52] have been evaluated specifically in patients with rib fractures. Although initial results have been underwhelming, their use has continued to increase in this patient population, and current studies are underway employing increased dosing regimens.

Locoregional anesthesia for rib fractures refers to therapy targeted to the intercostal innervation specifically and is applicable anywhere from the spinal cord to the terminal rami of the intercostal nerves. A thoracic epidural catheter is the most extensively studied locoregional anesthetic modality. Despite only being used in 3% of patients hospitalized with rib fractures, it is associated with decreased morbidity and mortality as compared to no locoregional anesthesia.[13,53,54] Alternatives to epidural anesthesia, including ultrasound-guided erector spinae and paravertebral catheters, eliminate the risk of an epidural hematoma and may be placed in the setting of a coagulopathy and irrespective of ongoing anticoagulation.[55] Surgeon-driven locoregional modalities, including continuous intercostal nerve block and video-assisted thoracoscopic surgery (VATS) intercostal nerve blocks with liposomal bupivacaine, carry the added advantage of intraoperative placement under direct visualization.[55-57] In practice, the choice of a locoregional modality will depend on the patient's injury pattern and local expertise. Some form of locoregional therapy, however, should be employed in all patients with rib fracture who do not respond to initial tiered therapy with multimodal agents. A recent practice management guideline from the Eastern Association for the Surgery of Trauma for pain management conditionally recommended routine use of both multimodal analgesia and thoracic epidural analgesia specifically in patients hospitalized with blunt thoracic trauma. The authors recognized, however, that the use of locoregional anesthesia itself was more important than the specific type selected.[58]

Indications for Surgery

SSRF is now performed routinely at most high-volume trauma centers.[14] Although familiarity with the technique of SSRF has improved markedly among trauma surgeons, ambiguity

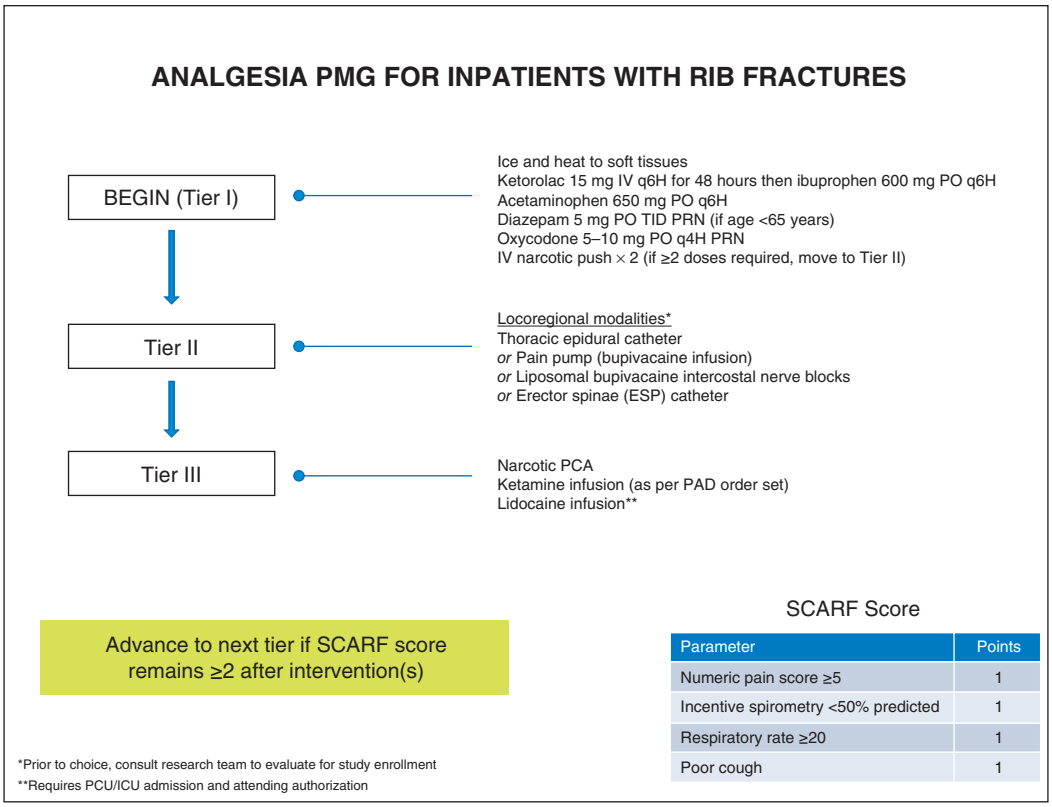

FIGURE 28-3 Denver Health Medical Center practice management guideline (PMG) for analgesia in patients with rib fractures. ICU, intensive care unit; IV, intravenous; PAD, pain, agitation, and delirium; PCA, patient-controlled analgesia; PCU, progressive care unit; PO, oral; PRN, as needed; q4H, every 4 hours; q6H, every 6 hours; SCARF, Sequential Clinical Assessment of Respiratory Function; TID, three times a day.

remains regarding the indications for surgery. Randomized controlled trials,[59-62] prospective nonrandomized trials,[63] and meta-analyses[64-67] have all shown improved outcomes with SSRF in terms of respiratory morbidity, length of stay, resource utilization, and, in some cases, mortality. Although sparse, data addressing long-term outcomes in patients with a flail chest managed operatively have also been favorable.[12,68,69] Accordingly, consensus documents conditionally recommend consideration of SSRF in all patients with flail chest.[52,70] It is important to note that the trials on which these recommendations are based vary widely in terms of the definition of flail chest, injury severity, time from injury to surgery, and surgical technique. In practice, SSRF should not be undertaken based on a radiographic finding of a flail segment alone. Rather, patients with a flail segment in conjunction with either a poor response to nonoperative therapy or respiratory failure due to rib fractures will likely derive the most benefit from surgery. The importance of patient selection is underscored by recent retrospective data suggesting little or no benefit of SSRF in certain cohorts of patients with a radiographic flail segment.[71-73]

Patients with multiple displaced rib fractures, in the absence of a flail segment, may also benefit from SSRF, although there are fewer data to support this recommendation. Many of the same pathophysiologic principles of flail chest such as painful motion at the fracture site causing splinting, displacement increasing the risk of nonunion, and risk of bony bridging to neighboring fracture fragments over time apply (Fig. 28-4). Several prospective studies have included patients with three or more bicortically displaced fractures, along with patients with a flail segment, and found benefit to SSRF.[74-78] One survey found that, in addition to the presence of three or more displaced fractures, at least two deranged pulmonary physiologic variables were required in order for respondents to recommend SSRF.[79] Multiple prospective trials that include patients with displaced fractures in the absence of a flail segment are currently underway. Pending the results of these studies, SSRF in this situation should be considered on a case-by-case basis and in the setting of a poor response to multimodal analgesia.

There is currently no evidence to support SSRF for nondisplaced fractures. Nondisplaced rib fractures, however, may undergo interval displacement due to patient motion, static and dynamic forces of chest wall muscles, and changes in intrathoracic pressure (Fig. 28-5). Patients with multiple nondisplaced fractures, and particularly those who worsen clinically, may warrant repeat CT imaging 48 to 72 hours after injury to assess for interval displacement, in which case SSRF may be reconsidered.

Additional potential indications for surgery include the following: (1) one or two painful, clicking, mobile rib

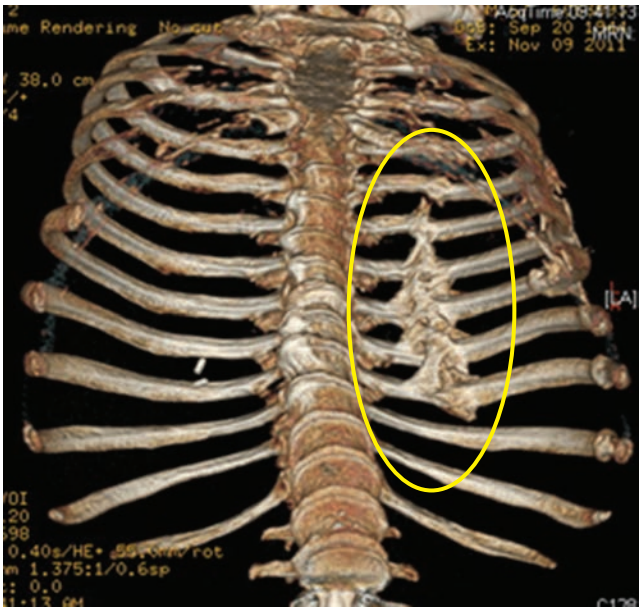

FIGURE 28-4 Bony bridging caused by multiple displaced posterior left-sided rib fractures. The consequences of the bridging for this patient were manifest as chronic dyspnea and a restrictive pattern on pulmonary function testing. (Reproduced with permission from Marasco S, Liew S, Edwards E, Varma D, Summerhayes R. Analysis of bone healing in flail chest injury: do we need to fix both fractures per rib? *J Trauma Acute Care Surg.* 2014;77(3):452-458.)

FIGURE 28-6 Impalement of the diaphragm and left lower lobe by a tenth rib fracture.

fractures in a highly functional patient (eg, professional athlete); (2) rib fracture impalement of internal organs, such as the lung, diaphragm, and spleen (Fig. 28-6); (3) "on the way out" of the thoracic cavity for other indications; and (4) following elective rib fracture or removal, as in the case of thoracic spine exposure. These indications have not been studied specifically, and recommendations are based on expert opinion as opposed to outcome data. Of these indications, painful clicking and impalement are most consistent with the benefits seen after SSRF in more severe injury patterns.

Contraindications to SSRF fall into three broad categories as follows: (1) patients who will not benefit from surgery; (2) patients who will likely benefit from surgery, but it must be delayed secondary to higher priority injuries; and (3) patients who may benefit from surgery and are undergoing a trial of nonoperative management in order to determine if it is needed. In general, patients who will require long-term mechanical ventilation for reasons unrelated to their chest wall injury will not benefit from SSRF, regardless of the pattern of rib fracture. Common examples of this clinical scenario include an associated severe traumatic brain injury, high spinal cord injury, and anoxic brain injury following cardiac arrest with some period of cardiopulmonary resuscitation (and a resultant anterior flail segment). Although there may be rare exceptions to this recommendation (eg, a patient with mild to moderate traumatic brain injury with a severe flail chest unable to wean from mechanical ventilation), SSRF in these patients should not be undertaken.

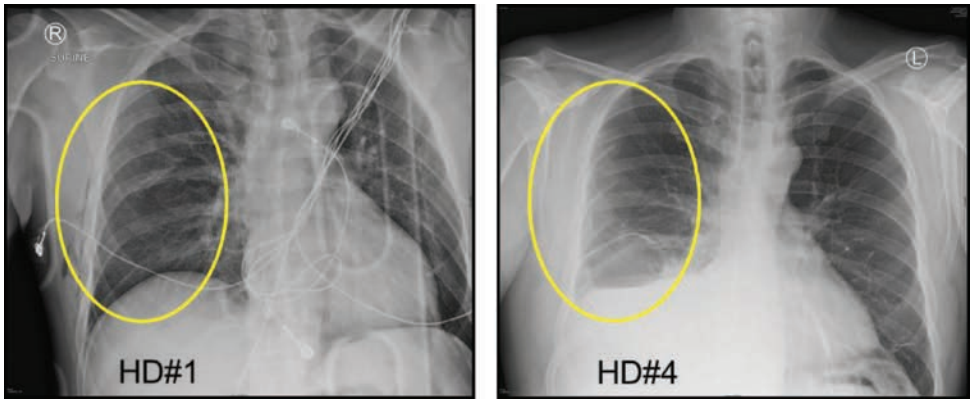

FIGURE 28-5 Interval displacement of right posterolateral rib fractures from hospital day 1 (HD#1) to hospital day 4 (HD#4). Note also the development of a right hemothorax.

One particular associated diagnosis that has received scrutiny in the literature is pulmonary contusion. An early report of SSRF in patients with severe pulmonary contusions concluded that surgery should not be undertaken, arguing that the main reason for pulmonary morbidity is the contusion itself, as opposed to the chest wall injury.[80] This study was limited by a small sample size, a relatively long interval from injury to surgery, and confounding by associated injuries. More recent studies have reported favorable outcomes after SSRF in patients with mild to moderate pulmonary contusions, and this diagnosis in and of itself should not be considered an absolute contraindication to surgery.[81] In practice, clinical judgment must be exercised regarding stability for transport to the operating room, positioning, and potential single-lung ventilation.

Pleural space infection has been considered a contraindication to SSRF due to the risk of postoperative infection in implanted hardware. The overall risk of hardware infection after SSRF is, however, less than 5%, and successful rib fixation with permanent hardware has been reported in the setting of severe pleural space infection.[82,83] The efficacy of SSRF in the setting of empyema remains to be determined.

Preinjury anticoagulation is not associated with worsened outcomes following either rib fractures or SSRF and is not considered a contraindication to surgery.[84] Open rib fractures are rarely encountered but may be considered for repair with permanent hardware after irrigation of the wound bed and in the setting of adequate soft tissue coverage of the hardware.

Elderly patients have traditionally been excluded from studies of SSRF due to a presumption that surgery would be poorly tolerated.[59] More recent data have suggested that the geriatric population may benefit even more from SSRF as compared to younger patients.[76,85] This benefit may be derived from the relative inability of elderly patients to tolerate the pain and respiratory depression from unstable fractures. Pending further data, SSRF should remain a treatment option for elderly patients with severe injuries to the chest wall.

Certain associated injuries preclude early SSRF, including shock with active resuscitation, intracranial hypertension, unstable spine injury, rupture of the thoracic aorta, and inability to position patients either prone or decubitus due to physiologic instability or implanted devices (eg, external fixator on pelvis or extremity). In these cases, patients require stabilization prior to SSRF. In the absence of these conditions and when indicated, SSRF should be performed as soon as possible following injury and ideally within 48 hours. Delays in surgery expose the patient to additional pulmonary morbidity from unstable fractures, prolong the time to definitive drainage of the pleural space (and potential provision of guided locoregional anesthesia), and increase the amount of tissue edema and inflammation. A multicenter study of time to SSRF found that, after adjustment for injury severity, outcomes were improved when surgery was performed within 48 hours.[86] These findings have been replicated in a subsequent single-institution analysis.[87] In addition to the aforementioned factors, time to surgery is commonly delayed due to lack of availability of surgeon and operating room. Therefore, trauma centers that perform SSRF with regularity are encouraged to develop a pathway to ensure operating room access for patients with severe injuries to the chest wall within 48 hours, similar to recommendations for other orthopedic injuries.[88]

In certain patients, the benefit of SSRF may not be certain at the time of initial assessment and imaging, so a trial of nonoperative management is warranted. One example of this situation might be a patient with three displaced fractures and marginal pain control after locoregional anesthesia. In general, trials of nonoperative management should be both standardized and brief, such that patients who fail do so early and before respiratory consequences occur. In general, patients who require locoregional anesthesia for three or more displaced rib fractures should be assessed for response within 12 hours, at which time the decision for surgery is made. Prolonged (ie, 7–10 days) trials of nonoperative management expose patients to the risks of pulmonary compromise, while delaying stabilization.

Indications for surgery in sternal fractures are less established as compared to rib fractures. Most surgeons who perform sternal fracture repair with regularity cite visible deformity, loss of sternal continuity, complete displacement, sternomanubrial joint dislocation/fracture, and persistent sternal mobility/clicking as indications for repair (Fig. 28-7).[89]

Surgery to repair chronic nonunions of rib and sternal fractures differs in many ways from acute SSRF, including indications, surgical technique, and likelihood of success.[90-92] In general, delayed fixation should be undertaken by surgeons with expertise in the management of bony nonunion, as these fractures routinely require reaming, gap bridging, and some form of bone grafting. Although some success in terms of pain relief has been reported in cases of painful clicking at the fracture sites,[93,94] the success of delayed SSRF is far lower than in the acute setting. When indicated, the surgery should be performed early during the index hospitalization.

Operative Technique

The surgical technique of rib repair has undergone refinement from the relatively morbid posterolateral thoracotomy to muscle-sparing, minimally invasive approaches. Although videoscopic extrathoracic[95,96] and intrathoracic[97,98] SSRF approaches have been described, most operations are performed via open incisions and using permanent plates and screws.

Prior to surgery, the patient's chest CT should be reviewed systematically in order to determine which fractures will be repaired. A data collection tool on which rib fractures can be checked off serially as they are repaired can be helpful to display in the operating room. (Fig. 28-8). In general, fractures of ribs 3 to 10 should be considered for repair. Fractures of ribs 1 and 2 are relatively difficult to access surgically and contribute minimally to respiratory function. Similarly, fractures of the floating ribs typically do not cause significant pain or pulmonary embarrassment. One exception may

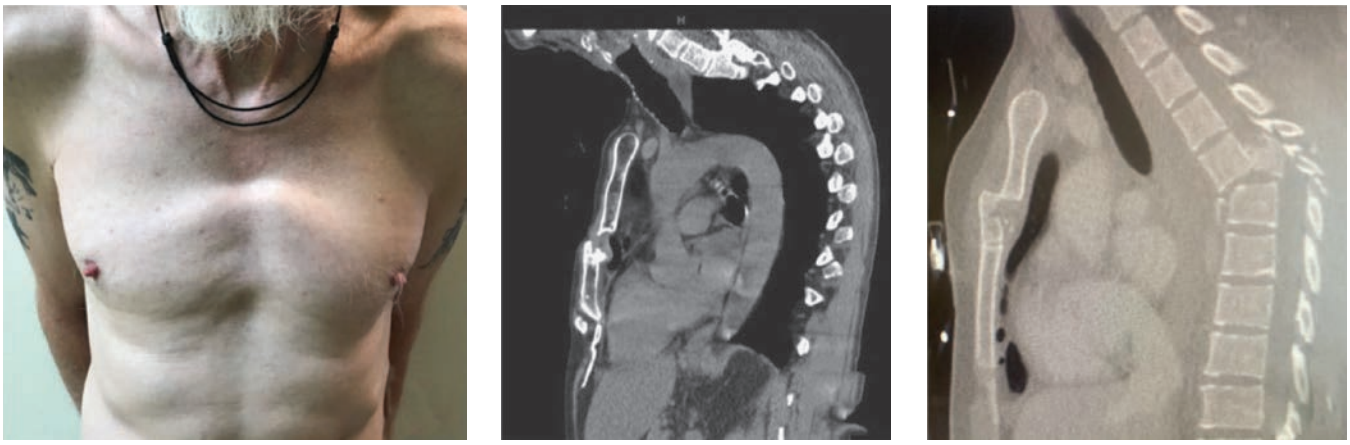

FIGURE 28-7 Examples of sternal fractures that underwent operative repair: (**A**) visible deformity; (**B**) loss of sternal continuity; (**C**) sternomanubrial joint fracture/dislocation with associated T6 vertebral body fracture.

be impalement of the liver, spleen, diaphragm, or kidney, in which case the fracture fragment may simply be resected. In general, at least 3 cm of distance is required between a posterior rib fracture and the transverse process to successfully place a plate. Practically, fractures within 5 cm of the transverse process should not be repaired, because the exposure required and the stability afforded by overlying muscle and ligaments in this area likely mitigate any additional benefit from surgical fixation. Anterior fractures may be stabilized to either the costal cartilage and/or the sternum.

Multiple fractures, as seen in a flail segment, should all be repaired. Although repair of single fractures (usually anteriorly) will theoretically eliminate the pathophysiology of flail chest, instability in the other fractures remains and places the patient at risk of both persistent pain and bony bridging.[99] Finally, there is no evidence to support an "every other" approach of rib fracture repair. Rather, it is recommended to repair each rib because the morbidity is relatively low and the untreated fractures may remain symptomatic, although this is not the practice in many centers.

Conceptually, both positioning and incision placement are dependent upon the location of fractures. Furthermore, incisions should be based on the borders of chest wall muscles as opposed to directly overlying the fractures such that muscles may be retracted as opposed to divided. Lateral rib fractures may be approached with the patient in the lateral decubitus position and through a 7- to 9-cm longitudinal incision, placed along the anterior border of the latissimus dorsi muscle and coursing obliquely (Fig. 28-9). The anterior border is then incised, and a flap is raised underneath the muscle

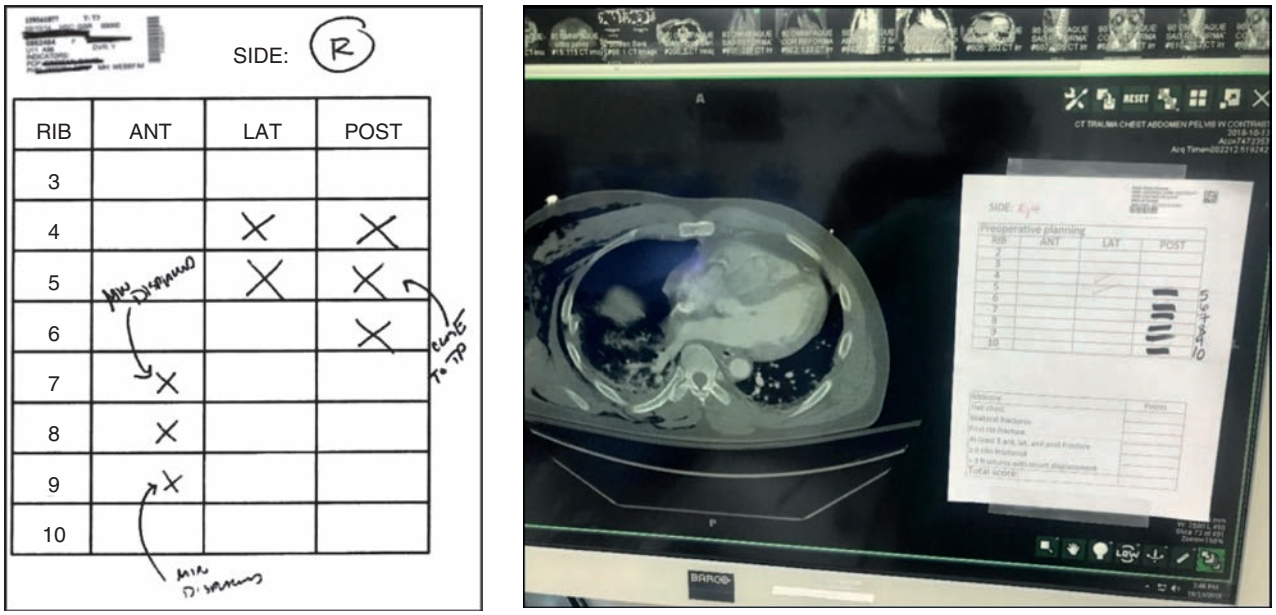

FIGURE 28-8 Example of a standardized data collection tool for preoperative planning of surgical stabilization of rib fractures. The tool is displayed alongside the patient's imaging so that fractures are checked off intraoperatively after they are repaired.

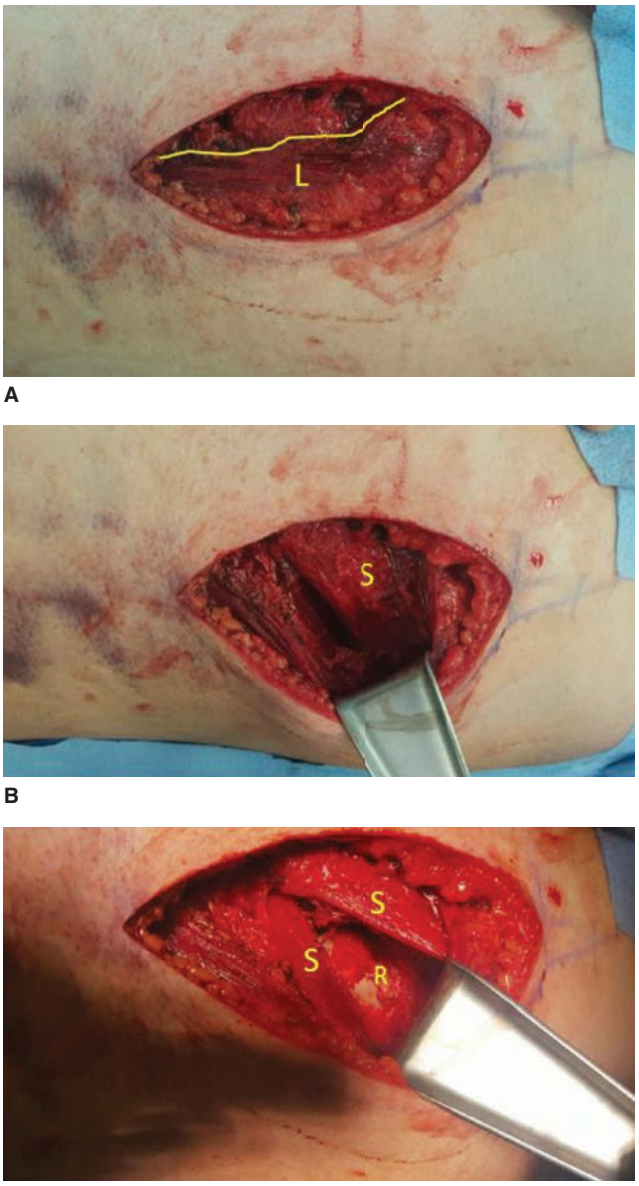

FIGURE 28-9 Surgical approach to lateral rib fractures. (**A**) The medial border of the latissimus dorsi muscle (L) is incised and a sublatissimus flap is raised. (**B**) The serratus anterior muscle (S) is split along the direction of its fibers. (**C**) The rib fracture (R) is encountered under the serratus anterior muscle (S).

such that it may be retracted posteriorly. This exposes the muscle branches of the serratus anterior, which may be split to expose the rib fractures. Care must be taken at this point to avoid injury to the long thoracic nerve, which courses down the anterior axillary line and superior to the serratus anterior muscle. Typically, three to five sequential fractures may be exposed through a single split of the serratus anterior muscle.

Anterior fractures may be exposed with the patient in the supine position and through an oblique incision along the inframammary fold. A subpectoral flap is then developed, which provides excellent exposure to anterior ribs 4 to 6. Anterior fractures of the third rib may be approached through a small horizontal incision directly over the fracture, with splitting of the fibers of the pectoralis major and minor muscles.

Posterior fractures are typically the most difficult to repair due to proximity to the transverse processes of the spine, angulation of the ribs, and subscapular location. These fractures may be approached with the patient in the prone position and the ipsilateral arm supported on a table that is lowered approximately 8 in relative to the operating table. This maneuver allows for lateralization of the scapula and facilitates exposure of posterior, subscapular fractures. A longitudinal incision is then made just medial to the scapular tip, and the triangle of auscultation is developed, raising both subtrapezial and sublatissimal flaps. This exposure also affords the opportunity to simultaneously address thoracic spine fractures (Fig. 28-10).

Patients with a flail segment typically have a combination of either anterior and lateral fractures or lateral and posterior fractures. Either fracture pattern may be approached through two of the incisions described earlier. Alternatively, a traditional posterolateral thoracotomy may be used. Another common fracture pattern is an anterior flail chest with bilateral anterior fractures. This fracture pattern may be exposed via bilateral inframammary incisions.

In addition to rib repair, SSRF affords an opportunity to perform pulmonary toilet, evaluate and manage intrapleural pathology, and provide guided locoregional anesthesia. The ideal approach involves routine use of both bronchoscopy and VATS during SSRF. Routine pleural irrigation at the time of SSRF is associated with a decreased likelihood of subsequent retained hemothorax, and resection/repair of lung parenchymal injury at the time of VATS decreases both duration of postoperative chest tubes and risk of infection.[100,101] Additional advantages of routine VATS include diagnosis and repair of occult injuries to the hemidiaphragm, instillation of directed locoregional anesthesia, directed placement of chest tubes, and education of surgical trainees.

Sternal repair was first undertaken in 1943 using a Kirschner wire.[102] Since then, permanent plates have become the standard modality of fixation, although absorbable plates have also been used.[103,104] The surgical technique consists of a midline, longitudinal incision exposing the fracture, evacuation of the surrounding hematoma, and debridement of nonviable tissue. Reduction forceps are then introduced laterally into the surrounding intercostal spaces, being careful to avoid injury to the internal thoracic vessels. Bicortical fixation is recommended, with screw length estimated by CT and intraoperative calibration.

Complications of Surgery

The incidence of complications following SSRF appears to be less than 5%,[82,105-107] although long-term follow-up has not been reported in most series. Intraoperative complications can involve inadvertent injury to chest wall nerves, intercostal vessels, and lung parenchyma. The nerves most commonly

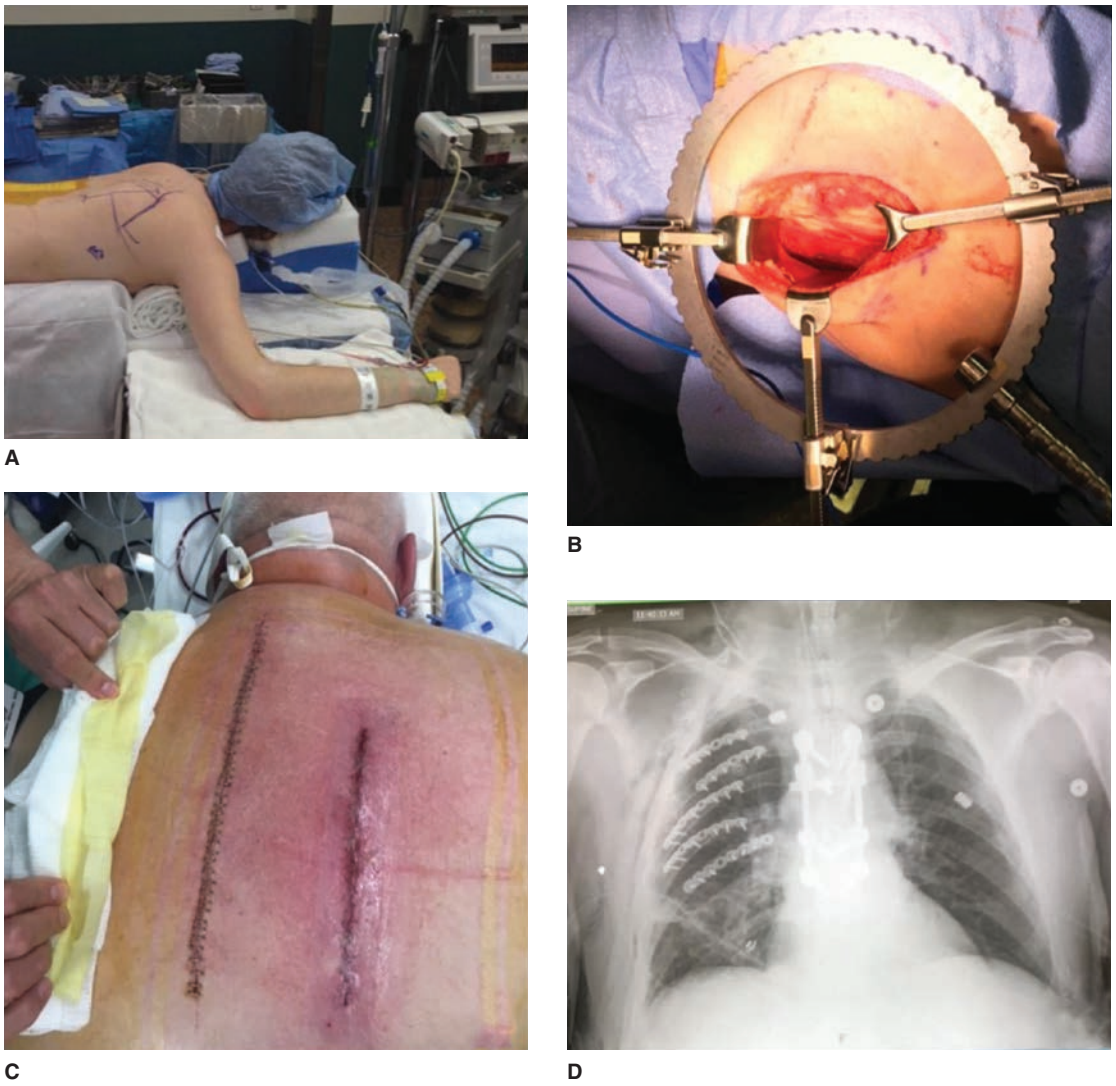

FIGURE 28-10 Positioning and exposure for posterior rib fractures. (**A**) The patient is positioned prone with the ipsilateral arm lowered in order to retract the scapula laterally. (**B**) A longitudinal incision is made over the triangle of auscultation. Note the erector spinae fibers at the base of the incision and the use of a self-retaining retraction system. (**C, D**) Simultaneous thoracic spine and posterior rib fractures.

encountered during SSRF are the long thoracic nerve during high lateral and axillary exposures, spinal accessory nerve during high posterior exposures, and the lateral cutaneous branches of the intercostal nerves in both. Although these nerves course in a usual location, injury leading to scapular and abdominal muscular dysfunction has been reported.[108,109]

Immediate postoperative complications are mostly due to bleeding, which may arise from injury to intercostal vessels or muscle bleeding from raising flaps. Surgical drains have not been shown to mitigate this risk and do not substitute for meticulous hemostasis at the time of surgery. Deep surgical site infection requiring hardware removal occurs in approximately 1% of cases of SSRF and is associated with an increased body mass index and hemorrhagic shock on presentation. Junker et al[110] recently reported an algorithm for management of suspected hardware infection, as well as a favorable salvage rate from hardware using antibiotic beads.

Late dislodgement and migration of hardware also appear to be relatively rare following SSRF.[107] The most common location for hardware to fail is posteriorly, likely due to both the angulation of the rib and shear forces exerted on the plate by the serratus muscles.[106] Most cases of hardware dislodgement are asymptomatic and occur long after the fracture has healed. Certain cases will result in uncomfortable, palpable subcutaneous hardware that may require removal. Absorbable plates, although not widely developed to date, may eliminate this risk.

Intercostal Muscles, Costal Cartilage, and Costal Margin

The costal cartilages, interchondral joints, and costal margin–diaphragm interface represent an interrelated group of structures, the injuries to which are largely unappreciated.[111] Fractures of the costal cartilages have been reported predominantly in

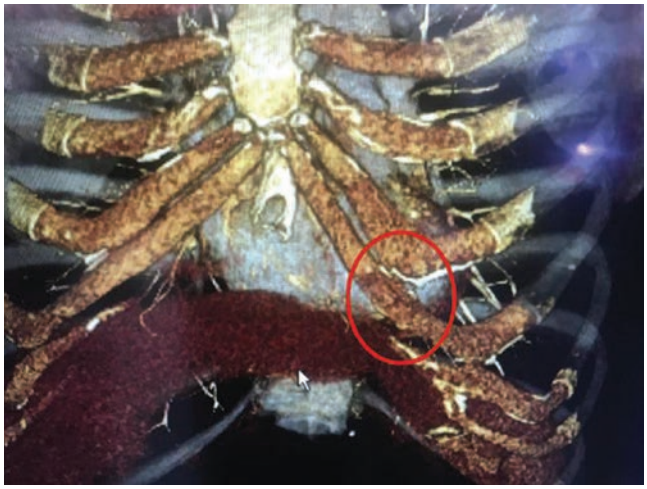

FIGURE 28-11 Computed tomography chest reconstructions formatted to costal cartilage and demonstrating an acute fracture of the left seventh costal cartilage.

the setting of professional contact sports.[112,113] Because diagnosis of these injuries is often delayed due to normal imaging, persistent pain and point tenderness should prompt three-dimensional reconstruction of the chest CT formatted specifically to cartilage[114] (Fig. 28-11). Although the results are favorable, data supporting the efficacy of surgical repair of costal cartilage fractures are limited to case reports.[115]

Costal margin rupture, with or without involvement of the diaphragm and intercostal muscles, represents a rare, elusive injury. Gooseman et al[116] recently proposed a unifying classification of such injuries to guide treatment. This system recognizes the spectrum of pathology, which may involve a tear of the diaphragm, through the costal margin, and finally one or more intercostal muscles and ribs. Injury to both intercostal muscle and costal margin should be suspected in the presence of posterior rib fractures and splaying of the ribs anteriorly on a CT of the chest. In extreme cases, complete loss of intercostal muscle may result in pulmonary herniation and necrosis (Fig. 28-12).[117] Management of these complex injuries may require a combination of suture cerclage of the ribs and costal cartilage/margin, intrathoracic mesh or extrathoracic mesh placement, and suture repair of the diaphragm.

INJURY TO THE LUNGS

Although physiologically complicated, the lungs are anatomically simple, consisting primarily of alveoli and blood vessels. The paired large pulmonary artery and vein are high-volume, low-pressure circuits (see Atlas Figures 32 and 33). The bronchial vascular bed is characterized by a higher systemic pressure but relatively small-caliber vessels. The anatomic simplicity of the lungs lends itself to a limited parenchymal response to trauma regardless of the severity and mechanism of injury. The alveoli can rupture, causing a pneumothorax. Compressed, contused, or otherwise mechanically disrupted pulmonary parenchyma can also lead to pulmonary contusion, compromising the ability of the injured lung to perform its basic functions. Hemothoraces are common, with up to 300,000 cases each year, and can result from bleeding of the injured parenchyma itself or the vasculature of the chest wall, particularly the intercostal and mammary arteries.[118,119] Associated bony injuries to the chest wall can increase respiratory compromise and distress.

Very large pneumothoraces produce tension by shifting the mediastinal structures toward the contralateral side with resulting anatomic distortion. This increase in intrathoracic pressure leads to decreased venous return, decreased cardiac output, and, if untreated, cardiac arrest. In contrast, large hemothoraces generally produce symptoms through the effects of hypovolemia, although a massive hemothorax may also produce tension physiology.

Presentation and Evaluation

Any patient with blunt or penetrating chest trauma is at risk for injury to the lung. The mechanism of injury, time from injury, vital signs, and neurologic status at the scene and any changes during transport are critical components of an adequate history, which can guide both rapid evaluation and treatment.

Physical examination alone may confirm the diagnosis of an injury to the lung. The presence of distended neck veins, tracheal deviation, subcutaneous emphysema, chest wall instability, absent breath sounds, or muffled heart sounds can provide crucial information allowing for both prompt diagnosis and treatment of a tension pneumothorax. Vital signs should be frequently monitored, with careful attention to the work of breathing and arterial saturation. Hypoxia and increased work of breathing may be manifested by anxiety, confusion, combative behavior, dyspnea, or the use of accessory muscles. Findings of subcutaneous air or decreased breath sounds should alert the clinician to the possibility of a closed or tension pneumothorax and/or hemothorax. Prompt placement of a 36F to 38F thoracostomy tube or 8.3F to 14F pigtail catheter if only a pneumothorax is present in an unstable patient is imperative because radiographic confirmation

may delay treatment and lead to further physiologic derangement (see Atlas Figure 21).

Hemodynamic instability in a patient with penetrating thoracic trauma is virtually always an indication for operative exploration. Conversely, hemodynamically stable patients with penetrating or blunt thoracic injury may benefit from additional imaging, including chest x-ray, ultrasound, and/or CT. A single anteroposterior image of the chest is commonly used as the initial imaging modality in injured patients. Injuries that can be identified using a chest x-ray include a pneumothorax, hemothorax, pulmonary contusion, rib fractures, mediastinal widening, or a suspected rupture of the hemidiaphragm. It is important to note that a routine chest x-ray is associated with a relatively low sensitivity (27%–83%) in the diagnosis of a pneumothorax, missing up to 50%[120-124]. Conversely, bedside ultrasound, as part of the extended focused assessment with sonography for trauma (E-FAST), has been shown to have sensitivity rates of 86% to 100% in the diagnosis of a pneumothorax but is limited in that it is unable to assess for injuries apart from a pneumothorax, hemothorax, or pericardial fluid.[121,125,126] Chest x-ray and bedside ultrasound have the advantages of being quick and portable and not requiring transport of patients. Although it does expose patients to considerably higher doses of radiation as compared to plain films, CT is the gold standard for imaging of the injured patient.[25,121,127,128] Over the past several years, this modality has become faster, more informative with higher resolutions and reconstruction capabilities, and safer with lower radiation doses.[129,130] Overall, studies have shown CT to identify occult injuries not identified on a chest x-ray in 18% to 71% of patients.[25,131,132] In addition to the imaging modalities mentioned earlier, stable patients may require esophagoscopy, bronchoscopy, and echocardiography.

Pneumothorax

Pneumothoraces not visualized on chest x-ray are often seen on CT. If they are small and the patient is asymptomatic, observation is typically all that is required. For patients undergoing operation for an associated injury or intubation for positive-pressure ventilation, the chance that a small pneumothorax will become clinically significant is relatively low, but all patients should be monitored for this possibility in the early phases after injury.[133]

In general, a large pneumothorax seen on CT, but not detected on a chest x-ray, is most often anterior. Evacuation of a larger collection can very effectively be undertaken by insertion of a thoracostomy tube or pigtail catheter, as noted earlier.

Hemothorax

Current practice management guidelines from the Eastern Association for the Surgery of Trauma recommend all hemothoraces be considered for drainage, regardless of size.[119] Although all hemothoraces should be considered for drainage, tube thoracostomies are associated with complication rates of 20% to 40%, and there is literature that suggests small-volume hemothoraces (<300 mL) are able to be successfully managed without tube thoracostomy.[118,134-136] If management without tube thoracostomy is elected, monitoring should be performed with serial chest x-rays to document resolution. Any moderate or large hemothorax, however, should be drained with a thoracostomy tube or pigtail catheter. The tube or catheter should be placed posteriorly to allow for dependent drainage. Although traditional teaching has included the use of a size 36F to 38F thoracostomy tube, more recent literature has shown no difference in outcomes with smaller-sized tubes, ranging from 20F to 32F, or pigtail catheters.[137,138]

In hemodynamically stable patients, indications for surgical intervention for hemothoraces in the acute setting include initial drainage of 1200 to 1500 mL or 200 mL/h of output for 2 to 4 hours after placement.[119,139] Blood left within the pleural cavity has a tendency to form mature clot resistant to subsequent drainage via a thoracostomy tube. Evaluation for effective drainage by repeat imaging is advised because undrained blood, or "retained hemothorax," may progress to a fibrothorax with lung entrapment or become infected, resulting in an empyema.

Pulmonary Contusion

Pulmonary contusions are the most common injuries of the lung from a blunt mechanism of trauma[140,141] (Fig. 28-13). In one series, pulmonary contusions were found in 27% of patients with an Injury Severity Score (ISS) of 15 or higher.[141] Although they can occur with any blunt mechanism or chest injury, they are highly associated with motor vehicle collisions, particularly front and lateral impacts, and rib fractures, especially a flail chest.[141] Traditionally the diagnosis of a pulmonary contusion was associated with high morbidity. The severity of these injuries ranges from clinically silent to more severe cases causing severe respiratory distress. With increased use of CT scans in the evaluation of trauma patients, pulmonary contusions, particularly minor ones, are now diagnosed

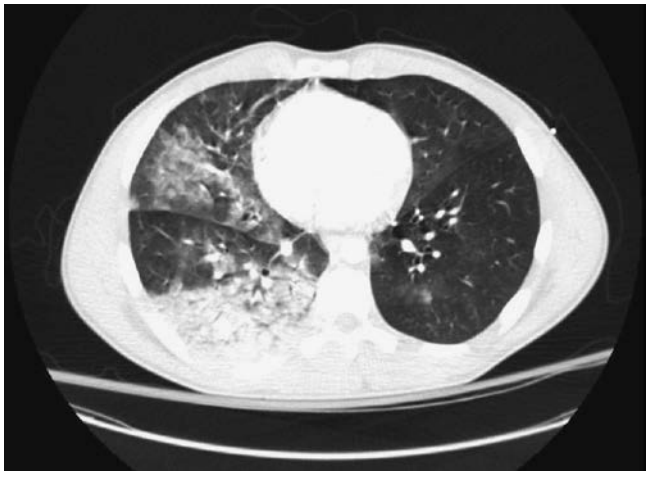

FIGURE 28-13 Pulmonary contusion.

more frequently.[142] In one series, 73% of pulmonary contusions were able to be visualized on a CT scan.[142] The clinical symptoms of severe pulmonary contusion include respiratory distress, increased work of breathing, hypoxia, and, less commonly, hypercarbia. One of the hallmarks of this pathology is that clinical symptoms and radiographic findings increase over time, appearing within 4 to 6 hours of injury and evolving over 3 days, and most resolve in 1 week.[143] Supportive treatment with judicious volume administration, pulmonary toilet, and supplemental oxygen is typically all that is necessary. For patients with concomitant rib fractures, adequate pain control is essential to allow for adequate pulmonary toilet. Noninvasive positive-pressure ventilation may be used in patients with significant hypoxemia who otherwise are not in respiratory distress and has been shown to avoid the need for intubation in approximately 10% of patients with acute lung injury.[144] Mechanical ventilation is indicated for respiratory distress or failure refractory to less invasive therapies.[141]

Lung Laceration

Patients with significant lung lacerations will often have large air leaks or, less commonly, hemoptysis. Bronchoscopy is the modality of choice to diagnose a tracheobronchial injury, which may also be the cause (see Chapter 29). Blood and secretions must be suctioned clear, allowing unimpaired visualization of the entire airway. When encountered, large air leaks from either a bronchus or lung resulting in respiratory compromise generally require thoracotomy. While also rare, significant hemoptysis can result in profound respiratory compromise, and bronchoscopy may permit localization of the bleeding to a specific pulmonary lobe or segment. Control of the airway is by a double-lumen endotracheal tube, selective mainstem intubation, or a bronchial blocker. Other adjuncts that may prove useful in optimal management include lateral decubitus positioning, catheter-based therapy, and surgery.

Indications for Operation

In addition to the volumes of blood from a thoracostomy tube mentioned earlier, thoracic trauma resulting in persistent hemodynamic instability, without another obvious source, should also prompt emergent thoracic exploration. Delaying emergent thoracic exploration may result in increases in morbidity and/or mortality.[145]

Care must be exercised when evaluating output from a thoracostomy tube. Although a dramatic decrease in output may signify a cessation of intrathoracic bleeding, it may also be the result of clotting of the thoracostomy tube. An increasing hemothorax in these instances may not be appreciated until visualized on subsequent chest x-ray or chest CT. Although a second chest tube may be helpful, patients with a large retained hemothorax should generally be explored and drained. A thoracoscopic approach is often successful, particularly if performed early within the first few days following injury, before the clot becomes organized and loculations and adhesions form.

Delayed operative intervention may be indicated for a variety of traumatic complications, including retained hemothorax, persistent air leak, missed injury, and empyema. Posttraumatic empyema is almost always best treated with operation. Many of these other nonemergent procedures can be performed using noninvasive methods, such as VATS.[146,147]

Surgical Exposure

There are a number of operative approaches to the thorax, each with advantages and disadvantages. Unlike an elective thoracotomy, in which the posterolateral approach is most commonly used, several important factors influence the choice of the incision for a traumatic injury. The overall clinical condition, hemodynamic instability, results of the imaging studies, and presence of concomitant injuries will influence the operative approach.

Commonly employed operative approaches include anterolateral, bilateral anterior ("clamshell"), and posterolateral thoracotomies and median sternotomy. As a general rule, an anterolateral thoracotomy, which can be extended as a clamshell, is the preferred incision for exploring the hemodynamically unstable patient. It affords excellent exposure to both pleural spaces and the anterior mediastinum. The main disadvantage of the anterolateral approach is the inability to provide adequate exposure of posterior structures. By extending the ipsilateral arm and placing a bump to elevate the thorax approximately 20°, the incision can be carried to the axilla, improving posterior exposure (Fig. 28-14).

A median sternotomy provides excellent access to the heart, great vessels, and anterior mediastinum. It is versatile and can be extended as an abdominal, periclavicular, or neck incision. Widely incising the pleura provides access to either hemithorax, whereas exposure of posterior structures is limited. The "trapdoor" incision is rarely used since left-sided

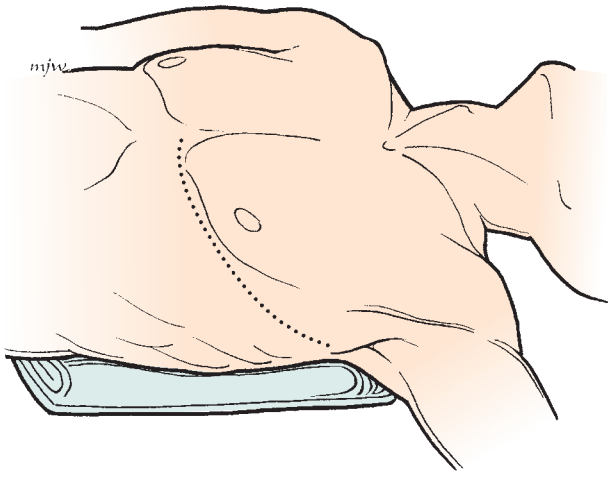

FIGURE 28-14 Illustration of incision for bilateral anterolateral thoracotomy.

thoracic vessels can be approached via sternotomy with extension.[148,149]

The posterolateral thoracotomy affords optimal exposure of the hemithorax, especially the posterior structures, and is the standard incision for most elective operations, as noted earlier. Its lack of versatility limits the usefulness in trauma, but it is the preferred approach to repair intrathoracic tracheal and esophageal injuries (see Chapter 29).

Operative Techniques

The use of a double-lumen endotracheal tube, as commonly used in elective thoracic operations, dramatically improves operative exposure. This adjunct is not, however, frequently used in trauma and, in particular, is not employed for emergency thoracotomies. Lung isolation in hemodynamically compromised trauma patients is not likely to be tolerated. In addition, the time typically required to ensure proper tube placement to facilitate single-lung ventilation is not warranted in an emergency. One exception may be in the setting of massive hemoptysis, where lung isolation may indeed be lifesaving. In contrast to other emergent thoracotomies, the placement of a double-lumen tube should be considered because it improves exposure and facilitates pulmonary resection. If a single-lumen tube is used, intermittently holding ventilation is advantageous during the critical steps of pulmonary repair or resection. If the patient's respiratory status is tenuous, however, any extended interruption of ventilation and oxygenation may precipitate decompensation. In this case, manual compression of the adjacent lung tissue may provide sufficient exposure to facilitate operative repair or resection.

Upon entering the chest, blood and clot should be evacuated, allowing a thorough examination and exploration of the hemithorax. The lung is mobilized by incising the inferior pulmonary ligament and lysing any adhesions. Exsanguinating hemorrhage demands immediate attention, and initial control is achieved with digital pressure. This allows time for ongoing volume resuscitation and an improved assessment of the injury. Hilar bleeding is a particularly significant challenge. Bleeding from the low-pressure pulmonary artery is more similar to a major systemic vein hemorrhage than arterial bleeding sources at other locations in the vasculature. There are several techniques for hilar compression. Finger occlusion or double looping placement of a Penrose drain around the hilum in a tourniquet fashion are both techniques that can be rapidly performed. With the latter technique, tightening the elastic Penrose around the hilum will effectively provide temporary vascular control. More definitive and secure control of the hilum can be achieved by placing a vascular clamp. Finally, the lung can be twisted on itself at the level of the hilum, which occludes the pulmonary artery and vein, as well as the mainstem bronchus. Clamping the hilar vessels or performing the "hilar twist" may, however, result in further decompensation in hemodynamically compromised patients. The rapid increase in pulmonary artery pressure can cause acute right heart dysfunction or failure, with catastrophic consequences.

There are a number of techniques for repair of the lung. The decision regarding the technique chosen will be influenced by the type and severity of the parenchymal injury, concomitant injuries, and the patient's physiologic status. Pneumorrhaphy is the simplest technique and is generally used to treat superficial pulmonary lacerations. The laceration is closed using an absorbable suture in either a running simple or mattress fashion. More extensive injuries require resection including simple wedge resection, pulmonotomy with selective vascular ligation, and nonanatomic and formal anatomic resections. Peripheral lacerations not amenable to simple repair can be treated by wedge resection using any of the commercially available cutting staplers. It is crucial, however, to determine the location of major pulmonary artery branches prior to firing the stapler when injuries are located closer to the hilum.

Significant lung injuries, particularly those from gunshot wounds, are often best treated with pulmonotomy[150-152] (Fig. 28-15) (see Atlas Figure 34). This is performed by placing the jaws of the stapler through the injury tract itself and firing it, similar to the technique used to expose and repair intraparenchymal hepatic injuries. This technique results in the exposure of bleeding vessels and injured airways for individual ligation. The staple line can be oversewn with a running absorbable suture to achieve adequate hemostasis and an airtight seal. In general, this method is most appropriate for peripheral injuries because this method is not typically appropriate for long central missile tracts.

Significant lobar injuries not amenable to pulmonotomy can be treated by nonanatomic resection or formal lobectomy. For the latter, the arterial and venous lobar branches must be dissected in the hilum and either ligated or stapled. Similarly, the lobar bronchus is identified and divided using a stapler. Prior to firing the stapler, and with the bronchus occluded by the stapling device, the lung is inflated. The lobe to be resected will not inflate, ensuring the appropriate bronchus is transected.

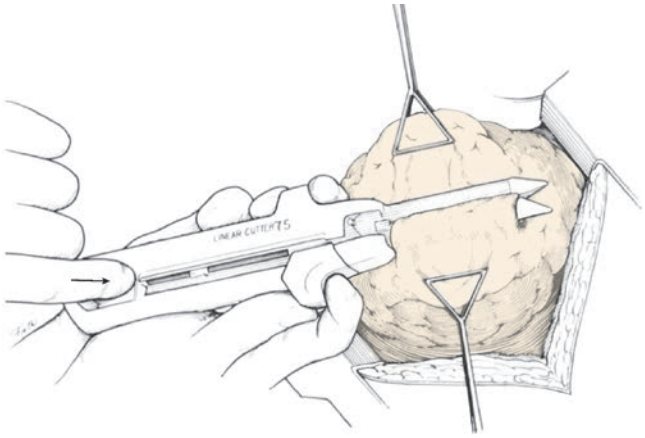

FIGURE 28-15 Illustration of a stapled pulmonotomy. (Reproduced with permission from Asensio JA, Demetriades D, Berne JD, et al. Stapled pulmonary tractotomy: a rapid way to control hemorrhage in penetrating pulmonary injuries. *J Am Coll Surg.* 1997 Nov;185(5):486-487. Copyright © 1997 American College of Surgeons. Published by Elsevier Inc. All rights reserved.)

Hilar injuries pose special challenges because hemorrhagic shock is almost always present and the anatomic challenges are significant. In very proximal hilar injuries, inflow occlusion is virtually always necessary in order to assess the extent of injury. Opening the pericardium and controlling the intrapericardial pulmonary artery and vein is a useful maneuver in this regard. Hilar injuries are rarely amenable to direct repair and may require pneumonectomy. Unfortunately, mortality after pneumonectomy for patients in shock approaches 100%, with patients dying from either uncontrolled hemorrhage or acute right heart failure.[153-155] If pneumonectomy is considered, it should be performed early, and rapid treatment of right heart dysfunction and support with extracorporeal membrane oxygenation may improve survival in these devastating injuries.[156]

The concept of damage control, originally described for penetrating abdominal trauma, has been expanded to include thoracic injuries as well. The well-established principles of hemorrhage control, resuscitation in the intensive care unit, and a planned, delayed definitive repair are applicable to patients with thoracic trauma with severely impaired physiology as well. Hemorrhage from named vessels and structures is controlled, the pleural cavity or cavities are packed, and the chest is left open. Experience has demonstrated that, when appropriately used, thoracic packing does not interfere with cardiac or pulmonary function. Once normal physiology is restored, the packs are removed, and the chest closed at a reoperation. In a series of 44 patients with a mean pH of 7.07 and a median ISS of 29 on admission, the mortality following the utilization of this technique was 23%. All patients surviving to chest closure were physiologically normal at the time of definitive operation, which on average was 2 to 3 days after the original emergency operation.[156]

Video-Assisted Thoracoscopic Surgery

Increasing experience with minimally invasive techniques has contributed to enthusiasm for VATS for a variety of sequelae of trauma.[146,147] As a diagnostic tool, VATS remains an acceptable alternative to laparoscopy to identify and repair penetrating diaphragmatic injuries. Persistent air leak, retained hemothorax, and, in selected patients, decortication for empyema are recognized indications for VATS. VATS is not, however, an emergent modality; emergent exploration for hemorrhage or severe parenchymal trauma should be performed using an open operative approach.

VATS is performed in the operating room under general anesthesia, with lung isolation achieved with a double-lumen endotracheal tube. Lung isolation provides superior exposure and an operative field with good visualization. The procedure is performed with the patient in the full lateral decubitus position with the affected side up. The operative field should be widely prepped and draped to facilitate conversion to a thoracotomy if indicated.

On single-lung ventilation, the first port is placed in the fourth or fifth intercostal space in the mid- or anterior axillary line. The tip of the scapula serves as a convenient landmark to facilitate appropriate positioning (Fig. 28-16). An angled thoracoscope is preferred for initial use, as it improves visualization of the pleural space recesses. An aspiration catheter can be placed coaxially to the optical port to facilitate the lavage and evacuation required for initial visualization. Additional ports can then be developed under direct visualization to address the pathology encountered.

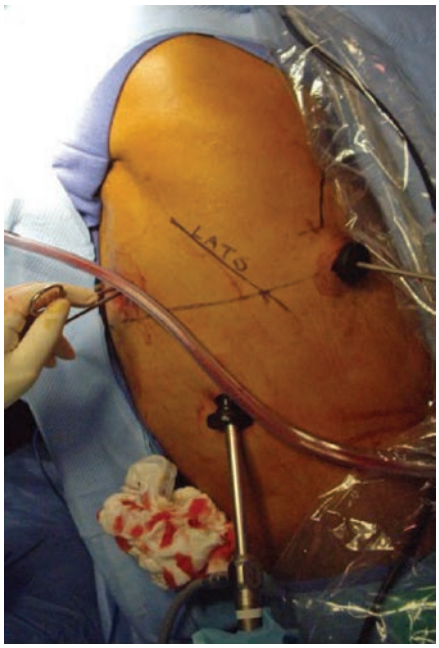

FIGURE 28-16 Landmarks for video-assisted thoracoscopic surgery port placement.

The instruments used for VATS are similar to those for laparoscopic procedures. Conventional open surgery forceps can also be used. Cautery, however, should be used cautiously and in close coordination with anesthesia, as oxygen-rich air leaks and cautery may interact to create a fire hazard with catastrophic results. On completion, the chest is irrigated with normal saline or sterile water. Using the existing port sites, chest tubes are positioned under direct visualization, and the lung reexpanded prior to closure. Following the procedure, a chest x-ray should be obtained and the thoracostomy tubes managed as they would be after a thoracotomy.

Outcomes

There is wide variability in the reported mortality after thoracic injury. With major blunt trauma, a mortality as high as 68% has been reported.[1,2] This is probably related to higher ISS, lower Glasgow Coma Scale score, and more associated nonthoracic injuries than in patients with penetrating injuries.[3,157] There is also variation in the reported mortality with penetrating trauma. Cardiac and major thoracic vascular injuries and the percentage of major pulmonary resections all contribute to poorer outcomes[3] (see Chapter 30). A relationship between the magnitude of the pulmonary resection and subsequent mortality has been well demonstrated.[3]

Complications of Injury to the Lung

PNEUMONIA

Pneumonia is the most common significant complication following pulmonary injury, and the relative risk is closely associated with the need for mechanical ventilation. Following thoracic injury, patients requiring intubation are approximately seven times more likely to develop pneumonia than those who do not.[1] Of all patients admitted with the diagnosis of pulmonary contusion (Fig. 25-13), nearly 50% will develop pneumonia, barotrauma, and/or major atelectasis, and 25% will go on to develop acute respiratory distress syndrome.[1]

RETAINED HEMOTHORAX

It has been estimated that tube thoracostomy fails to completely evacuate a hemothorax in over 5% of patients.[158] Typically, small hemothoraces will be reabsorbed; however, posttraumatic empyema and, less commonly, fibrothorax with an entrapped lung are known sequelae of a retained hemothorax, as previously noted.[134,158,159]

The diagnosis of retained hemothorax requires a chest CT because plain chest x-ray has been shown to be inadequate in effectively characterizing this entity.[160] There is wide variability, even among trauma centers, regarding the treatment of retained hemothoraces. Many patients require more than one procedure to evacuate the pleural space. In general, CT-estimated retained hemothorax volumes less than 300 mL can be safely observed in the absence of infection, whereas those greater than 300 mL will likely benefit from evacuation.[118] The timing of VATS has been somewhat controversial, with early studies reporting optimal results when the retained hemothorax was evacuated within the first few days following injury.[147,161] A more recent multicenter study found no significant impact of the timing of VATS and successful evacuation of the pleural space.[48]

EMPYEMA

Empyema, an infection of the pleural space, is diagnosed by positive pleural cultures or frank purulence. Overwhelmingly, the most common cause of posttraumatic empyema is a retained hemothorax, with both postpulmonary resection and postpneumonic etiologies much less common. A recent large multicenter study reported that empyema developed in 26.8% of patients with a retained traumatic hemothorax.[159]

Empyema has been characterized by three often overlapping stages, including exudative, fibrinopurulent, and organizing. Although most early-stage postpneumonic empyemas can be successfully treated by thoracostomy tube drainage and antibiotics, this is not the case for posttraumatic empyema. Delay in evacuating a retained hemothorax and an appreciable inflammatory response with resultant loculations make simple tube thoracostomy inadequate treatment. Both VATS and thoracotomy are acceptable modalities, with VATS more successful in the earlier stages and thoracotomy best for later-stage empyema or failed initial therapy. In a large, single-institution series of 125 consecutive patients with posttraumatic empyema, VATS and thoracotomy were performed in 20% and 80% of patients, respectively. Mortality was 4% and associated with ruptured lung abscesses.[161] It is important to note that failure of the first intervention to treat empyema is an independent predictor of mortality.[162] Therefore, it is essential that thoughtful judgment is exercised when considering treatment options.

PERSISTENT AIR LEAK AND BRONCHOPLEURAL FISTULA

A true bronchopleural fistula is a centrally located communication between a lobar or segmental bronchus and the pleural cavity. This specific complication is uncommon following trauma but may occur with an injury to a major bronchus or following pulmonary resection for a lung injury. Most posttraumatic air leaks are actually communications from the lung parenchyma to the pleural space and are more accurately termed *parenchymal–pleural* or *alveolar–pleural fistula*. Traditionally, however, bronchopleural fistula refers to any air leak from the lung to the thoracic cavity.

Although there is no agreed upon definition of what constitutes a "persistent" air leak, it is generally a leak that continues beyond 5 to 7 days.[163] This entity can be challenging to manage, especially in the ventilated patient in whom large leaks may result in loss of effective tidal volume and, consequently, hypoxia and/or hypercarbia. The diagnosis is usually not subtle, with persistent, vigorous air bubbling through the water-seal chamber of the collection system of the thoracostomy tube. Bronchoscopy should be performed if there is concern for an associated major airway injury.

Although the vast majority of air leaks will resolve within 7 days, those that persist will require treatment. The management of the air leak is complicated if the patient is on mechanical ventilation, in which case safely minimizing the mean and end-inspiratory plateau pressure is a useful strategy. Autologous blood pleurodesis, various commercially available sealants, endobronchial one-way valves, Heimlich valves, and operative therapy are among the management options to treat a persistent air leak.[164]

CHYLOTHORAX

A primary traumatic chylothorax, characterized by milky chest tube output, is uncommon after traumatic injury or surgery. The diagnosis is established by analyzing the content of the effusion and documenting the presence of fat (triglyceride levels >110 mg/dL) with or without predominant lymphocytes in the effusion. The primary complications of chylothorax are nutritional depletion, electrolyte abnormalities, and compromised immune function. Nonoperative management includes lung expansion to promote tamponade, total parenteral nutrition, enteral medium-chain triglycerides, and octreotide. Persistent chylous drainage for 5 to 7 days is a failure of nonoperative management. Although there are a few reports of successful embolization of the thoracic duct, direct ligation following lymphangiographic localization is the preferred approach.[165,166]

Trachea, Bronchi, and Esophagus

Joseph J. DuBose • Thomas M. Scalea • James V. O'Connor

KEY POINTS

Injury to Trachea and Bronchi

- Direct laryngoscopy, video laryngoscopy, bronchoscopic-guided intubation, and a surgical airway are all methods to establish a secure airway in a patient with a tracheal injury.
- The classic presentation of a distal tracheal or proximal bronchial injury is a large pneumothorax and a significant air leak and/or persistent pneumothorax following insertion of a thoracostomy tube.
- The distal half of the trachea, the right mainstem bronchus, and the proximal left mainstem bronchus are best approached through a right posterolateral thoracotomy.
- During repair of a mainstem bronchus, a single-lumen endotracheal tube in the contralateral mainstem bronchus allows for ventilation and an easier repair.
- Tracheal repair is accomplished with interrupted absorbable sutures.

Injury to Esophagus

- The accuracy of combining a contrast esophagram and esophagoscopy approaches 100%.
- As opposed to the trachea, the blood supply to the esophagus courses longitudinally in the submucosa, allowing for full mobilization.
- The extent of the mucosal defect is exposed by incising the muscular layer until both ends of the mucosal tear are visualized.
- A tension-free esophageal repair is performed in two layers, with absorbable sutures on the mucosa and permanent interrupted sutures on the muscular layer.
- A vascularized intercostal muscle pedicle is ideal to buttress a repair of the thoracic esophagus.

INTRODUCTION

Thoracic trauma can result in a variety of clinical entities that demand thoughtful management in order to achieve optimal outcome. The bony thorax, major vascular structures, esophagus, trachea, and lung are all vital structures at risk following injury to the chest. Even potential spaces between these structures can manifest serious acute pathologies, such as a pneumothorax or hemothorax, that require knowledge of both emergent and less acute management considerations. In an effort to optimally address each of these traumatic pathologies most effectively, the editors of *Trauma* have thoughtfully distributed their discussion across several chapters constructed by experts. The focus of this chapter will be injuries specifically to the trachea, bronchi, and esophagus. The other aforementioned entities, including the thoracic wall, pneumothorax, and hemothorax, are discussed elsewhere (see Chapter 28).

INJURIES TO THE TRACHEA AND BRONCHI

Tracheobronchial injuries are infrequent but potentially life threatening. The incidence of blunt and penetrating injury is 0.4% and 4.5%, respectively.[1] Although these injuries occur more commonly in the cervical trachea and may be the result of either mechanism, thoracic tracheobronchial trauma generally is related to blunt injuries from high-speed motor vehicle crashes.[2-6] Most penetrating injuries to the cervical trachea, although straightforward to repair, may be associated with significant injuries to blood vessels, esophagus, and thoracic duct.[7]

Presentation and Evaluation

Cervical tracheal injuries are often obvious on physical examination.[8] A large volume of subcutaneous air and/or air

exiting from the missile tract may be observed. Patients often present in respiratory distress requiring urgent airway control. Direct laryngoscopy, video laryngoscopy, bronchoscopic guided intubation, and a surgical airway are all methods to establish a secure airway. The choice of technique depends on the specific injury, impending loss of airway, and the skill of the providers. Extreme care must be taken when intubating, because a partial tracheal injury can be converted to total circumferential disruption. The resultant loss of airway can lead to a respiratory arrest and, if the airway cannot be secured, death. Similarly, blindly placing an airway through a cervical wound with air escaping through it is treacherous. The airway may inadvertently be inserted into the mediastinum with catastrophic results. To avoid this, the trachea must be visualized and controlled and an endotracheal or tracheostomy tube inserted under direct vison. The classic presentation of a distal tracheal or proximal bronchial injury is a very large pneumothorax, a large air leak through a thoracostomy tube, and/or persistent pneumothorax despite the presence of a tube.

Patients with a suspected tracheobronchial injury must undergo emergent bronchoscopy (Fig. 29-1). Flexible fiberoptic bronchoscopy is the technique most often used. To achieve an unobstructed view of the mucosa and perform a thorough bronchoscopic examination, it is essential to clear the airway of blood and secretions. More than three-quarters of blunt tracheobronchial injuries occur within 2 cm of the carina.[6]

The entire circumference of the trachea must be examined. If the cervical trachea is at risk and the patient is intubated, the endotracheal tube may have been inserted distal to the suspected injury. In these cases, the endotracheal tube should be carefully withdrawn, keeping the bronchoscope distal to the endotracheal tube to ensure control of the airway. When the examination is complete, the endotracheal tube can be advanced distally over the bronchoscope and secured.

As computed tomography (CT) scanning has evolved, it is now used in the evaluation of potential tracheal injuries.[8] In the case of penetrating injury, a trajectory that is clearly remote from the trachea should effectively rule out the possibility of a tracheal injury. Three-dimensional reformatting of the images may demonstrate a tracheal injury, although a negative study does not effectively rule out the presence of an injury.[9-11] Bronchoscopy remains the diagnostic modality of choice. It defines the location and extent of the injury and should be performed by the operative surgeon.

Operative Exposure and Repair

As noted earlier, the management of a tracheobronchial injury begins with establishing a secure airway using the techniques listed.[9,12] The location and extent of the airway injury must then be completely characterized and associated injuries evaluated.

Intraoperative airway management necessitates close cooperation between the anesthesiologist and the surgeon. An injury to the cervical trachea can be managed with a single-lumen endotracheal tube. If necessary, the airway can be intubated across the operative field (Fig. 29-2). The surgical repair is facilitated by maintaining the mean airway pressure as low as possible, consistent with adequate oxygenation and ventilation. Brief periods of apnea afford improved visualization of the operative site. Intraoperative airway

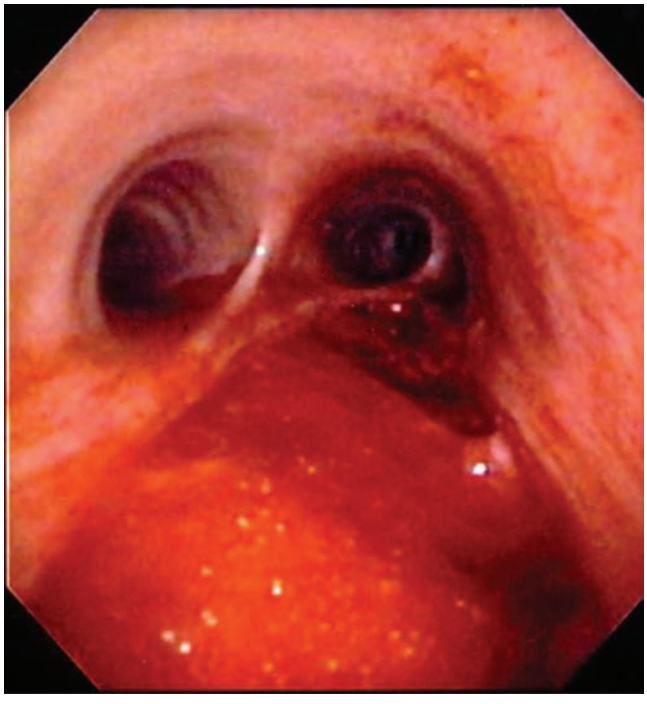

FIGURE 29-1 Tracheal injury visualized with preoperative bronchoscopy.

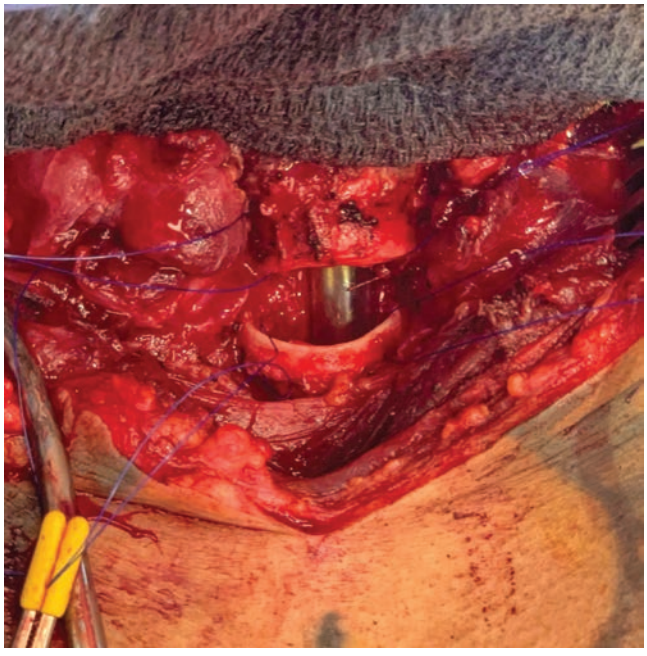

FIGURE 29-2 Tracheal injury with stay sutures placed to control edges and endotracheal tube distally advanced.

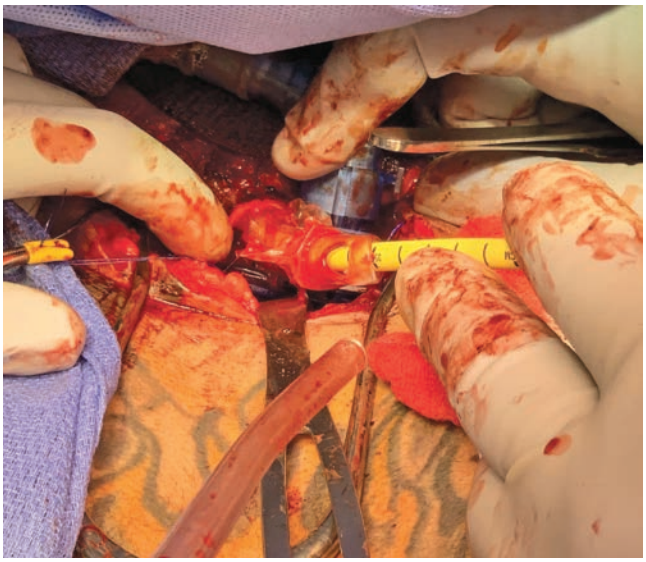

FIGURE 29-3 Retrograde placement of bougie cannula through oropharynx, facilitating advancement of endotracheal tube.

management is further complicated when an emergent surgical airway was placed through the tracheal injury and oral or nasal intubation is not possible. In this rare circumstance, a bougie is passed retrograde through the tracheal defect into the oral cavity, and an endotracheal tube is inserted over the bougie and guided into the distal trachea (Fig. 29-3)

Although operative repair is the mainstay of treatment for tracheobronchial injuries, there is a limited role for both stent placement and nonoperative management.[12-14] Conservative management is reserved for highly selected patients with small (<2 cm), linear, nontransmural tears.[15]

Appropriate tracheal exposure is determined by the anatomic location of the airway injury. The arterial blood supply to the trachea is segmental arising from the inferior thyroid and bronchial vessels, and the main vessels are at 3 and 9 o'clock. The proximal half of the trachea can be exposed through a collar incision, blunt dissection in the pretracheal plane will facilitate mobilization, and a partial sternotomy is needed rarely (Fig. 29-4).

The distal half of the trachea, the right mainstem bronchus, and the proximal left mainstem bronchus are best approached through a right posterolateral thoracotomy. A double-lumen endotracheal tube will greatly enhance operative exposure with repair of a mainstem bronchus. Another option is a single-lumen endotracheal tube in the contralateral mainstem bronchus (Fig. 29-5). Widely opening the mediastinal pleura and doubly ligating and dividing the azygous vein will provide the desired exposure. If an esophageal injury has been excluded, placing an esophageal bougie or nasogastric tube will facilitate dissection in the plane between the esophagus and trachea. The distal left mainstem bronchus is approached through a left posterolateral thoracotomy. This approach, while necessary, is complicated by the aortic arch.

Tracheal repair is accomplished with interrupted absorbable sutures. Simple lacerations are closed primarily, whereas

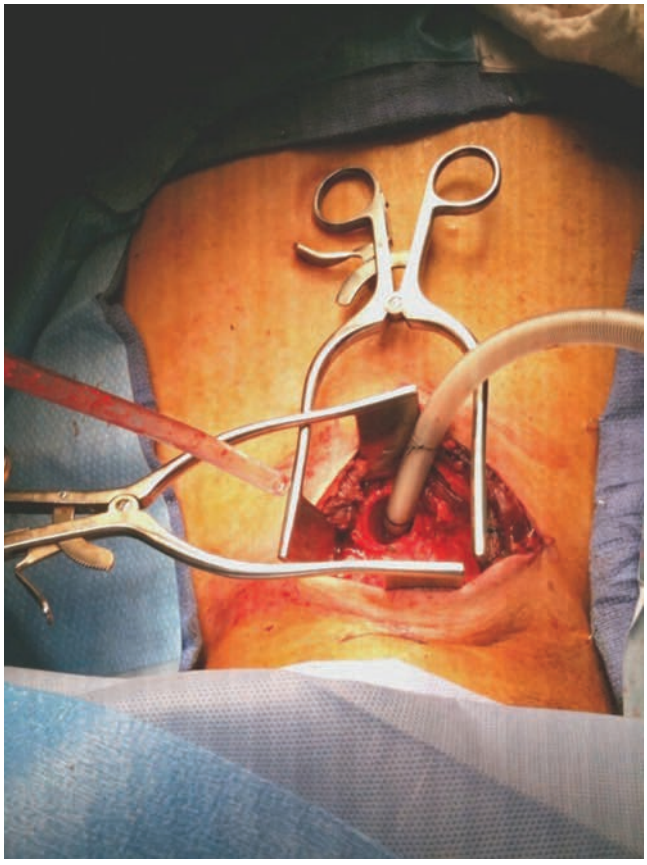

FIGURE 29-4 Tracheal intubation on the operative field. Partial sternotomy was chosen to obtain control of the great vessels.

more extensive injuries may require some minimal debridement to healthy tissue prior to repair. Extensive circumferential injures necessitate an end-to-end anastomosis, while preserving the blood supply to avoid suture line ischemia. This is always performed at a reoperation. If necessary, additional length can be achieved by mobilizing the trachea by blunt dissection in the avascular pretracheal plane. Other maneuvers such as a laryngeal release are rarely needed. In extreme circumstances, approximately half of the length of the trachea can be resected and a primary end-to-end anastomosis performed. Care must be exercised when placing the sutures, avoiding the endotracheal tube and its cuff. Lower tidal volume ventilation and brief periods of apnea will allow precise suture placement. After the tracheal repair is completed and before the thorax is closed, it is wise to have the anesthesiologist ensure the endotracheal tube is movable, confirming the endotracheal tube has not been inadvertently caught by a suture. Ideally, patients are extubated in the operating room to highly humidified supplemental oxygen.

A concomitant vascular or esophageal injury should be primarily repaired. The presence of suture lines in apposition increases the possibility of a fistula. The risk of this dreaded complication is reduced by interposing a vascularized muscle between the suture lines. In the neck, the sternal head

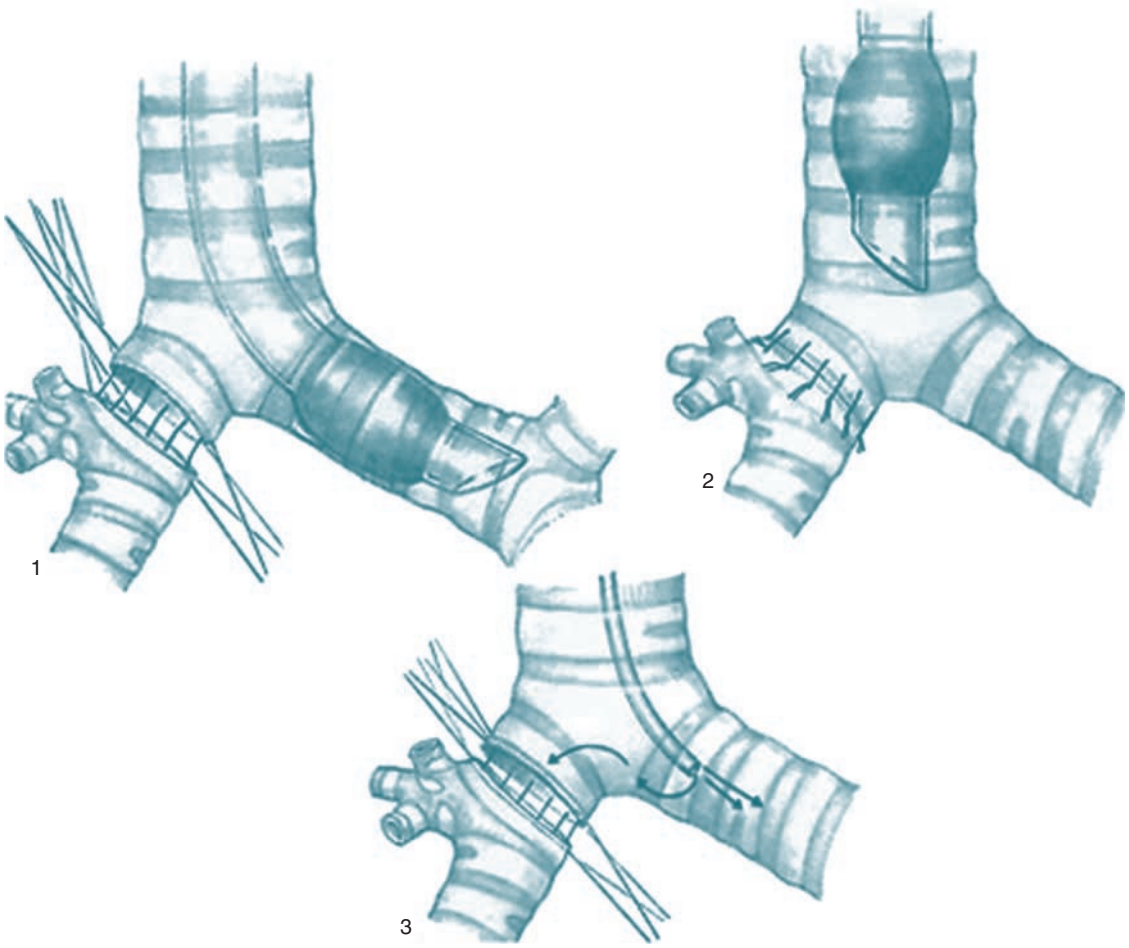

FIGURE 29-5 Intraoperative airway management using a single-lumen endotracheal tube during repair of a ruptured mainstem bronchus. or detached sternocleidomastoid muscle is ideal, whereas an intercostal muscle pedicle is ideal in the chest.

Infrequently, tracheobronchial injures are complicated by severe respiratory failure on presentation, which may be refractory to aggressive, conventional ventilator management. In these instances, immediate operation on a patient with profound hypoxia and/or hypercarbia would be fatal. Venovenous extracorporeal membrane oxygenation can provide optimal support during surgical repair.[16]

Outcomes

Mortality ranges from 0% to over 40%, with most deaths the result of associated injuries.[7,9,12,17] Complications are common, occurring in approximately 25% of patients, and are divided into short and long term.[9,12,17] Sepsis, pneumonia, and respiratory failure are among the common short-term complications encountered.

The major long-term complications are tracheal stenosis, abnormal phonation, and vocal cord paralysis. Laryngeal injuries and injury to the recurrent laryngeal nerve, from the initial injury or during the operative repair, commonly result in dysphonia. Tracheobronchial stenosis is an uncommon but potentially devastating complication, and initial symptoms may be underappreciated. Wheezing from air moving through the stenotic airway may be attributed to reactive airway diseases such as asthma or chronic obstructive pulmonary disease. Any patient presenting with new respiratory symptoms following tracheobronchial repair must be evaluated for airway stenosis. Although a detailed history, physical examination, pulmonary function tests, flow-volume loops, CT imaging, and bronchoscopy are each important in establishing the diagnosis, bronchoscopy is essential. It identifies the severity, location, and extent of the stenosis. Once the diagnosis is confirmed, initial management consists of controlling the airway. This is crucial in patients with high-grade lesions. Subsequent therapy is rigid or balloon dilation, which should be performed under direct visualization. Surgical treatment for postrepair airway obstruction is typically reserved for severe and relatively short-segment lesions.

The surgical treatment for posttraumatic stenosis varies by location of the stenosis but most commonly consists of resection and end-to-end anastomosis or tracheal sleeve resection.

INJURIES TO THE ESOPHAGUS

Esophageal injuries, although rare, are nonetheless serious, especially when they involve the thoracic esophagus. Blunt esophageal injuries are extremely rare but may occur as the result of a direct blow against a hyperextended neck or overpressure of the esophageal lumen.[18] Due to the protection of the bony thorax, esophageal injuries are much more common in the neck than the thorax. Overwhelmingly, esophageal injuries are the result of penetrating trauma.[19-22] A large, multicenter study of penetrating esophageal injuries was conducted by the American Association for the Surgery of Trauma (AAST) and involved 34 trauma centers in the United States. Penetrating esophageal injuries were identified in 405 patients over a span of 10.5 years, and 98% had associated injuries.[19] This high percentage of associated injuries is similar to other series.[22]

Presentation and Evaluation

Patients with an injury pattern or trajectory adjacent to the esophagus require evaluation. Although physical examination may be helpful in diagnosing an injury to the cervical esophagus, it is rarely useful for an intrathoracic injury. Saliva exiting a neck wound confirms the diagnosis of an injury to the cervical esophagus. Unfortunately, physical findings are often nonspecific, occurring in less than 25% of patients.[13] A patient with an injury to the thoracic esophagus may present with a concomitant pneumothorax or hemothorax from an associated injury to the lung and/or vascular structures. Drainage from a thoracostomy tube with obvious saliva or food particles warrants urgent esophageal evaluation.[19,20,23,24]

CT scanning has become more widely used in the evaluation of penetrating thoracic injuries, because it will define the missile trajectory to determine if the esophagus is at risk. If oral contrast has been administered, CT may identify extraluminal extravasation. The ability to obtain three-dimensional mediastinal imaging makes CT more attractive than a simple contrast study. CT is a static examination, however, and cannot assess the passage of contrast moving through the esophagus, as with an esophagram.

A contrast esophagram has traditionally been used to evaluate both the cervical and the thoracic esophagus. If correctly performed, the entire esophagus can be evaluated. In intubated patients, contrast can be instilled via a nasogastric tube that is pulled back so the tip rests in the proximal esophagus. Contrast studies may, however, miss esophageal injuries, and obtaining high-quality contrast studies may be difficult. Esophagoscopy is an excellent study that allows direct visualization of the location and extent of an esophageal injury. It has a negative predictive value of 100% but a positive predictive value of only approximately 33%.[24-26] The accuracy of combining an esophagoscopy and a contrast study approaches 100%.[24] Performing esophagoscopy first avoids contrast obscuring the esophageal mucosa.

Operative Exposure and Repair

Because esophageal injury is uncommon, most single-institution studies include only a small numbers of trauma patients for analysis.[25-33] Larger published series are either multicenter studies or use large data banks.[20-27] Iatrogenic esophageal injuries are quite different than those due to external trauma, are typically located in the cervical esophagus, and are commonly successfully managed nonoperatively. Conversely, surgical repair remains the mainstay for noniatrogenic esophageal injuries.

The cervical esophagus is exposed through an incision along the anterior border of the left sternocleidomastoid muscle. Lateral retraction of this muscle and blunt dissection in the avascular prevertebral plane will allow a Penrose drain to encircle the esophagus, achieving 360° exposure. As opposed to the trachea, the blood supply to the esophagus courses longitudinally in the submucosa, allowing for full mobilization. During dissection, care must be exercised to avoid injuring the recurrent laryngeal nerves that lie in the tracheoesophageal grove.

It is important to remember that the esophagus lacks a serosal layer and, therefore, is more prone to a postoperative leak. If this occurs in the cervical esophagus, it is easily managed without serious complications. A leak from a repair of the thoracic esophagus in the mediastinum, however, can cause significant morbidity and mortality. A fundamental principle in repairing esophageal injuries is visualizing the entire extent of the mucosal injury. The defect in the muscular layer is almost always less extensive than that in the mucosa. The extent of the mucosal defect is exposed by incising the muscular layer until both ends of the mucosal tear are visualized. A tension-free esophageal repair is performed in two layers—the mucosa is approximated with interrupted sutures, either absorbable or nonabsorbable, and the muscular layer is closed with interrupted nonabsorbable sutures (Fig. 29-6). The repair can be facilitated by placing a nasogastric tube, and the area is widely drained.

Intrathoracic esophageal injuries require more extensive exposure. The operative principles are preservation of esophageal length, primary repair, buttressing the repair, wide drainage, antibiotics, and enteral feeding access. Preoperative localization of the site of injury is imperative, because it influences the surgical approach. With the exception of its most distal segment, the intrathoracic esophagus is approached through a right posterolateral thoracotomy. The azygous vein is doubly ligated and divided, and the lung is retracted. The mediastinal pleura is widely opened to expose the esophagus, which is mobilized by blunt dissection. Devitalized mediastinal and esophageal tissues are debrided. A vascularized intercostal muscle pedicle is ideal to buttress the repair because it is robust and easily harvested[24] (Fig. 29-7).

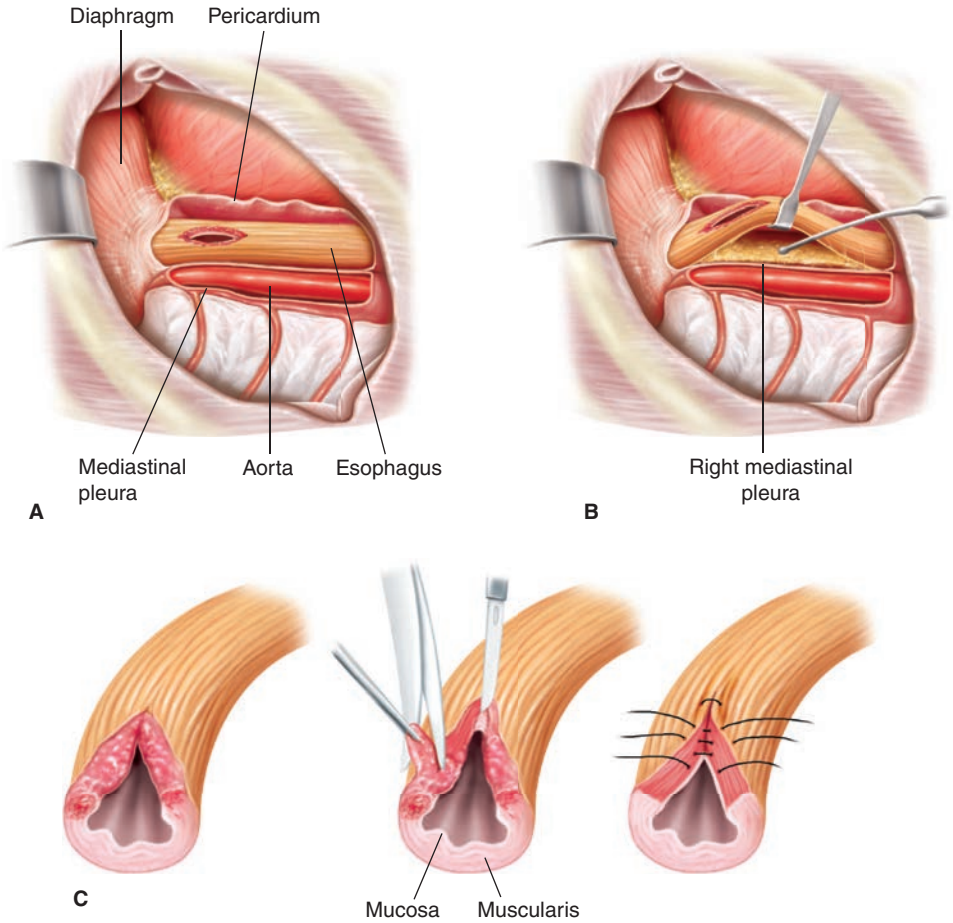

FIGURE 29-6 (**A**) Necrotic mediastinal pleura has been excised, and esophageal tear has been debrided. (**B**) Elevation of the esophagus on a rubber drain allows for debridement of the right mediastinal pleura if indicated. (**C**) Debridement of the esophageal rupture. Muscularis is incised superiorly and inferiorly to allow visualization of the extent of mucosal defect before two-layer closure of the perforation if possible. (Reproduced with permission from Patterson GA, ed. *Pearson's Thoracic and Esophageal Surgery*. Vol. 2. 3rd ed. Philadelphia, PA: Elsevier; 2008. Copyright © Elsevier.)

Wide mediastinal drainage is mandatory, and distal enteral feeding access is placed. A contrast study is performed approximately 1 week postoperatively, and if no leak is noted, oral feedings are started.

There are several surgical approaches to the distal esophagus and esophagogastric junction including a left sixth or seventh interspace posterolateral thoracotomy, a laparotomy, or a thoracoabdominal approach. Injuries to the distal intrathoracic esophagus are best approached via thoracotomy. The choice of incision to expose the esophagogastric junction is influenced by the exact location of the injury and associated injuries. If there are concomitant abdominal injuries, laparotomy alone may be sufficient, whereas associated intrathoracic injuries may require thoracotomy or thoracoabdominal incision. Distal esophageal injuries lend themselves to reinforcement with a fundal wrap.

Regardless of the location, a primary buttressed repair and adequate mediastinal drainage are the optimal treatment. Esophageal excision and resection with diversion should be avoided, and every effort should be made to preserve esophageal length. In rare circumstances, the magnitude of the esophageal injury or the patient's clinical condition precludes definitive repair. In these instances, a damage control procedure may be lifesaving. Creating a controlled esophageal fistula by using a surgeon-created large T-tube is an effective option.[34] This technique, combined with wide drainage, controls mediastinal contamination and preserves esophageal length. A devastating injury to the stomach and esophagogastric junction presents a unique challenge. These are not amenable to T-tube drainage; however, retrograde esophageal drainage after resection may prove useful. Continuity is reestablished by an esophagojejunostomy performed several months later.[34,35]

Endoluminal Stents

The use of endoluminal esophageal stents for the management of benign esophageal perforation has increased significantly over the past several years. Several investigators have examined their limited experience using stents for esophageal perforations for both iatrogenic and trauma indications.[36-40]

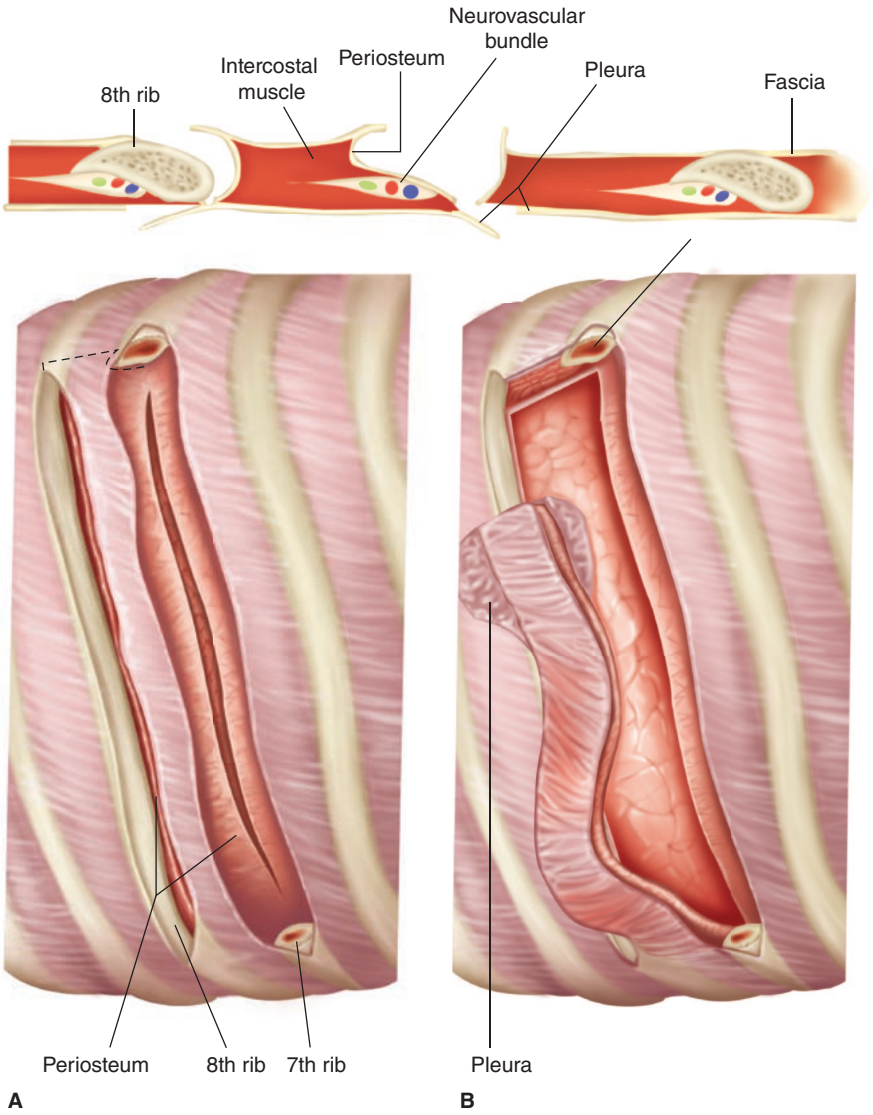

FIGURE 29-7 Construction of intercostal musculopleural flap. (**A**) Periosteum of the rib inferior to thoracotomy incision is incised, and the subjacent pleura is mobilized. (**B**) The neurovascular bundle is divided anteriorly, and the flap is created. (Reproduced with permission from Patterson GA, ed. *Pearson's Thoracic and Esophageal Surgery.* Vol. 2. 3rd ed. Philadelphia, PA: Elsevier; 2008. Copyright © Elsevier.)

Data for iatrogenic esophageal injuries suggest that covered stents are associated with similar effectiveness, but have lower morbidity, shorter hospital stay, and lower costs when compared to surgery.[36] An appropriate study of the use of this modality among trauma patients has yet to be conducted. However, a stent may represent a suitable alternative for damage control because it will limit ongoing contamination due to a persistent esophageal leak.

Outcomes

Esophageal trauma results in significant morbidity and mortality. Mortality ranges from 0% to 44% and is related to delays in treatment, associated injuries, and esophageal resection rather than primary repair.[27,41,42] In the large AAST series, the mortality was 19%.[19] Complications are common, with esophageal-related complications ranging between 38% and 66%.[31,41,42] Independent risk factors for these complications include delays in operative treatment, higher grade esophageal injury, and resection and diversion.[41,42] Prompt diagnosis and operation, a precise technical repair, and consideration of a damage control procedure in dire circumstances are essential for a satisfactory outcome.

In the previously mentioned largest study to date of penetrating esophageal injuries, Asensio et al[19] found that patients subjected to lengthy evaluations had higher complication rates overall and higher esophageal-related complications specifically, compared to counterparts who proceeded directly to operation for diagnosis and received operative treatment in an expedited fashion. This finding has been confirmed by

other investigators and emphasizes the need for expeditious evaluation and definitive management.[21,22]

NONMALIGNANT TRACHEOESOPHAGEAL FISTULA

An acquired, nonmalignant tracheoesophageal fistula is a dreaded, but rare, complication. Contemporary endotracheal tubes with high-volume, low-pressure cuffs have virtually eliminated this dreaded complication among ventilated patients. Combined airway and esophageal injuries repaired without muscle interposition, however, are at risk to develop a tracheoesophageal fistula. The clinical presentation initially may be subtle, with symptoms ascribed to a respiratory problem. Recurrent pneumonia and a persistent cough with an unidentified cause mandate an evaluation to rule out this complication. Once diagnosed, treatment commonly requires surgical intervention, with division of the fistula, repair of the respective tracheal and esophageal defects, and interposition with a well-vascularized muscle pedicle. Ideally, this is accomplished once the patient is liberated from mechanical ventilation, as the operative repair is more complex on mechanical support. The use of covered tracheal or esophageal stents has been described for patients who are not operative candidates, as has operative diversion.[36-40] Avoiding rather than treating this complication is the preferred strategy. As described earlier, with a combined airway and esophageal injury, a precise technical repair of each individual structure and muscle interposition will greatly reduce the chance of this complication.[41] The same strategy is used with a combined esophageal and vascular injury. Each undergoes primary repair, and a muscle buttress is placed between the suture lines. Unlike a tracheoesophageal fistula, the presentation of a carotid artery–esophageal fistula with acute hemorrhage can lead to death in the unattended patient.

Heart and Thoracic Vessels

Matthew J. Wall Jr • Ravi K. Ghanta • Kenneth L. Mattox

KEY POINTS

Injury to the Heart

- Avoid overaggressive resuscitation with crystalloid solutions in patients with suspected cardiac/vascular injuries.
- The pericardial view of the focused assessment with sonography for trauma examination provides a rapid and accurate diagnosis of a hemopericardium.
- The majority of penetrating wounds to the heart can be managed with suture repair of the myocardium.
- An injury adjacent to a coronary artery is repaired with deep mattress sutures passing underneath the vessel.
- Complex cardiac injuries involving the cardiac valves or the atrial/ventricular septa are extremely uncommon and are usually repaired with cardiopulmonary bypass in a subacute manner.
- Consider pericardial tears and possible cardiac herniation with high-energy lateral blunt trauma and posttrauma positional hypotension.
- Screening for blunt cardiac injury involves history and physical examination, electrocardiogram, and in some centers, measurement of troponin I.

Injury to the Thoracic Vessels

- Contrast-enhanced computed tomography (CT) of the chest can be a useful screening test for stable patients with the following injuries: penetrating wound with mediastinal traverse; any thoracic trauma and mediastinal or supraclavicular hematoma; and blunt trauma with symptoms or signs or x-ray findings of an injury to the descending thoracic aorta.
- Anatomic and physiologic classification of blunt injury to the thoracic aorta guides therapy, particularly recognizing that small, stable injuries can be observed.
- The management of blunt injury to the descending thoracic aorta has evolved, with CT of the chest the most common screening test, endovascular repair the most common technique of repair, and delayed repair often employed.
- For endovascular repair of blunt injury to the descending thoracic aorta, it is important to understand issues of room setup, vascular access, device sizing, seal zones, injury configuration, and vascular anomalies.
- Many patients with penetrating thoracic vascular injuries are unstable and have the diagnosis made during an emergent exploration, usually via a left anterolateral thoracotomy, bilateral anterolateral thoracotomy, or less commonly, a median sternotomy.
- Endovascular repair of thoracic outlet vascular injuries performed in an operating room with imaging capability permits the application of this technology to complex and unstable patients. The endovascular snare technique allows through-and-through access for even transected vessels permitting nonsurgical repair of these complex injuries.

INTRODUCTION

The heart, the thoracic aorta, and its tributaries are enclosed in the thoracic skeleton composed of the manubrium, sternum, clavicles, rib cage, and vertebral bodies. This rigid cage protects the heart, lungs, and great vessels. The bony structures can also create unique forms of injuries as they cause deflection of bullets, altering vectors of the original direction of penetration or by secondary fragments.

Blunt forces can lead to crushing, traction, or torsion injuries to the heart and great vessels from deceleration. Penetrating trauma to the heart and great vessels usually leads to immediate tamponade or exsanguination but may follow a

pattern of injury similar to blunt trauma, including partial transection with formation of a traumatic false aneurysm, an intimal flap, thrombosis, or a rare arteriovenous fistula.

There has been a profound shift in the management of thoracic vascular injuries over the past two decades. Improvements in imaging technology have resulted in a shift from plain films and catheter angiography to computed tomography (CT) imaging for screening and diagnosis. In addition, advances in endovascular therapy have changed the way these injuries are managed.

INJURY TO THE HEART

Incidence

Penetrating cardiac trauma is a highly lethal injury, with only 25% to 50% of victims surviving long enough to reach the hospital in reviews from medical examiners; however, in one extraordinary series of 1198 patients with penetrating cardiac injuries in South Africa, only 6% of patients reached the hospital with any signs of life.[1]

With improvements in organized emergency medical transport systems, more patients with a significant cardiac injury reach the emergency department with signs of life in the modern era. It is somewhat frustrating, however, to note the overall mortality for penetrating trauma has not changed significantly, even in the major trauma centers.[2]

The actual incidence of blunt cardiac injury (BCI) is unknown. Because thoracic trauma has historically been responsible for 25% of deaths from motor vehicle crashes, it is possible that 10% to 70% of this subgroup may have been the result of blunt cardiac rupture.[3] There has been confusion historically, as the term *cardiac contusion* has been applied to a wide spectrum of pathology, making epidemiology of BCI difficult to define.

Mechanism

PENETRATING CARDIAC INJURY

Penetrating trauma is a common mechanism for cardiac injury, with the predominant etiologies being from knives and firearms (Table 30-1). In a review of 711 patients with penetrating cardiac trauma, 54% sustained stab wounds and 42% had gunshot wounds. Because of an anterior and left lateral location, the cardiac chambers at greatest risk for injury are the right and left ventricles. The right ventricle was injured in 40% of patients, the left ventricle in 40%, and the right atrium in 24%. With its posterior location, the left atrium was injured in only 3% of patients. The overall mortality was 47%, and one-third of injuries involved multiple cardiac structures.[4] More complicated intracardiac injuries involving the coronary arteries, the cardiac valves, and septae were noted as well. Septal injuries result in intracardiac fistulas such as atrial or ventricular septal defects, but only 2% of patients surviving the initial cardiac repair required reoperation for a residual defect in a delayed fashion in one review.[4] Thus, the majority of injuries are simple lacerations to the myocardium and are readily managed by the general, trauma, or acute care surgeon.

TABLE 30-1: Etiology of Traumatic and Iatrogenic Injuries of the Heart

1. Penetrating
   a. Low energy
      - Stab wounds—knives, ice picks, fence posts, wire, sports injuries
   b. High energy
      - Gunshot wounds—handguns, rifles, nail guns
      - Shotgun wounds—close range versus distant
      - Blast—fragments
2. Nonpenetrating (blunt)
   a. Motor vehicle collision
   b. Vehicle–pedestrian collision
   c. Falls from height
   d. Crush—industrial accident
   e. Blast—explosives, fragments, improvised explosive devices
   f. Assault
   g. Sternal or rib fractures
   h. Recreational—sporting events, rodeo, baseball
3. Iatrogenic
   a. Percutaneous interventions
   b. Pericardiocentesis
4. Others
   a. Electrical
   b. Embolic—missiles/fragments
   c. Factitious—needles, foreign bodies

Retained intrapericardial foreign bodies after penetrating wounds can sometimes cause complications of acute suppurative pericarditis, chronic constrictive pericarditis, foreign body reaction, and a hemopericardium.[5] On occasion, needles and other foreign bodies have been noted after deliberate insertion by patients with psychiatric diagnoses. A report by LeMaire et al[5] recommended removal of intrapericardial foreign bodies that are greater than 1 cm in size, are contaminated, or produce symptoms.

Intracardiac missiles can be embedded in the myocardium, retained in the trabeculations of the endocardial surface, or free in a cardiac chamber. These result from direct cardiac injury or injury to a peripheral venous structure with embolization to the heart. Observation might be considered when the missile is small, right-sided, embedded completely in the wall, contained within a fibrous covering, not contaminated, and producing no symptoms. Right-sided missiles, however, can embolize to the pulmonary artery, where they can be removed with catheter-based techniques, if large. In rare cases, they can embolize through a patent foramen ovale or atrial septal defect. Any left-sided missile can embolize systemically shortly after the initial injury, causing an arterial occlusion.

BLUNT CARDIAC INJURY

As previously mentioned, blunt cardiac injury, or BCI, has replaced the term *cardiac contusion* and describes injuries

ranging from insignificant bruises of the myocardium to cardiac rupture. These injuries can be caused by direct energy transfer to the heart, by a mechanism of compression of the heart between the sternum and the vertebral column, or by a sternal or rib fracture. Cardiac rupture during external cardiac massage as part of cardiopulmonary resuscitation (CPR) can occur as well, particularly in patients with a prosthetic heart valve.

The spectrum of BCI includes septal rupture, wall rupture, coronary artery thrombosis, cardiac failure, rupture of chordae tendinae/papillary muscles, and simple and complex dysrhythmias. Mechanisms with significant energy transfer are motor vehicle collisions, vehicular–pedestrian collisions, falls, crush injuries, blasts/explosions, and assaults. In one report, a fatal cardiac dysrhythmia occurred when the sternum was struck by a baseball, which may be a form of commotio cordis.[6]

The biomechanics of blunt cardiac rupture include the following: (1) direct transmission of increased intrathoracic pressure to the chambers of the heart; (2) a hydraulic effect from a large force applied to the abdominal or extremity veins, causing the force to be transmitted to the right atrium; (3) a decelerating force between fixed and mobile areas, explaining atriocaval tears; (4) a direct force causing myocardial contusion, necrosis, and delayed rupture; and, as noted earlier, (5) penetration from a broken rib or fractured sternum.[7] From autopsy data, BCI with chamber rupture occurs most often to the left ventricle. In contrast, in patients who arrive alive to the hospital, right atrial disruption (superior vena cava–atrial junction, inferior vena cava–atrial junction, or right atrial appendage) is more common. Blunt rupture of the cardiac septum occurs most frequently near the apex of the heart, whereas injury to only the membranous portion of the septum is the least common cause of a blunt ventricular septal defect. Multiple cardiac ruptures and disruption of the conduction system have been reported as well. Traumatic rupture of the thoracic aorta is also associated with lethal cardiac rupture in almost 25% of patients.

IATROGENIC CARDIAC INJURY

Iatrogenic cardiac injury can occur with insertion of a central venous catheter, cardiac catheterization procedures, endovascular interventions, and pericardiocentesis. Cardiac injuries caused by insertion of a central venous catheter usually occur from either the left subclavian or the left internal jugular vein.[8] Insertion of left-sided central lines or introducer sheaths, particularly during dilation of the tract, can lead to perforation of the innominate vein, superior vena cava, or right atrium. These small perforations sometimes lead to a compensated cardiac tamponade. Drainage by pericardiocentesis is often unsuccessful, and evacuation via a subxiphoid pericardial window or full median sternotomy is sometimes required. At operation, when the pericardium is opened, the site of injury has sometimes sealed and may be difficult to find. Perforation causing tamponade has also been reported with insertion of a right internal jugular introducer sheath for vascular interventions such as a transjugular intrahepatic portacaval shunt.

Complications from coronary catheterization, including perforation of the coronary arteries or a cardiac chamber and dissection of the thoracic aorta, are rare but can be catastrophic and require emergency surgical intervention.[9]

Other iatrogenic potential causes of cardiac injury include the aforementioned external and internal cardiac massage, transthoracic percutaneous interventions, and during intracardiac injections.[10]

ELECTRICAL INJURY

Cardiac complications after electrical injury include the following: immediate cardiac arrest; acute myocardial necrosis with or without ventricular failure; myocardial ischemia; dysrhythmias; conduction abnormalities; acute hypertension with peripheral vasospasm; and asymptomatic, nonspecific abnormalities evident on an electrocardiogram (ECG). Damage from electrical injury is due to direct effects on the excitable tissues, heat generated from the electrical current, and associated injuries from falls, explosions, or fires.[11]

Clinical Presentation

PENETRATING CARDIAC INJURY

Wounds involving the entire chest, especially the precordium and epigastrium, can cause a cardiac injury. Patients with cardiac injury can present with a clinical spectrum from asymptomatic with normal vital signs to a cardiac arrest. Up to 80% of stab wounds that injure the heart, however, will eventually cause tamponade.

Rapid bleeding into the pericardium favors clotting rather than defibrination. As pericardial blood accumulates, a decrease in ventricular filling occurs, leading to a decrease in stroke volume. A compensatory rise in catecholamines leads to tachycardia and increased right heart filling pressures. The limits of right-sided distensibility are reached as the pericardium fills with blood and the septum shifts toward the left side, further compromising left ventricular function. As little as 60 to 100 mL of blood in the pericardial sac can produce the clinical picture of tamponade.[12] The rate of accumulation depends on the location of the wound. Because it has a thicker wall, wounds to the ventricle seal themselves more readily than wounds to the atrium. Patients with freely bleeding injuries to the coronary arteries can present with rapid onset of tamponade combined with cardiac ischemia.

The classic findings of the Beck triad (muffled heart sounds, hypotension, and distended neck veins) are seen in a minority of acute trauma patients. Pulsus paradoxus (a substantial decrease in systolic blood pressure during inspiration) and Kussmaul sign (increase in jugular venous distention on inspiration) may be present but are also not reliable signs. A more valuable and reproducible sign of pericardial tamponade is narrowing of the pulse pressure. An elevation of the central venous pressure often accompanies overaggressive hyperresuscitation with crystalloid solutions, but in such instances, a widening of the pulse pressure occurs.

Gunshot wounds to the heart with a larger injury and a larger pericardial defect are more frequently associated with hemorrhage than with tamponade. Thus, these patients often present with exsanguination into a pleural cavity.

BLUNT CARDIAC INJURY

Clinically significant BCI includes the injuries listed earlier. These injuries present with tamponade, hemorrhage, or severe cardiac dysfunction. Septal rupture and valvular dysfunction (leaflet tear, papillary muscle or chordal rupture) can initially appear without symptoms but then cause delayed heart failure.

BCI can also present as a dysrhythmia for unknown reasons. Premature ventricular contractions are common, but ventricular tachycardia, ventricular fibrillation, and supraventricular tachycardia can occur usually within the first 24 to 48 hours after injury.

As previously noted, a major difficulty in managing BCI relates to old nonspecific terms such as *cardiac contusion*. It is best to describe these injuries as BCI followed by the clinical manifestation, such as dysrhythmia or heart failure.[13]

PERICARDIAL INJURY

Traumatic pericardial rupture is rare, and most patients with pericardial rupture do not survive transport to the hospital due to other associated injuries. Pericardial tears secondary to increased intra-abdominal pressure or lateral deceleration forces can occur on either side of the pericardium, to the diaphragmatic surface of the pericardium, or to the mediastinum. Cardiac herniation with cardiac dysfunction can occur as the heart is displaced into either pleural cavity or even into the abdomen depending on the tear. With a right pericardial rupture, the heart can become twisted, preventing venous return, leading to the surprising discovery of an "empty" pericardial cavity at resuscitative left anterolateral thoracotomy. With a left-sided cardiac herniation through a pericardial tear, a trapped apex of the heart prevents the heart from returning to the pericardium, and the term *strangulated heart* has been applied.[14,15]

Unless the heart is returned to its normal position, hypotension and cardiac arrest can occur. One clue to the presence of cardiac herniation in a patient with blunt thoracic injury is sudden loss of pulse when the patient is repositioned, such as when moved or placed on a stretcher.[14]

The overall mortality of patients treated at trauma centers with such an injury remains as high as 64%.[16] An overwhelming majority of these cases are diagnosed either intraoperatively or at autopsy.[14] The clinical presentation of pericardial rupture with cardiac herniation can mimic that of pericardial tamponade with low cardiac output due to impaired venous return; however, when the heart returns to its normal position in the pericardium, venous return resumes. As noted, positional hypotension is the hallmark of cardiac herniation due to pericardial rupture, whereas pericardial tamponade is associated with persistent hypotension until the pericardium is decompressed.[14] Therefore, a high index of suspicion is helpful when evaluating polytrauma patients with unexplained positional hypotension.

Evaluation

PHYSICAL EXAMINATION

The diagnosis of a cardiac injury requires a high index of suspicion. On initial presentation to the emergency center, airway, breathing, and circulation under the Advanced Trauma Life Support protocol are evaluated and treated as needed.[17] Intravenous access is obtained, and a blood specimen is sent for type and crossmatch. The patient is examined for the Beck triad as well as for pulsus paradoxus and Kussmaul sign. These findings suggest cardiac injury but, as noted previously, are present in only 10% of patients with cardiac tamponade. The patient undergoes simultaneously a focused assessment with sonography for trauma (FAST) (see later). If the FAST demonstrates pericardial fluid in an unstable patient (systemic blood pressure <90 mm Hg), transfer to the operating room is immediate if the patient has signs of life.

Patients in extremis from suspected or confirmed tamponade or intrapleural hemorrhage require emergency department thoracotomy for resuscitation. The current indications for this procedure by surgical personnel are divided into two categories and include the following[18] (see Chapter 17):

Salvageable postinjury cardiac arrest

- Patients with penetrating thoracic trauma and less than 15 minutes of prehospital CPR
- Patients with penetrating nonthoracic trauma and less than 5 minutes of prehospital CPR
- Patients with blunt trauma and less than 10 minutes of prehospital CPR

Persistent severe postinjury hypotension (systolic blood pressure <60 mm Hg) due to

- Cardiac tamponade
- Hemorrhage: intrathoracic, intra-abdominal, extremity, cervical
- Air embolism

If vital signs are regained after resuscitative thoracotomy, the patient is transferred to the operating room for definitive repair.

IMAGING

A surgeon-performed ultrasound (FAST) examination of the pericardial sac is highly accurate in determining the presence of an acute hemopericardium, hemothorax, or pneumothorax (see later). The routine chest x-ray is most valuable in diagnosing a hemothorax, pneumothorax, or track of a missile; confirming the presence of a missile in the mediastinum; or documenting the presence of a mediastinal or extrapleural hematoma. Thoracic CT will do all the same, as well as document trajectory and precisely locate a missile and confirm injuries to other structures in the mediastinum.

ECG

In cases of BCI, conduction disturbances can occur, with sinus tachycardia being the most common. Other common disturbances include T-wave and ST-segment changes, sinus bradycardia, first- and second-degree atrioventricular block, right bundle branch block, right bundle branch block with hemiblock, third-degree block, atrial fibrillation, premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation. Thus, a screening 12-lead ECG is in the BCI guideline from the Eastern Association for the Surgery of Trauma.[19]

CARDIAC ENZYMES

The relationship between troponin levels and prognosis of BCI has been controversial.[20] Therefore, troponin measurements are not performed in all centers unless one is evaluating concomitant coronary artery disease.[20] Recent data, however, suggest that a normal ECG and troponin I effectively rule out BCI.[21,22]

FAST

The FAST examination evaluates four anatomic windows for the presence of pericardial or intra-abdominal fluid. Ultrasonography in this setting is not intended to reach the precision of studies performed in the radiology or cardiology suite but is intended to determine the presence of abnormal fluid collections.[23] Ultrasonography is safe, portable, and expeditious and can be repeated as indicated. If performed by a trained surgeon in patients with truncal trauma, primarily penetrating wounds to the chest and blunt trauma to the abdomen, the overall sensitivity and specificity were 83.3% and 99.7%, respectively, in one study.[24] In the same study, the sensitivity was 100% and specificity was 99.3% in patients with possible cardiac injuries from precordial or transthoracic wounds.[24] Two other ultrasound studies in patients with possible penetrating cardiac wounds from the same surgeon authors documented accuracies of 100% and 97.3%, respectively.[25,26] In urban environments with rapid transport times, the initial FAST to determine a hemopericardium may be falsely negative on rare occasions, and all negative FAST examinations are repeated in 15 minutes. As previously noted, the extended FAST looking at the pleural space has been adopted by many.[27] Finally, limited cardiac ultrasound is being used by the intensive care unit (ICU) to evaluate cardiac function and volume status (see Chapter 18).

FORMAL ECHOCARDIOGRAPHY

To evaluate more subtle findings of BCI such as wall motion or valvular or septal abnormalities in the stable patient, formal transthoracic echocardiography or transesophageal echocardiography is obtained. Transthoracic echocardiography is helpful but can have limited use in evaluating BCI because many patients have significant injury to the chest wall as well.

Formal echocardiography is most useful in the following situations: (1) diagnosing intrapericardial blood and tamponade physiology; (2) intraoperative evaluation of the pericardial cavity and heart during a nonthoracic procedure; (3) diagnosis of cardiac septal defects and valvular insufficiency; and (4) differentiating between ventricular dysfunction and cardiac tamponade, particularly in older patients. Of interest, most BCIs identified by echocardiography rarely require acute treatment.

SUBXIPHOID PERICARDIAL WINDOW

A subxiphoid pericardial window can be performed in the emergency department or in the operating room with the patient having either general or local anesthesia. In a prospective study, Meyer et al[28] compared the subxiphoid pericardial window with echocardiography in cases of penetrating cardiac injury and reported that the sensitivity and specificity of subxiphoid pericardial window were 100% and 92%, respectively, compared with 56% and 93%, respectively, with echocardiography. The authors suggested that the difference in sensitivity may have been due to the presence of a hemothorax, which can be confused with pericardial blood, or due to the fact that pericardial blood had drained into the pleural cavity.[28] The availability of the surgeon-performed FAST examination has almost eliminated the role of subxiphoid pericardial window in the evaluation of cardiac trauma. If necessary, pericardial exploration performed via a transdiaphragmatic route during laparotomy is more useful to diagnose a hemopericardium than pericardiocentesis (Fig. 30-1).

PERICARDIOCENTESIS

Pericardiocentesis has had significant historical support, especially years ago when the majority of penetrating cardiac wounds were produced by ice picks and the (surviving)

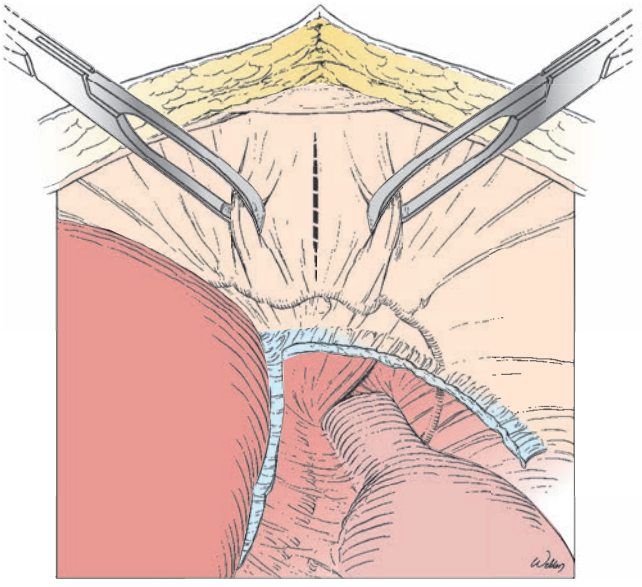

FIGURE 30-1 Transdiaphragmatic exploration of the pericardium during laparotomy. (Copyright © Baylor College of Medicine.)

patients arrived several hours and/or days after injury. In such instances, there was a natural triage of the more severe cardiac injuries, and the intrapericardial blood had become defibrinated and was easy to remove. As there are now probably more injuries from pericardiocentesis than accurate diagnoses, almost all trauma surgeons discourage the use of pericardiocentesis to diagnose acute cardiac trauma.[10] One indication for its use would be an iatrogenic injury caused by cardiac catheterization, at which time immediate decompression of the tamponade may be lifesaving, especially in the setting when a surgeon is not available.

Treatment

PENETRATING INJURY (SEE ATLAS FIGURE 29)

Because of the lethality of penetrating cardiac injuries, expeditious transport to an appropriate facility is important to survival. Rapid transport times and successful endotracheal intubation are positive factors for survival when the patient suffers a pulseless cardiac injury; however, recent data on hypovolemic patients suggest that positive-pressure ventilation may have an adverse effect on cardiac output.[29,30]

In the arrested or moribund patient with a positive pericardial FAST examination, exposure of the heart is accomplished via a left anterolateral thoracotomy as previously noted (Fig. 30-2).

This allows access to the pericardium and heart and exposure of the descending thoracic aorta for cross-clamping, if necessary. This incision can be extended across the sternum to gain access to the right side of the chest and for better exposure of the right atrium. Manual access to the right hemithorax from the left side of the chest can be achieved via the anterior mediastinum by blunt dissection as well. This allows rapid evaluation of the right side of the chest for major injuries without transecting the sternum or placing a separate chest tube. Once the left pleural space is entered, the lung can be retracted superiorly to allow clamping of the descending thoracic aorta distal to the left subclavian artery. The amount of blood present in the left chest suggests whether hemorrhage or tamponade is the primary issue. The pericardium anterior to the phrenic nerve is opened, injuries are identified, and control of hemorrhage or repair is performed.

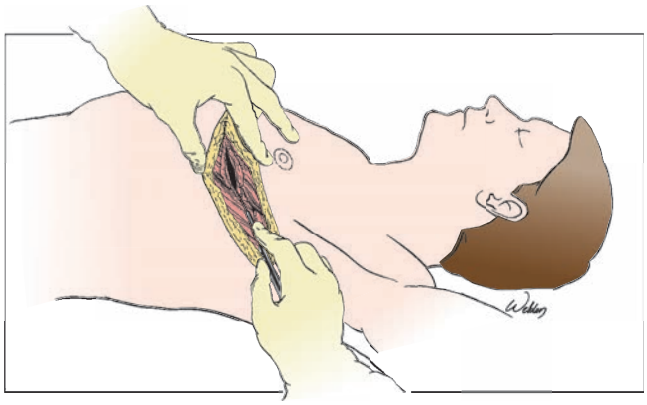

FIGURE 30-2 Left anterior thoracotomy (extension across the sternum if required). (Copyright © Baylor College of Medicine, 2005.)

In hemodynamically stable patients, particularly those with stab wounds to the precordium, a median sternotomy can be used. This allows exposure of the anterior structures of the heart but limits access to the posterior mediastinal structures and descending thoracic aorta for cross-clamping. Although posterior injuries can be addressed, these require skillful retraction and visualization during repair.

Poor technique during cardiac repair can result in enlargement of the injury or injury to the coronary arteries. If the initial treating physician is uncomfortable with suturing the injured heart, a Satinsky vascular clamp can be applied to the atrium or digital pressure to the ventricle until an experienced surgeon arrives. A large hole in a ventricle may require temporary insertion of a Foley balloon catheter, the use of crossed horizontal mattress sutures on either side of the injury, temporary occlusion of the superior and inferior vena cavae (inflow occlusion), or the intravenous injection of 3 mg of adenosine. Because cardiorrhaphy in the emergency center carries a 30% incidence of needlestick to the operator, a special skin stapler allows for rapid cardiac repair without the use of a needle[31] (Fig. 30-3). Repairs are definitive, although they can be buttressed in the operating room.

Injuries adjacent to coronary arteries can be managed by placing mattress sutures deep to the artery, avoiding it (Fig. 30-4). Mechanical support or cardiopulmonary bypass is required in less than 2% to 3% of patients in the acute setting.[4]

For stable patients with multiple thoracic gunshot wounds, diagnosis in the past was accomplished with chest x-rays in two projections, fluoroscopy, angiography, or echocardiography. Recently, multidetector CT scan has been used to determine missile tracks and localize any fragments. As previously noted, treatment of retained intracardiac missiles is individualized.[32-34] Removal is recommended for intracardiac missiles that are left-sided, larger than 1 to 2 cm, or rough in shape, or that produce symptoms. Although a direct approach, either with or without cardiopulmonary bypass, has been advocated, a large percentage of right-sided foreign bodies can now be removed by endovascular techniques, as mentioned earlier. Alternatively, those in the periphery of the atrium or right ventricle can be trapped with encircling sutures against the thinner chamber walls, the muscle incised, the missile removed, and then cardiorrhaphy performed.

Balloon occlusion of the aorta was described in the Korean War by the late Carl Hughes.[35] Resuscitative endovascular balloon occlusion of the aorta (REBOA) via femoral artery access is now being used to avoid the need to open the chest to clamp the descending thoracic aorta. Of interest, it has become common in the treatment of ruptured abdominal aortic aneurysms.[36,37] For trauma, REBOA is primarily recommended for hemodynamically unstable patients with an intact cardiac rhythm and a subdiaphragmatic injury or pelvic fracture. In such a patient, the balloon is inflated at the diaphragm (zone) or at the bifurcation of the abdominal aorta (zone 3), respectively.[38,39] This technique is less

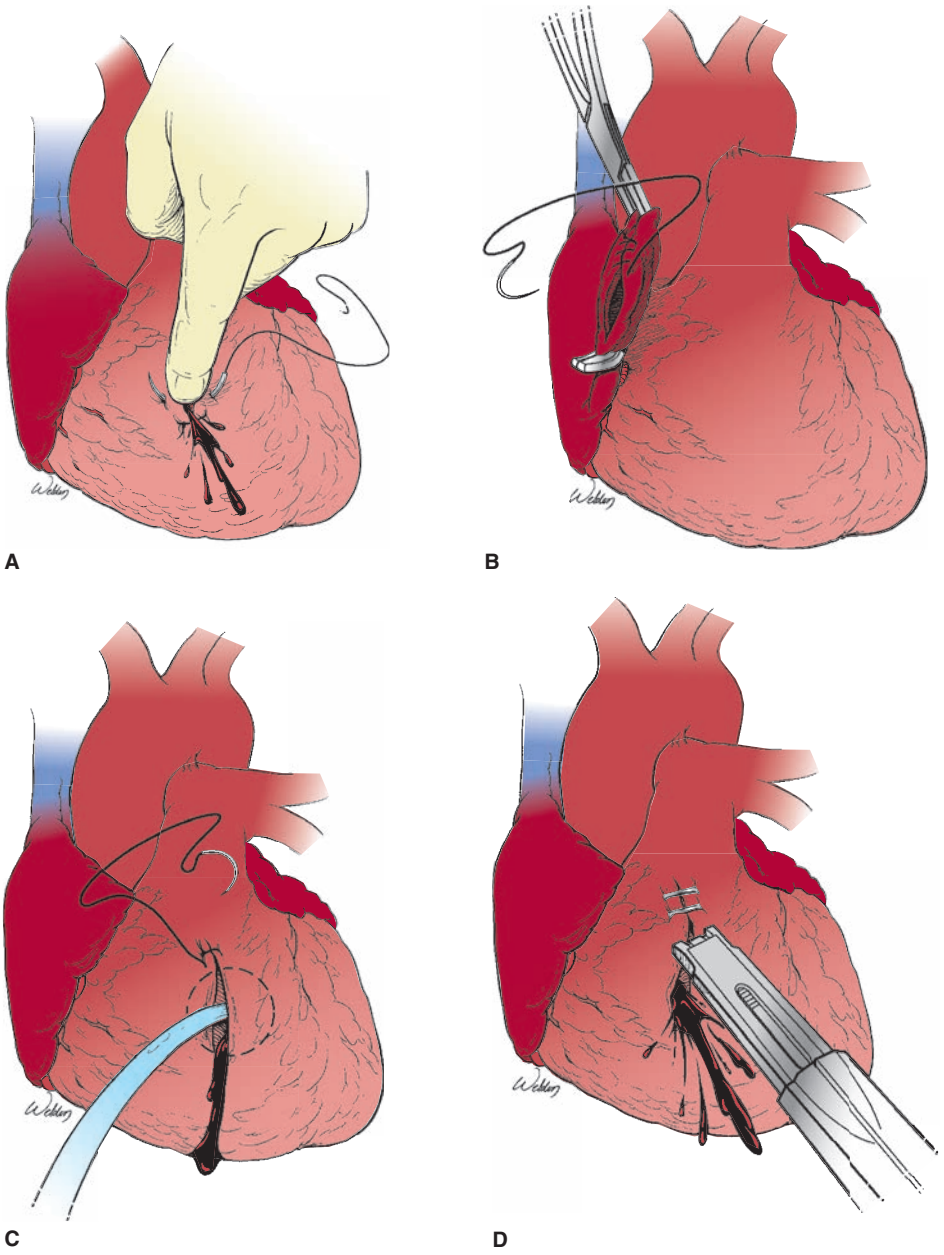

FIGURE 30-3 Temporary techniques to control bleeding. (**A**) Finger occlusion; (**B**) partial occluding clamp; (**C**) Foley balloon catheter; (**D**) skin staples. (Copyright © Baylor College of Medicine, 2005.)

useful for thoracic vascular injuries, as inflation of the balloon would occlude the aorta distal to potential injuries resulting in increased hemorrhage. It has its own complication profile, with reports of femoral access issues leading to amputation[40] (see Chapter 13).

BLUNT CARDIAC INJURY

Patients with new-onset cardiac arrhythmias without hypotension after blunt thoracic trauma are presumed to have a BCI and are admitted to a monitored bed.[13] Other patients with blunt thoracic injury and unexplained hypotension (rule out cardiogenic shock), presumed new-onset cardiac arrhythmias, and hypotension or a prior history of cardiac disease or surgery are admitted to an ICU.[13]

Results with Routine Cardiac Injuries

Many factors determine survival in the patient with a traumatic cardiac injury, including the following: mechanism of injury; location of injury; associated injuries; injury to a coronary artery or cardiac valve; presence of tamponade; length of prehospital transport; requirement for resuscitative

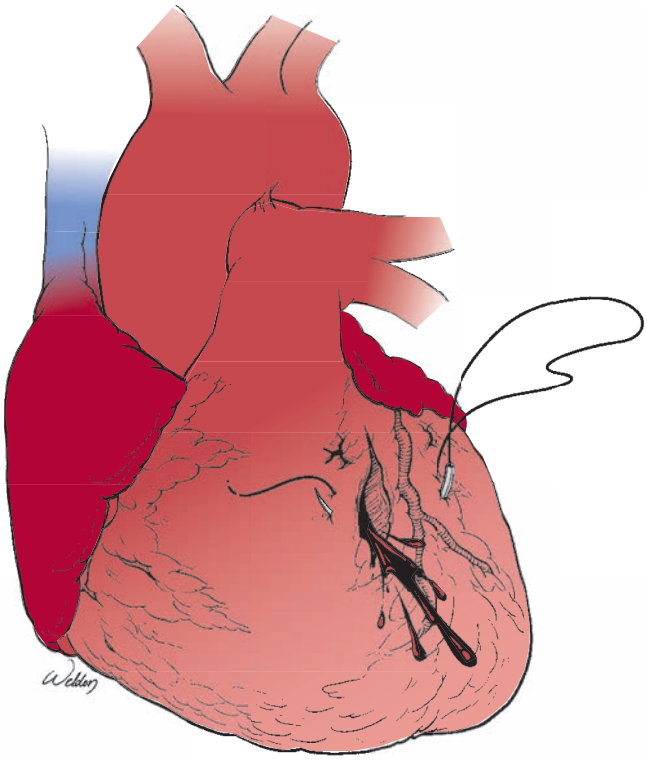

FIGURE 30-4 Injuries adjacent to coronary arteries can be addressed by placing sutures deep, avoiding injury to the artery. (Copyright © Baylor College of Medicine, 2005.)

thoracotomy; and experience of the trauma team. The overall hospital survival rate for patients with penetrating heart injuries who arrive with signs of life ranges from 30% to 85%, with rates of approximately 15% for those requiring emergency center thoracotomy and 74% to 86% for those stable enough to undergo operating room thoracotomy.

The survival rate for patients with stab wounds is 70% to 80%, whereas survival after gunshot wounds ranges between 30% and 40%. Blunt cardiac rupture has a worse prognosis than penetrating injuries to the heart, with a survival rate of approximately 20%.

Complex Cardiac Injuries

Complex cardiac injuries include those to the coronary artery or valvular apparatus (annulus, leaflet, papillary muscles, and chordae tendineae), intracardiac fistula, and delayed tamponade. These injuries have been reported to have a broad incidence (4%–56%), depending on the definition. Injury to the coronary artery is rare, occurring in 5%–9% of patients with cardiac injuries, and has a 69% mortality rate.[4] An injury to a distal coronary artery is most often controlled by simple ligation, but bypass grafting using a saphenous vein may be required for an injury to the proximal left anterior descending or right coronary artery.[4] Off-pump bypass can be used for such an injury in the unlikely event that the patient is hemodynamically stable.

Injury to the valvular apparatus is rare (0.2%–9%) and can occur after either blunt or penetrating trauma.[4] The aortic valve is most frequently injured, followed by the mitral and tricuspid valves. Unfortunately, many patients with injury to the aortic valve usually die in the prehospital period.

If severe cardiac dysfunction exists at the time of the initial operation and valvular injury is identified, immediate valve repair or replacement may be required; otherwise, delayed repair is more commonly advised. These injuries are usually identified postoperatively after the initial cardiorrhaphy and resuscitation have been performed in a patient with a new-onset postoperative murmur and/or hemodynamic deterioration. The timing of repair depends on the patient's condition.[4]

Intracardiac fistulas including ventricular septal defects, atrial septal defects, and atrioventricular fistulas have an incidence of 1.9% among all cardiac injuries. Management depends on symptoms and degree of cardiac dysfunction, with only a minority of these patients requiring repair.[4] These injuries are also usually identified after primary repair is accomplished, and they can be repaired after the patient has recovered from the original and associated injuries. Echocardiography should be obtained before repair so that specific anatomic sites of injury and operative planning can be accomplished.

Follow-Up

As discussed earlier, secondary sequelae in survivors of cardiac trauma include valvular abnormalities and intracardiac fistulas. Early postoperative clinical examination and ECG findings to diagnose these entities are unreliable. Thus, echocardiography is recommended during the initial hospitalization in all patients to identify an occult injury and establish a baseline study.[4,28,41] Because the incidence of late sequelae can be as high as 56%, follow-up echocardiography 3 to 4 weeks after injury has been recommended by some.[28,41]

INJURY TO THE THORACIC GREAT VESSELS

Injury to the thoracic great vessels—the aorta and its brachiocephalic branches, the pulmonary arteries and veins, the superior and intrathoracic inferior vena cava, and the innominate and azygos veins—occurs following blunt or penetrating trauma. Exsanguinating hemorrhage, the primary acute manifestation, also occurs in the chronic setting when a posttraumatic false aneurysm ruptures.

The operative treatment of great vessel injuries, primarily late traumatic false aneurysms and arteriovenous fistulas, was well described during World War II.[42] Current knowledge regarding the treatment of injured thoracic great vessels has been derived primarily from experience with civilian injuries related to improvements in emergency medical services and increased experience with elective surgery of the thoracic aorta and its major branches.[43]

TABLE 30-2: Common Anomalies of the Thoracic Aorta

Common origin of innominate and left common carotid arteries ("bovine arch")
Ductus diverticulum
Persistent left ductus arteriosus
Aberrant takeoff of the right subclavian artery from the descending thoracic aorta
Dextroposition of the thoracic aorta
Coarctation of the thoracic aorta
Origin of left vertebral artery off the aortic arch
Pseudocoarctation of the thoracic aorta ("kinked aorta")
Double aortic arch
Right ductus arteriosus

A detailed understanding of normal and variant anatomy and structural relationships is important in the evaluation of imaging studies. Venous anomalies occur, with the most common being absence of the left innominate vein and a persistent left superior vena cava. Anomalies of the aortic arch are relatively common and can mimic injuries or have implications for repair (Table 30-2). Knowledge of such anomalies is essential for both open and catheter-based therapies. For open cases, knowledge of aortic anomalies is helpful when dissecting to achieve vascular control around the often large hematoma that significantly distorts the anatomy. For endograft repair, vascular anomalies can affect the ability to achieve adequate seal zones. Aberrancies in the site/origins/outflow of the vertebral arteries can also significantly alter strategies and potential need for additional revascularization.

Etiology and Pathophysiology

More than 90% of thoracic great vessel injuries are due to penetrating trauma or therapeutic misadventures.[43] Iatrogenic lacerations of various thoracic great vessels, including the arch of the aorta, have been reported as complications of placement of percutaneous central venous catheters. The placement of chest tubes or pigtail catheters has caused injuries to the intercostal arteries and major pulmonary and mediastinal vessels as well. Finally, intra-aortic cardiac assist or occlusion balloons can produce injury to the thoracic aorta.

During emergency center resuscitative thoracotomy, the aorta may be injured during clamping if a crushing (nonvascular) clamp is used. Overinflation or migration of the balloon of a Swan-Ganz catheter has produced iatrogenic injuries to pulmonary artery branches with resultant fatal hemoptysis. Thus, once a linear relationship has been established between the pulmonary artery diastolic pressure and the pulmonary capillary wedge pressure, further "wedging" is unnecessary. Covered stent grafts being used for endovascular repairs of vascular injuries can cause iatrogenic injury through access, fixation, puncture, rupture, or occlusion. Self-expanding metal stents have recently produced perforations of the aorta and innominate artery following placement into the esophagus and trachea, respectively.[44]

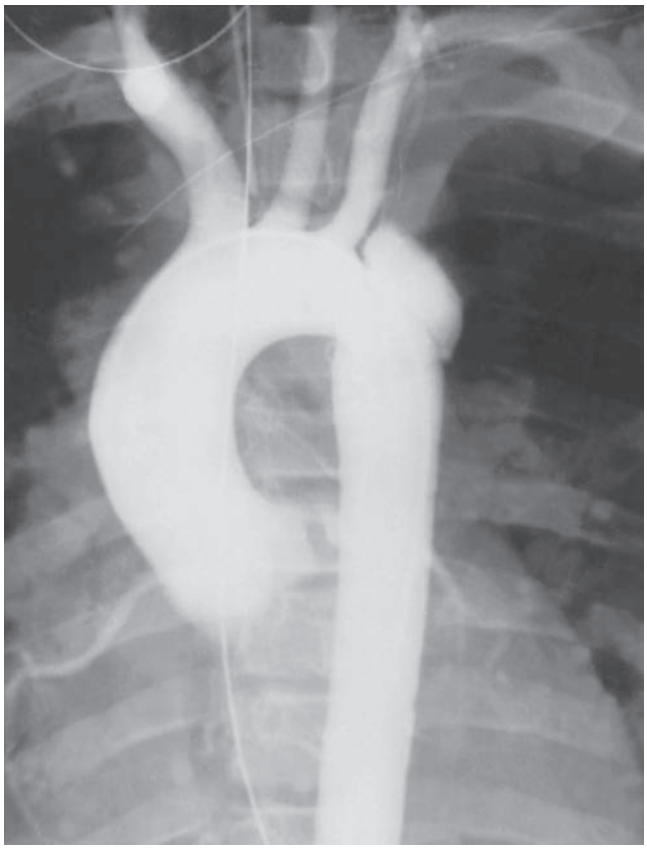

FIGURE 30-5 Aortogram demonstrating the classic intimal tear and traumatic pseudoaneurysm of the descending thoracic aorta.

The great vessels susceptible to injury from blunt trauma commonly include the origin of the innominate artery, pulmonary veins, vena cava, ascending aorta, and, most commonly, the descending thoracic aorta.[45] Aortic injuries have caused or contributed to 10% to 15% of deaths following motor vehicle accidents in the past 50 years before the introduction of airbags. These injuries commonly involve the proximal descending aorta (54%–65% of cases) (Fig. 30-5), but can involve other segments, such as the ascending aorta or transverse aortic arch (10%–14%), the mid- or distal descending thoracic aorta (12%) (Fig. 30-6), or multiple sites (13%–18%).

The postulated mechanisms of blunt great vessel injuries include the following: (1) shear forces caused by the relative mobility of a portion of the vessel adjacent to a fixed portion; (2) compression of the vessel between bony structures; and (3) abrupt, profound intraluminal hypertension during the traumatic event. The pericardial attachments of the pulmonary veins and vena cavae and the fixation of the descending thoracic aorta at the ligamentum arteriosum and diaphragm enhance their susceptibility to blunt rupture by the first mechanism. At its origin, the innominate artery may be "pinched" between the sternum and the vertebrae during sternal impact and cause what is actually an aortic arch injury.

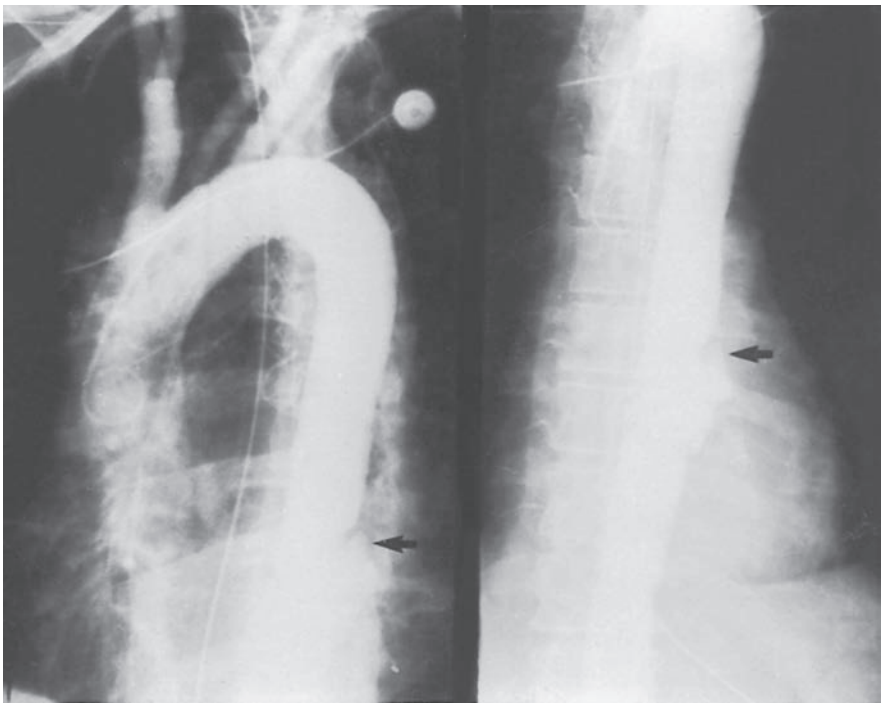

FIGURE 30-6 Aortogram in a patient with blunt chest trauma demonstrating an intimal tear of the descending thoracic aorta at the diaphragm.

Blunt aortic injuries may be partial thickness (traumatic true aneurysm)—histologically similar to an intimal tear—but most commonly are full thickness (traumatic false aneurysm) and, therefore, equivalent to a ruptured aortic aneurysm that is contained by surrounding tissues.

The histopathologic similarities between aortic injuries and nontraumatic aortic catastrophes suggest that similar therapeutic approaches be employed. Therefore, in hemodynamically stable patients, the concepts of permissive hypotension and minimization of arterial pressure impulse (dP/dT), which are widely accepted in the treatment of aortic dissection and aneurysm rupture, should be considered in the initial treatment of patients with blunt aortic injuries.

In contrast to patients with aortic medial disease where the adventitia is the restraining barrier, it is the intact parietal pleura that contains the hematoma and prevents a massive hemothorax around a full-thickness blunt injury to the descending thoracic aorta.

True traumatic aortic dissection, with a longitudinal separation of the media extending along the length of the aorta, is extremely rare.[46] The use of the term *dissection* in the setting of aortic trauma should thus be equally rare. Similarly, the terms *aortic transection* and *blunt aortic rupture* should be used only when describing specific injuries (ie, full-thickness lacerations involving either the entire or partial circumference, respectively). The term *blunt aortic injury* is probably most accurate and descriptive.

Patients with injury to a thoracic great vessel almost always have associated head, abdominal, and extremity injuries. Often, preexisting medical conditions are present, such as diabetes mellitus, hypertension, coronary artery disease, or cirrhosis. In addition, these patients may be taking a variety of medications, including aspirin, warfarin, platelet inhibitors, or other anticoagulants. These interfere with the clotting mechanism, and adaptations in treatment may be required.

Classification of Blunt Aortic Injury

ANATOMIC

Several anatomic classification systems of aortic injury have been proposed.[47,48] Azizzadeh et al[47] proposed a classification describing intimal tears, intramural hematoma, pseudoaneurysm, and rupture. Starnes et al[48] suggested a classification based on the presence of an abnormality in the aortic external contour (Table 30-3). Those without a contour abnormality were subdivided into intimal tears and large intimal flaps. Those with aortic contour abnormalities were subclassified into pseudoaneurysm and rupture. This is a functional

TABLE 30-3: Classification of Blunt Injuries to Thoracic Aorta

External aortic contour abnormality	Type
Absent	Intimal tear <10 mm
	Large intimal flap >10 mm
Present	Pseudoaneurysm
	Rupture

Source: Data from Starnes BW, Lundgren, RS, Gunn M, et al. A new classification scheme for treating blunt aortic injury. *J Vasc Surg.* 2012;55:47.

classification, and they noted that no patient with normal external aortic contour died of aortic injury in their experience. Eight of nine patients with free rupture died, raising the question of futility in these patients. The authors recommended the following: use of anti-impulse therapy and observation for initial intimal tears less than 10 mm; selective management of intimal flaps greater than 10 mm; semielective treatment of stable patients with pseudoaneurysms; and consideration of earlier treatment of patients with an abnormality of the external aortic contour and a traumatic brain injury because such patients might benefit from an increased blood pressure. In addition, they noted that coverage of the orifice of the left subclavian artery orifice was well tolerated in most patients.

PHYSIOLOGIC

Three distinctly different groups of patients with thoracic aortic trauma exist (Table 30-4). The epidemiology of aortic injury is changing, perhaps due to restraints and airbags in vehicles, road design, rapid accident notification, and emergency medical service (EMS) transport. The mortality statistics reveal that patients with exsanguinating hemorrhage almost all die within the first 0 to 2 hours of injury. Those who die in the emergency department, operating room, or ICU within 2 to 4 hours of injury often have extensive multisystem injury with hemorrhage, often from sites other than the thoracic aorta.

Patients who died several hours after injury from a traumatic brain injury but were found to have an unoperated thoracic aortic injury were subsequently analyzed by Mattox et al.[49] Cohorts of this group who remained moderately hypotensive did *not* die from an aortic rupture. This led to a policy of using drugs to alter the aortic shear force in patients with known aortic injuries who also had severe injuries to the brain or to multiple organs. The continuing lack of aortic-related mortality in this cohort led to a purposeful delay in aortic repair. The timing of such later repair and the technique of the repair are matters of local judgment. Hemodynamically stable patients who die and are subsequently found to have an aortic injury most often have injury to the brain as the cause of death.[49]

Prehospital Management

In patients with significant penetrating or blunt thoracic trauma, interventions performed by paramedics during transport can include judicious administration of intravenous fluids and endotracheal intubation when indicated.[50] In patients with acute injuries to a thoracic great vessel, excessive fluid resuscitation with the goal of increasing blood pressure to normal or supernormal levels increases mortality and other postoperative complications.[51]

Evaluation in the Emergency Center

HISTORY

In a patient with penetrating thoracic trauma, information regarding the length of a knife, or the firearm type, number of rounds fired, and the patient's distance from the firearm should be sought from the patient or witnesses.

Although the head-on motor vehicle collision is often considered the typical mechanism for blunt aortic injury, recent epidemiologic data reveal that up to 50% of cases occur following side-impact collisions. These injuries have also been reported following equestrian accidents, blast injuries, auto–pedestrian crashes, crush injuries, and falls from heights of 30 feet or more.[52] EMS personnel should be queried about the amount of hemorrhage at the scene, any history of intermittent paralysis following the accident, and hemodynamic instability during transport. Employing patterns of injury, the extent and location of damage to the vehicle parallel the potential injuries to the patient and may suggest the possibility of injury to a great vessel.[53]

PHYSICAL EXAMINATION

Upon arrival in the emergency center, each patient is given a rapid, thorough primary and secondary survey. External signs of penetrating or blunt trauma are noted. With an intrapericardial vascular injury, the previously described classic signs of pericardial tamponade (distended neck veins, pulsus paradoxus, muffled heart sounds, and elevated central venous pressure) may be present but occur infrequently. Clinical findings associated with injury to a thoracic great vessel include the following: hypotension; upper extremity hypertension; unequal blood pressures or pulses in the extremities (upper extremity from injury to the innominate or subclavian artery, or lower extremity from pseudocoarctation syndrome); external evidence of major chest trauma (eg, steering wheel imprint, hoofprint on chest); expanding hematoma at the thoracic outlet; intrascapular murmur; palpable fracture of the sternum; palpable fracture of the thoracic spine; and left flail chest.

TABLE 30-4: Groups of Patients with Injury to Thoracic Aorta

Group	Description	Time to diagnosis	Location of death	Mortality	Cause of death
1	Dead/dying at scene	<60 min	Scene/EMS	100%	Bleeding
2	Unstable during transport	1–6 h	EMS/EC	>96%	Multisystem trauma
3	Stable	14–18 h	ICU	5%–30%	CNS injury

CNS, central nervous system; EC, emergency center; EMS, emergency medical services; ICU, intensive care unit.

IMAGING

Upon arrival, a supine anteroposterior chest x-ray should be performed, ideally in the emergency center and not in a distant radiologic suite. Emergency physicians, radiologists, and surgeons should develop diagnostic experience viewing supine portable chest x-rays because many trauma patients are hemodynamically unstable or have suspected spinal injuries, making an "upright" chest x-ray unsafe to obtain. In many patients with injury to a great vessel, the radiologic findings are sufficient to warrant further investigation or direct transport to the operating room.

For penetrating injuries, it is helpful to place radiopaque markers to identify the surface wounds. Radiographic findings that suggest a penetrating wound to a thoracic great vessel include the following: large hemothorax; foreign bodies (bullets or fragments) or their trajectories in proximity to the great vessels; a foreign body out of focus with respect to the remaining x-ray, which may indicate an intracardiac location; a trajectory with a confusing course, which may indicate a migrating intravascular bullet (Fig. 30-7); and a "missing" missile in a patient with a gunshot wound to the chest, suggesting distal embolization in the arterial tree.

Several x-ray findings have been associated with blunt injuries of the descending thoracic aorta. Although widening of the mediastinum is nonspecific, the most reliable of these signs is the "double shadowing" of the aortic knob contour (Table 30-5). Mediastinal widening at the thoracic outlet and leftward tracheal deviation are suggestive of an injury to the innominate artery. These signs are secondary to a mediastinal hematoma, which is an indirect sign of injury to a thoracic great vessel. The presence of any of these signs is a positive screening test and warrants further investigation. Currently, screening contrast CT of the chest is commonly obtained in these patients and has replaced the screening chest x-ray.

Due to the density of important structures, missile wounds that appear to traverse the mediastinum create concern regarding injury to the heart, esophagus, trachea, spinal cord, or major vessels. Mediastinal transverse with paraplegia suggests a posterior trajectory, with injures to the heart and vascular structures less likely. Should a cardiac or vascular injury be present, tamponade or major hemorrhage is usually obvious and precludes the need for a CT. Therefore, multidetector CT scanners are often used in stable patients to demonstrate missile trajectory.

Initial Treatment and Screening

TUBE THORACOSTOMY

When the chest x-ray indicates a significant hemothorax, a chest tube can be placed and connected to a collection system

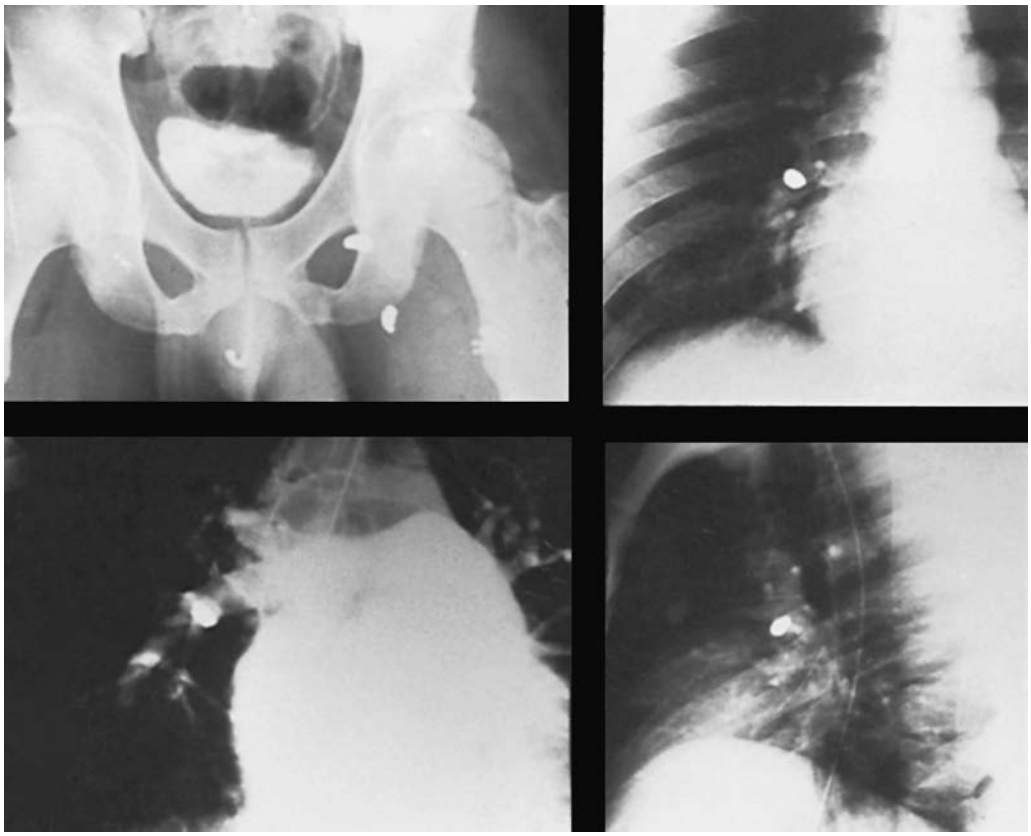

FIGURE 30-7 Series of x-rays demonstrating the entrance site of a bullet in the left groin. The bullet embolized to the right pulmonary artery, as confirmed by arteriography.

TABLE 30-5: Radiographic Clues That Should Prompt Suspicion of an Injury to a Thoracic Great Vessel

Fractures	Sternum
	Scapula
	Multiple left ribs
	Clavicle in multisystem injured patient
Mediastinal clues	Obliteration/double shadow of aortic knob contour
	Widening of the superior mediastinum >8 cm
	Depression of the left mainstem bronchus >140° from trachea
	Loss of paravertebral pleural stripe
	Calcium layering at aortic knob
	Deviation of nasogastric tube in the esophagus
	Lateral displacement of the trachea
	"Funny looking" mediastinum
Lateral chest x-ray	Anterior displacement of the trachea
	Loss of the aorta/pulmonary artery window
Other findings	Apical pleural hematoma
	Massive left hemothorax
	Obvious blunt injury to the diaphragm

that allows for autotransfusion. As previously noted, an output of 1500 mL over the first 15 minutes or significant ongoing hemorrhage (>200–250 mL/h) is an indication for an emergent or urgent thoracotomy.[54]

EMERGENCY CENTER THORACOTOMY

Emergency center thoracotomy in patients presenting with signs of life and hemodynamic collapse may reveal injuries to major thoracic vessels. These injuries require temporizing maneuvers to gain rapid control of bleeding and allow resuscitation and then subsequent transfer to the operating room for definitive repair.[55] Subclavian vessel injuries, for example, can be controlled by intrapleural packing, clamping at the thoracic apex, or inserting intravascular balloon catheters. Aortic injuries can be controlled with aortic or partial occluding clamps. Major hemorrhage from the pulmonary hilum can be temporarily managed by cross-clamping the entire hilum proximally or twisting the lung 180° after releasing the inferior pulmonary ligament.[56]

INTRAVENOUS ACCESS AND FLUID ADMINISTRATION

Currently, unless a patient is in extremis, large-bore intravenous catheters are inserted, but high-volume resuscitation is avoided until the time of vascular control at operation. If a subclavian venous catheter is required in a patient with an upper thoracic injury, the contralateral side should be used for cannulation. The treatment of severe shock should start with blood transfusion; however, rapid infusions of excessive volumes of either blood or crystalloid solutions prior to operation may increase the blood pressure to a point that a protective soft perivascular clot is dislodged and fatal exsanguinating hemorrhage ensues.

The principles of permitting moderate hypotension (systolic blood pressure of 60–90 mm Hg) and limiting fluid administration until achieving operative control of bleeding are cornerstones in the management of ruptured abdominal aortic aneurysms and equally apply to acute injuries to thoracic great vessels. Following guidelines developed with the military, a conscious patient with a radial pulse is not resuscitated until the time of operative vascular control.[57] Aggressive preoperative fluid resuscitation also increases postoperative respiratory complications and may contribute to an increased mortality when compared to fluid restriction.[51] With both penetrating and blunt chest trauma, associated pulmonary contusions are common and provide an additional rationale for limiting the infusion of preoperative crystalloid solutions.

IMPULSE REDUCTION THERAPY/β-BLOCKADE FOR SUSPECTED BLUNT AORTIC INJURY

The pharmacologic reduction of arterial impulse (dP/dT) has remained a critical component of the treatment of aortic dissection since its original description by Wheat et al[58] in 1965. Based on the similarity between aortic dissection and blunt aortic injury, this principle was first applied in 1970 using β-blockade to reduce aortic impulse for patients with suspected or confirmed blunt injury to the thoracic aorta. Subsequent reports have described using this therapy in hemodynamically stable patients who had proven blunt aortic injuries but required a delay in definitive operative treatment.[59] Some centers routinely begin impulse reduction therapy as soon as an injury to the thoracic aorta is suspected—prior to obtaining diagnostic studies—in an attempt to reduce the risk of fatal rupture during the interval between presentation and confirmation of the diagnosis. Although retrospective studies suggest that this policy is safe, no prospective studies have demonstrated either the safety or efficacy of such treatment.

SCREENING/PLANNING CT SCAN FOR THORACIC VASCULAR INJURY

Following blunt trauma, the potential for thoracic great vessel injury, and, therefore, the need to proceed with further investigation, are determined based on the following: (1) the mechanism of injury; (2) physical examination; (3) the standard chest x-ray; or (4) a screening CT scan.

All of these factors must be considered in concert. Traumatic ruptures of the thoracic aorta have occurred following seemingly innocuous mechanisms, including low-speed automobile crashes (<10 mph) with airbag deployment and intrascapular back blows used to dislodge an esophageal foreign body. Additionally, 50% of patients with thoracic vascular injuries from blunt trauma present without any external physical signs of injury. In addition, 7% of patients with

blunt injury to the aorta and brachiocephalic arteries have a normal-appearing mediastinum on admission chest x-ray.

As previously noted, multidetector CT scan of the chest is recommended as a screening test for blunt injury to the thoracic aorta.[60-62] As resolution and experience in using CT to plan operations increase, it is important to ensure that the appropriate information regarding extent of injury, anatomy, and aberrant branches is obtained. Because it is the most common location for blunt aortic injuries, CT scan as a diagnostic test is most helpful to diagnose an injury of the proximal descending thoracic aorta. Motion artifact in the proximal ascending aorta, however, can be difficult to interpret on CT. A CT scan gated to cardiac motion may better delineate the ascending aorta and provide increased resolution.[63]

The diagnostic controversy regarding CT for thoracic injuries lies in the technology and technique, which has evolved at a very rapid rate. It is important to understand that a 4-channel, 16-detector machine has different capabilities than a 64-channel/detector machine. The protocols for obtaining the CT examination, such as number and spacing of detectors, channels, pitch, slice thickness, contrast injection, timing, and reconstruction, can significantly alter the information obtained. Thus, it is important to be familiar with the appropriate protocols needed.

The raw CT data are manipulated in a "postprocessing" function to deliver the final images. The previous static CT film images are now read on digital displays where a knowledgeable observer can further manipulate the image. Three-dimensional reconstructions, although impressive to view, consume processing resources and have not been necessary in the acute evaluation of all blunt aortic injuries (Fig. 30-8).

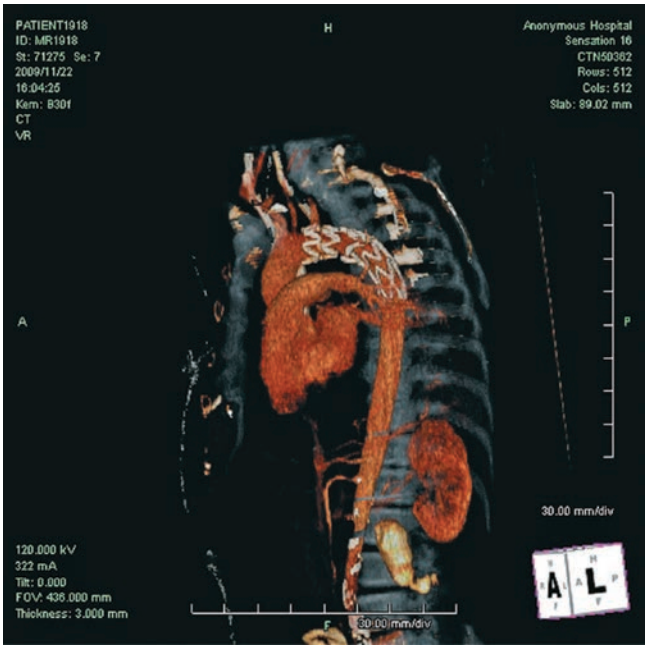

FIGURE 30-8 A three-dimensional reconstruction of the computed tomography in a patient with an injury to the aortic isthmus showing the thoracic endograft deployed.

FIGURE 30-9 Multiplanar reformatting display of a typical injury through the descending thoracic aorta distal to the left subclavian artery. This allows the viewer to align the slice along the axis of the aorta. The small cube in the lower right corner represents the orientation.

Multiplanar reformatting is a postprocessing mode where the CT slice can be angled and positioned to best display the pathology. This is most useful for the evaluation of blunt aortic injury when the CT slice/virtual gantry is aligned with the curvature of the ascending/arch/descending thoracic aorta, and the slices can traverse through the aorta (Fig. 30-9). This is helpful not only for diagnosis, but also for planning, selecting endovascular devices, and evaluating seal zones for the device. Center-line flow analysis displays the aorta as a straight line along its center allowing precise measurements of diameter and accurate measurements of seal zones for planning (Fig. 30-10). If the clinician directly caring for the patient cannot manipulate and interpret the images themselves, much useful information as well as artifacts may not be appreciated. This may explain some of the conflicting reports and opinions on the utility of CT for screening or diagnosis. With appropriate scanners, protocols, processing, display, and experience, CT potentially yields more information than catheter angiography.

If a mediastinal hematoma is visualized on CT, formal aortography was obtained in the past to specifically determine the site of the injury and to identify any vascular anomalies that required modifications in the operative approach. With improved resolution of the screening CT of the chest, this study is no longer needed for screening. In current practice, this now occurs just prior to placing an endograft.

Algorithms can be constructed to aid the surgeon in reaching a diagnosis and treating a patient with an injury to the thoracic aorta (Fig. 30-11). As experience has developed with endovascular repair, the CT scan has been extremely helpful

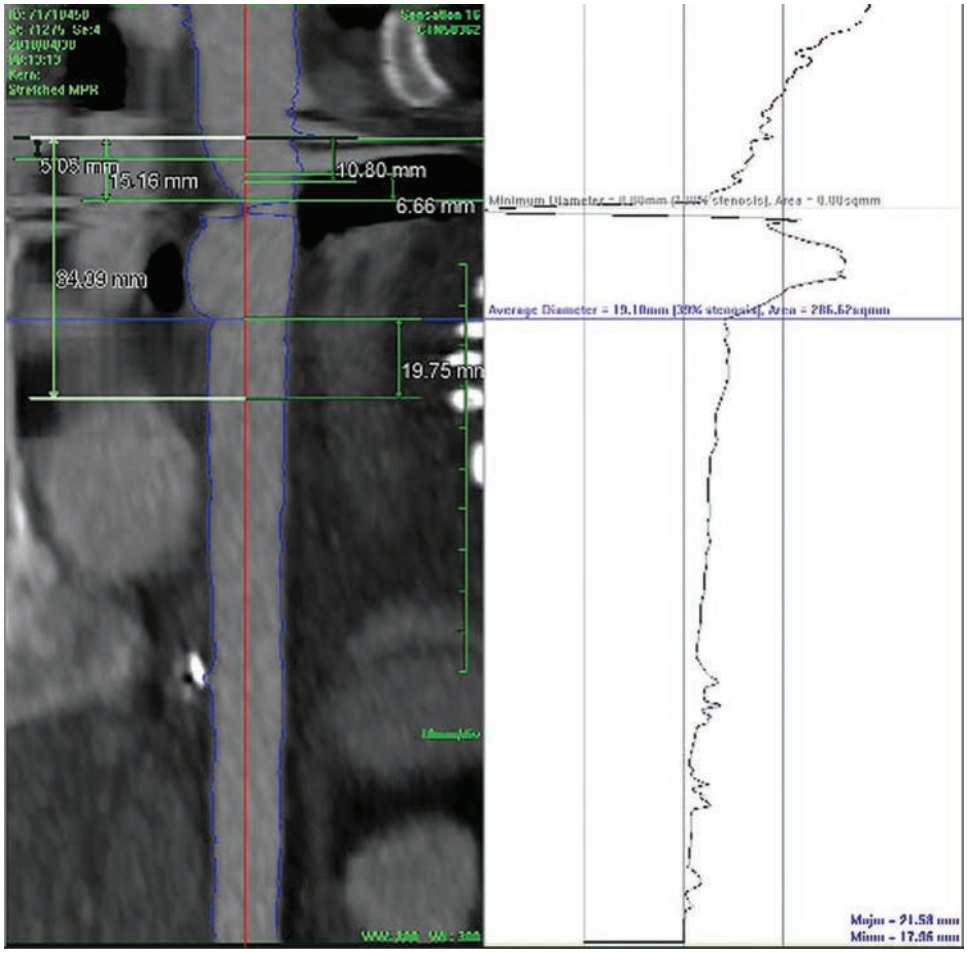

FIGURE 30-10 Center-line flow analysis of a patient with injury at the aortic isthmus. This view electronically straightens the aorta along the center-line axis of flow, allowing accurate measurements regarding landing zones/seal areas and the device length to be determined. This analysis shows that by covering the left subclavian artery, a 15- to 16-mm proximal seal area is available and a 35-mm area will need to be covered. This display also shows the average aortic diameter to be 19 mm. This can be useful to plan difficult cases for which the landing zones/seal area are difficult to precisely determine.

for preoperative planning for evaluation for access and stent graft repair. The CT protocol for thoracic trauma, however, has much less information than the protocol for planning elective stent grafting. Initial CT scans are often performed on underresuscitated patients, with highly compliant/dynamic aortas. Intraoperative planning with intravascular ultrasound is frequently performed and very useful. Transesophageal echocardiography has added little in the screening or diagnosis of thoracic aortic injury, except perhaps intraoperatively when operating on another cavity. Magnetic resonance angiography can generate similarly detailed information; however, its application in these potentially unstable trauma patients is not currently practical. In patients who are treated in a delayed fashion with a very complex injury, it can be helpful to get a stent graft protocol CT after resuscitation.

CATHETER ARTERIOGRAPHY

In the past, catheter angiography was recommended to diagnose suspected penetrating injuries to the thoracic aorta or to the innominate, carotid, or subclavian arteries in stable patients. As noted earlier, however, experience with chest CT arteriography (CTA) has replaced catheter angiography as an initial screening test or to plan procedures. Any questionable findings on the CTA can be further evaluated by catheter arteriography or intravascular ultrasound if needed. Also, catheter arteriography or CTA is helpful for localizing the injury and planning the appropriate incision. Proximity of a missile trajectory to the brachiocephalic vessels, even without any physical findings of vascular injury, can be an indication for imaging, recognizing also that thoracic outlet vascular injuries may involve multiple vessels.[64] Catheter arteriography, however, has recognized limitations. A "negative" aortogram may convey a false sense of security if the laceration has temporarily "sealed off" or if the column of aortic contrast overlies a small area of extravasation (Fig. 30-12). Therefore, an effort must be made to obtain views tangential to possible injuries (Figs. 30-13 and 30-14). In addition, CTA has the limitations of scatter adjacent to a missile, which may obscure a possible injury.

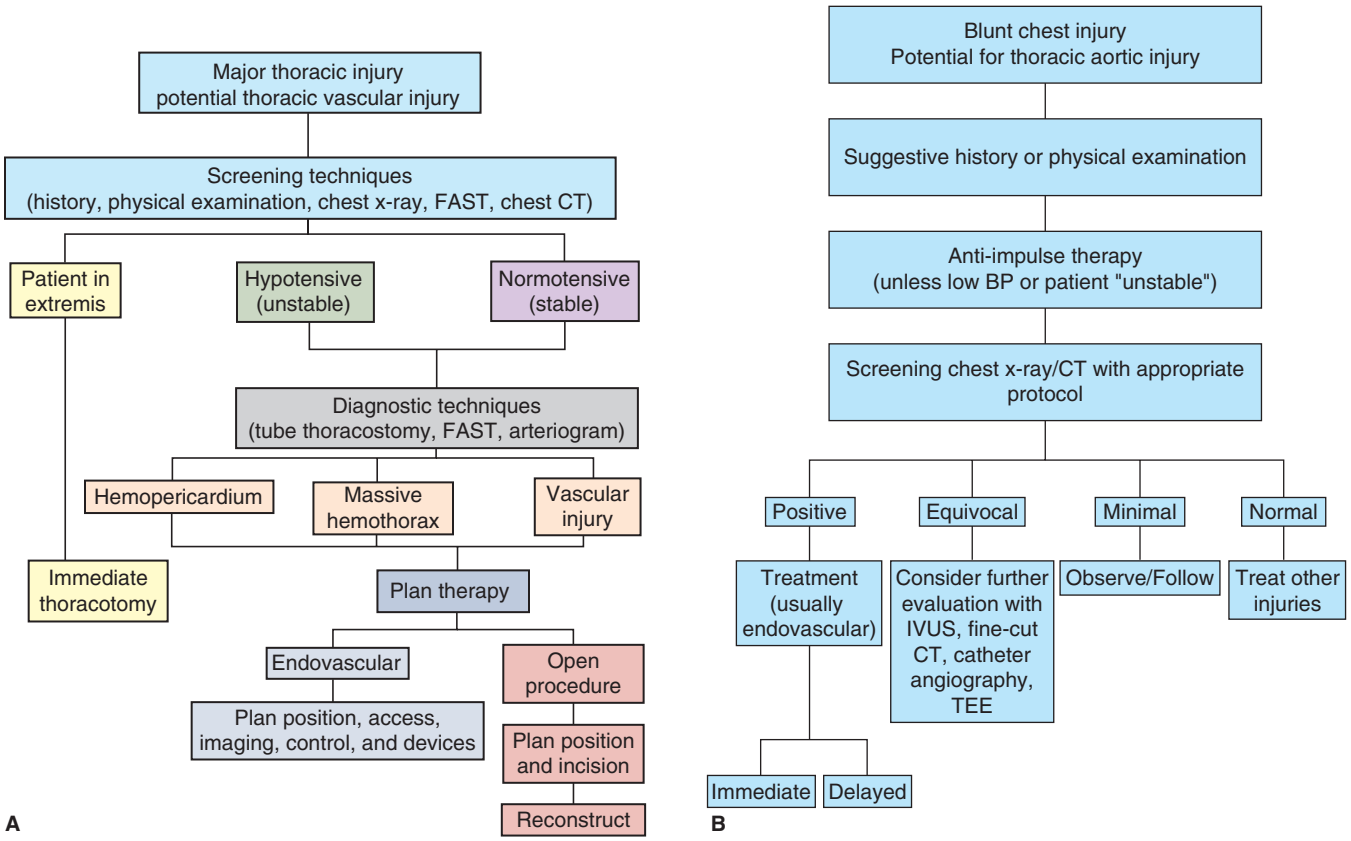

FIGURE 30-11 (**A**) Algorithm for an approach to patients with suspected thoracic vascular injury. (**B**) Algorithm for the evaluation and treatment of a patient suspected of having a blunt injury to the thoracic aorta. BP, blood pressure; CT, computed tomography; FAST, focused assessment with sonography for trauma; IVUS, intravenous ultrasound; TEE, transesophageal echocardiography.

Treatment Options

NONOPERATIVE MANAGEMENT

Nonoperative management of blunt injuries to the thoracic aorta should be considered in patients who have potentially lethal associated injuries or contraindications to early repair. Examples would include the following: traumatic brain injury; risk factors for infection (major burns, sepsis, heavily contaminated wounds); severe multisystem trauma with hemodynamic instability; poor physiologic reserve; and a minimal aortic injury.

In such instances, nonoperative management is actually a purposeful delay in operation while attempts are made to achieve physiologic optimization and improve the potential outcome of repair. Nonoperative management has also been used successfully in patients with "nonthreatening" aortic lesions, such as minor intimal defects and small traumatic false aneurysms. Close observation without operation is similarly reasonable for small intimal flaps involving the brachiocephalic arteries in asymptomatic patients, as many such lesions will heal spontaneously.

With the increased use of endograft repair as well as patients with an increased number of associated injuries, blunt injuries to the thoracic aorta are often definitively repaired more than 24 hours after presentation when the patient is optimized. In the multicenter report by Demetriades et al,[59] delayed repair (>24 hours) of stable patients with blunt injury to the thoracic aorta was associated with improved survival, but also a longer stay in the ICU and a higher complication rate.

Although apparent minor vascular injuries may resolve or stabilize, their long-term natural history remains uncertain. Life-threatening complications of great vessel injuries—including rupture and fistulization with severe hemorrhage—occurring more than 20 years after injury have been reported.[52] Therefore, careful follow-up, including serial imaging studies, is a critical component of nonoperative management. Avoiding hypertension and the use of impulse control agents are recommended as well when patients with blunt injuries to the thoracic aorta are managed nonoperatively.

ENDOVASCULAR REPAIR: GENERAL PRINCIPLES

There are many new techniques and devices for the endovascular approach to injuries to the thoracic aorta and entries in the thoracic outlet. With better understanding of the endovascular tools, this approach has increasingly been adopted by

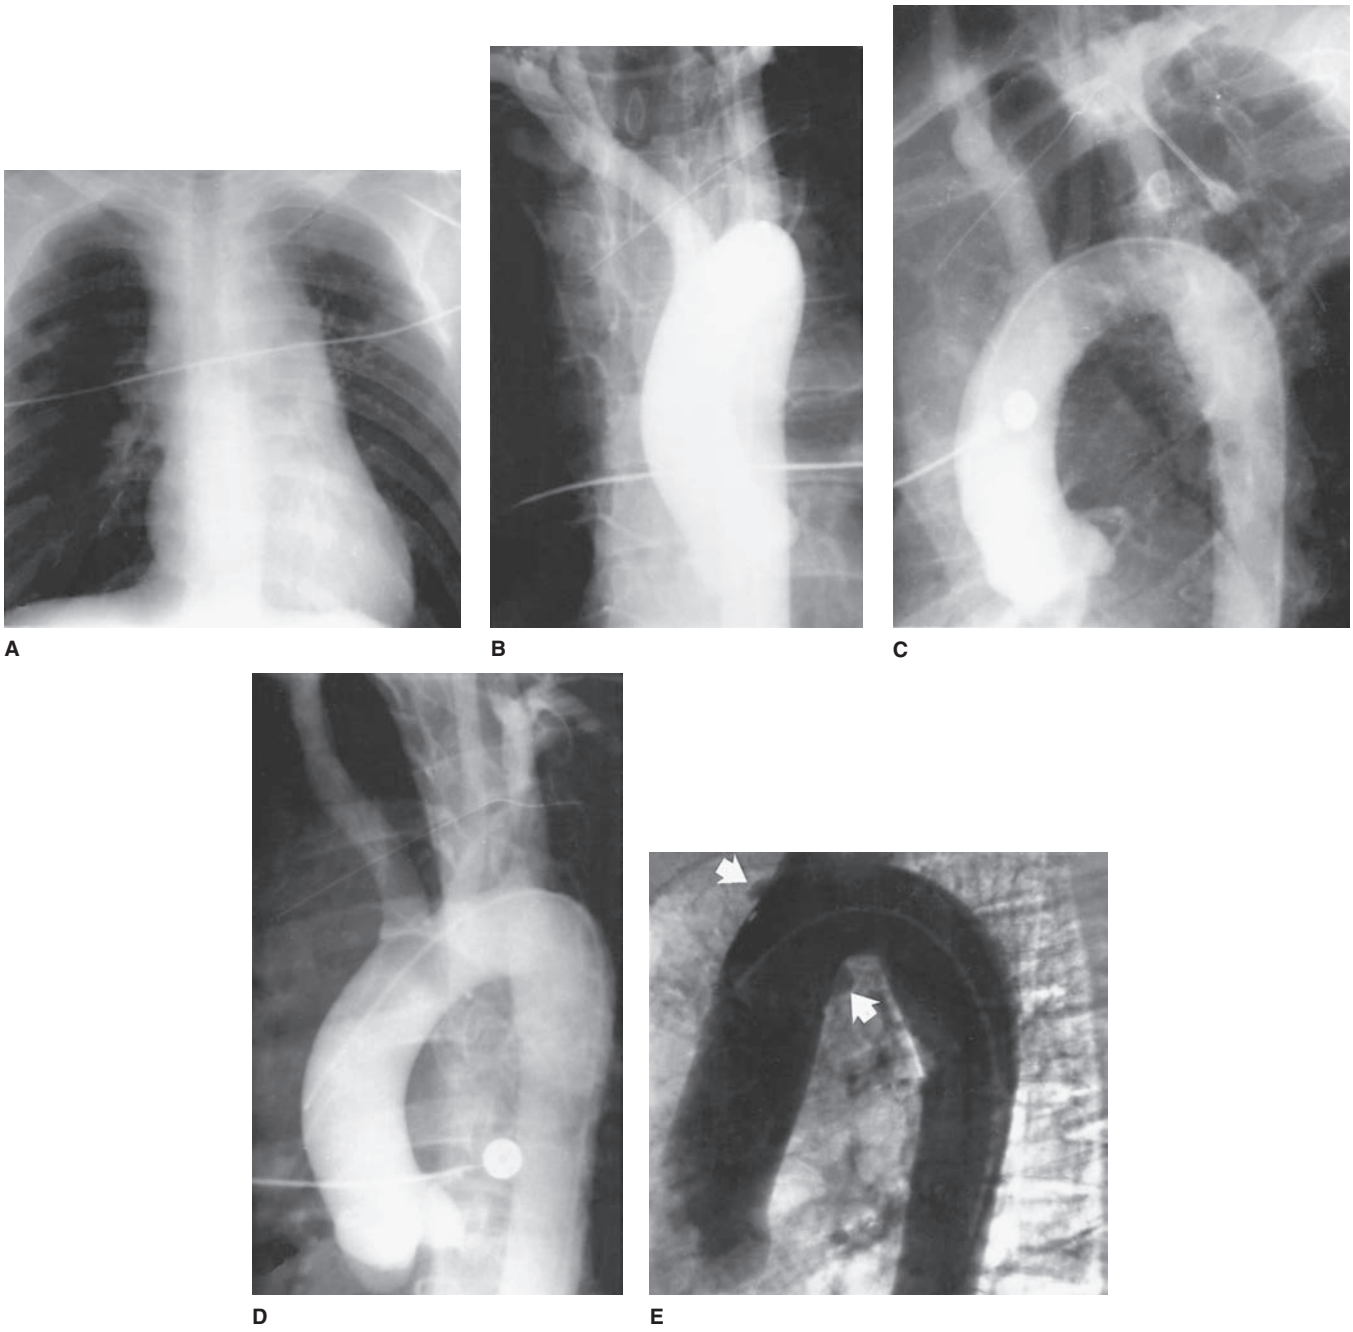

FIGURE 30-12 Misdiagnosis by aortography. (**A**) Chest radiograph of a patient with a tiny puncture wound from a Philips screwdriver at the left sternal border in the second intercostal space. The patient arrived in the emergency room 30 minutes after being wounded and had stable vital signs for the following 48 hours. (**B**) Anteroposterior projection of the aortogram was interpreted as showing no injury. (**C**) Left anterior oblique projection of the aortogram was also interpreted as showing no injury. (**D**) Near-lateral projection of the aortogram was also read as normal by staff radiologist. (**E**) Subtraction aortography in the lateral projection demonstrates tiny outpouching of the thoracic aorta anteriorly at the base of the innominate artery and posteriorly on the undersurface of the transverse aortic arch (arrows). Penetrating injury of the transverse aortic arch was confirmed intraoperatively. (Reproduced with permission from Mattox KL. Approaches to trauma involving the major vessels of the thorax. *Surg Clin North Am*. 1989;69:83. Copyright © Elsevier.)

vascular and cardiothoracic surgeons. One limit has been the perception that a full endovascular suite is required. Although this multimillion-dollar investment may be helpful, the majority of these endovascular repairs can be performed with a small inventory of devices including a portable vascular bed and a portable vascular C-arm.

Analogies between the open and endovascular approach can be easily drawn. For an open approach, an incision is made to access the area of concern. For the endovascular approach, vascular access in an appropriate site is obtained. To access the injury via the open approach, a retractor is placed and dissection occurs from the outside to identify target vessels.

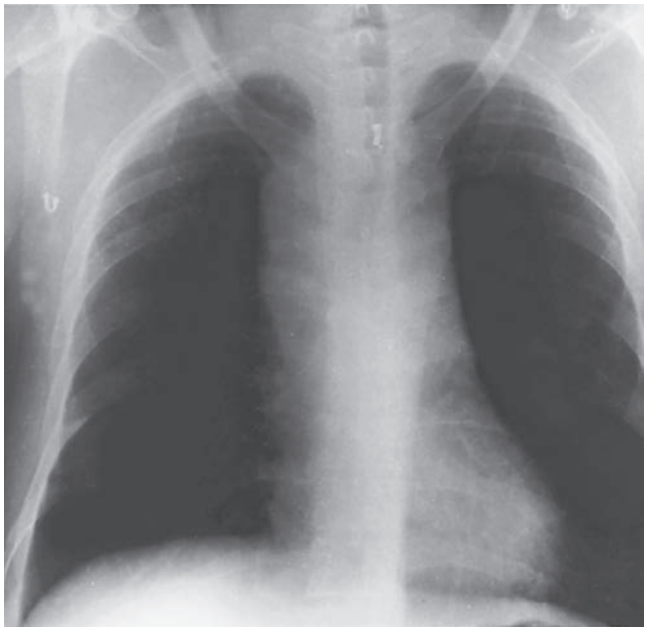

FIGURE 30-13 Plain chest x-ray of a patient with a penetrating wound of the ascending aorta.

In the endovascular approach, access with a wire sheath and a catheter is used to approach the injury from inside the vessel. To achieve vascular control via the open approach, vascular clamps are used from the outside. To achieve control via the endovascular approach, a balloon is used. To repair an injury via the open approach, a vascular suture or vascular graft is used. For the endovascular approach, a covered stent is used. To ligate branches directly, suture or clips are used. For the endovascular approach, coils or glue are used. When one becomes familiar with the endovascular tools and parallels to open instruments, these repairs becomes less daunting.

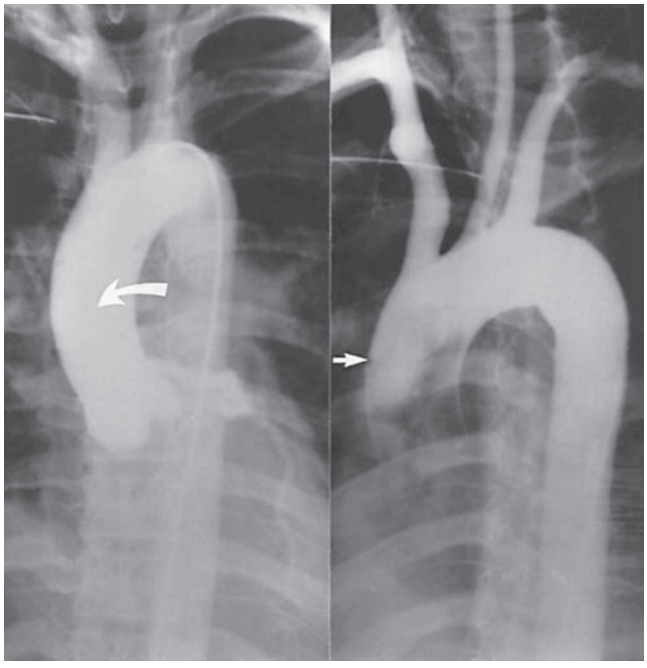

FIGURE 30-14 Aortogram of the patient in Fig. 30-13 demonstrating no apparent injury in the anteroposterior projection, but revealing a defect in the anterior aortic wall on the left anterior oblique projection (*arrows*).

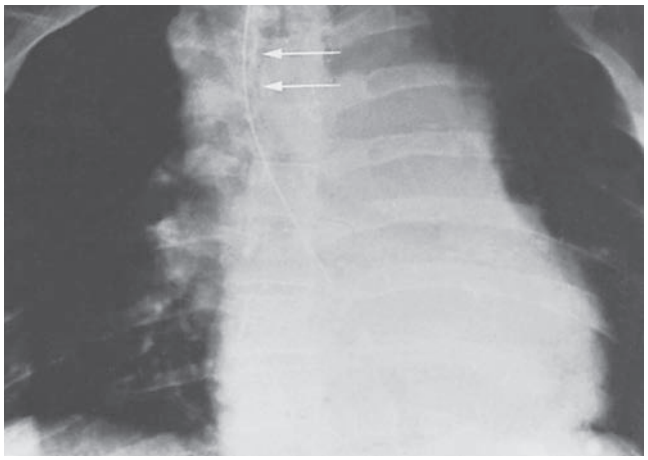

FIGURE 30-15 Plain chest x-ray in a patient with a blunt injury to the descending thoracic aorta. Note the rightward deviation of both the trachea and nasogastric tube in the esophagus.

OPEN SURGICAL REPAIR: GENERAL PRINCIPLES

As previously noted, indications for urgent transfer to the operating room for thoracotomy include hemodynamic instability, significant hemorrhage from chest tubes, and radiographic evidence of a rapidly expanding mediastinal hematoma (Fig. 30-15).

DAMAGE CONTROL

Patients with "physiologic exhaustion" often require damage control management for survival. The two approaches to thoracic damage control are as follows: (1) definitive repair of injuries using quick and simple techniques that control hemorrhage during a single operation; and (2) abbreviated thoracotomy; reversal of hypothermia, acidosis, and coagulopathy; and a planned reoperation for definitive repairs.[55]

Pulmonary tractotomy allows rapid management of associated penetrating injuries to the lung.[65] Severe vascular injuries in the pulmonary hila can be quickly controlled by performing a pneumonectomy using stapling devices. Temporary vessel ligation or placement of intravascular shunts in the common carotid or subclavian arteries can control bleeding and maintain arterial flow until the reoperation. En masse suture closure of the chest wall muscles is more hemostatic than towel-clip closure. A Bogotá bag or vacuum pack may be used as a temporary closure of a median sternotomy in cases with associated cardiac dysfunction.

Endovascular Repair

DESCENDING THORACIC AORTA

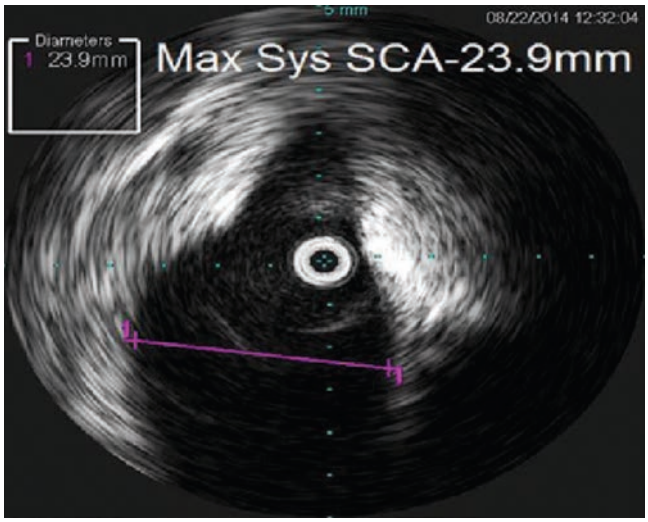
Beginning in the late 1990s, case reports and small series of thoracic endografting for acute transections of the proximal

descending thoracic aorta were reported.[66-69] These were often custom devices using aortic or iliac artery extenders.[70] Not infrequently, the left subclavian artery was occluded by the endograft, with the need for a subsequent left carotid–subclavian bypass in some patients. Iatrogenic injury to the access site of the femoral or iliac artery was occasionally reported. Although the majority of reports have focused on the proximal descending thoracic aorta, isolated reports exist for repair of injury to the ascending aorta and transverse arch.[71]

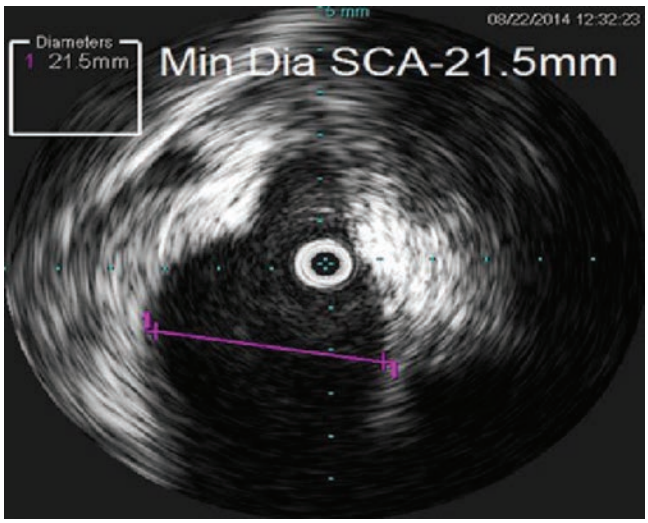
In the United States, several commercial devices have been approved by the US Food and Drug Administration for thoracic aortic aneurysms and are used off label in patients with traumatic injuries to the descending thoracic aorta. The average diameter of the thoracic aorta among patients with aortic tears is 19.3 mm. Because manufacturers recommend 15% to 20% oversizing, thoracic endovascular devices need an aortic diameter of greater than 18 mm. Smaller aortas treated with endografts require custom or off-label abdominal devices, and smaller aortic devices are being developed. With greater oversizing, compression and infolding have been reported, and infolding can result in thrombosis of the aorta. Over 85% of blunt injuries in the descending thoracic aortic are less than 1 cm from the orifice of the left subclavian artery. An endovascular seal zone length on either side of the pathology of 1 to 2 cm is recommended. Additionally, the young patient's aorta has significant angulation in the potential proximal seal zone, which can cause leading edge "beaking" and infolding. This has implications for where to land in the space between the stent on the endograft in relation to this angulation. Thus, consideration for covering the orifice of the left subclavian artery 40% to 80% of the time can be influenced by the intracerebral and spinal circulation as well as a history of a prior coronary artery bypass using the left internal mammary artery. Dominant left vertebral arteries or those with blind posterior intracommunicating arteries may require revascularization with the aforementioned bypass from the left common carotid artery to the left subclavian artery. More recently, endovascular techniques with fenestration at the orifice of the left subclavian artery or chimney grafts have been used.[71]

As previously noted, preoperative planning includes vascular, cardiothoracic, and acute care surgeons and a protocol-driven CTA of the chest, abdomen, and pelvis. Goals of the CT are to define the following: (1) size and extent of the aortic injury; (2) angulation of the arch at its junction with the descending thoracic aorta; (3) diameter and length of aorta proximal and distal to the injury to help determine seal zones; (4) location of the injury in relation to the orifice of the left subclavian artery; (5) size of the vertebral arteries; and (6) angulation of aortic branches. All of this information helps to determine which introducer sheaths and devices are appropriate to cover the aortic injury.

The patient with a blunt injury to the descending thoracic aorta is often young and has a very compliant aorta. As noted, these patients are often underresuscitated, and their aortic diameter is often very small. It has been noted that the diameter of the descending thoracic aorta on thoracic CT varies, perhaps with the cardiac cycle. Intravascular ultrasound (IVUS) can be very helpful to interrogate aortic size in systole, as well as the location of branch vessels and appropriate seal zones. Following experience with the use of IVUS for ruptured abdominal aneurysms, many endovascular surgeons have begun the routine use of IVUS during endograft repair of blunt injury to the descending thoracic aorta.[72,73] The IVUS probe is passed on the working wire, and aortic diameter and seal zones are assessed. The IVUS catheter can then be used as the exchange catheter for the stiff wire used to deploy the endograft. The dynamic nature of the aortic diameter in these patients is striking (Fig. 30-16). Because the screening chest CT for trauma is often not adequate for planning, our service routinely uses IVUS to do final planning of seal zones and selection of appropriate stent graft.



A



B

FIGURE 30-16 Intravascular ultrasound of the descending thoracic aorta at the left subclavian artery during the cardiac cycle. Note the marked difference in diameter between end systole (**A**) and end diastole (**B**). This can have a significant effect on endograft sizing.

A recent report comparing sizing based on CT with intraoperative IVUS noted that the size of the planned endograft was changed based on IVUS over 50% of the time, particularly for more proximal aortic repairs covering the left subclavian artery.[72]

Access can often be a problem in young patients, especially females, with small iliac/femoral arteries that preclude safe placement of the introducer sheath. Currently, the smallest commercially available thoracic endografts require a 7- to 8-mm diameter of the external iliac artery. Direct introduction or sewing of an extra-anatomic graft to the common iliac artery or abdominal aorta to allow deployment of an endovascular stent graft may be necessary in an occasional patient. It should be noted that the majority of morbidity/mortality from thoracic endograft repair is from disruption of iliac vessels during placement of the endograft.

In a composite report using a variety of approved and customized endografts, 239 patients were treated for blunt injury to the proximal descending thoracic aorta (Table 30-6).[74] Among the 239 patients, there were nine deaths (3.8%) and one paraplegia (<0.5%). Even with potential selection bias, the lower mortality and almost nonexistent paraplegia rate makes consideration for endovascular repair very compelling, particularly in a delayed fashion.[59,61,75,76] Yet to be answered are the engineering challenges of graft compression and infolding, as well as the need for smaller sizes, conformation of the endograft to the curvature of the arch, tailored/branched grafts, and improved delivery systems. The short- and mid-term follow-up have favored endovascular stenting, and this has been enthusiastically adopted by most centers.[77] The long-term fate of endovascular stent grafts, however, is currently being assessed.[78]

With changes in the presenting patient population, as well as endograft-related diagnosis, imaging, and engineering technology, the timing, diagnosis, and management of blunt aortic injuries have been evolving rapidly. The report by Demetriades et al[59] of the American Association for the Surgery of Trauma (AAST) multicenter study, with its two follow-up manuscripts, documented significant shifts in diagnosis and management. In his Scudder Oration, "Blunt Thoracic Aortic Injuries: Crossing the Rubicon," comparing the early AAST report (Fabian et al[79]) with the latter AAST reports (Demetriades),[59,61,80] Demetriades noted the following: cross-sectional imaging is now routinely used for screening; purposeful delay in definitive treatment is commonly performed; endovascular repair is now the most common repair performed, practically displacing open repair; endovascular repair has a 60% decrease in mortality and paraplegia; and endovascular repair results in an increase in access and device-related complications and concern for long-term sequale.[79,80] These reports have been the most comprehensive to date and are a template to track results as the technology evolves. Studies documenting the rate of aortic dilation after endograft repair are being reported and will be important for assessing the long-term durability of endograft repair.[78] With better imaging, there is recognition that minimal blunt aortic injuries often heal spontaneously and do not require intervention. With improvements in vascular access and devices that are able to accommodate the smaller patient, endovascular repair can be applied to more patients. Multiple follow-up studies continue to support endovascular repair in blunt injury to the descending thoracic aorta.[81] It is clear, however, that the treatment for a specific patient will continue to be individualized, and multiple approaches (nonoperative/delayed/open/endograft) will continue to be needed.[59,61,76,81]

TABLE 30-6: Comparison of Open versus Endovascular Treatment of Blunt Injury to Thoracic Aorta

	Open operations	Endograft repair
Mortality	0%–55%	0%–12%
Average mortality	13%	3.8%
Paraplegia	0%–20%	<1%
Average paraplegia	10%	1 out of 239 cases
Complications	ARDS	LSCA occlusion
	CNS problems	Graft compression
	Neurologic	Access site problems

ARDS, adult respiratory distress syndrome; CNS, central nervous system; LSCA, left subclavian artery.

The Endovascular Procedure The patient is placed supine on a vascular table with the imager and display on the patient's left. Extraneous monitoring devices such as ECG leads are removed so as not to impede imaging of the left chest, and the patient is prepared so access to both groins is available. In addition, with consideration for fenestration of the orifice of the left subclavian artery, access to the left arm is made available. When preoperative imaging has documented a steep angulation of the arch that may lead to difficult tracking of the endograft, access to the right arm is needed so that through-and-through access can be obtained to assist in tracking the endograft around the arch. It has been found that tracking of the device works best with access from the right groin. In patients who can be heparinized, percutaneous access through both groins with a pre-close technique is often used. Otherwise, percutaneous diagnostic access is obtained from the left groin with device access obtained via cutdown of the right groin.

For patients with small vessels and difficult access, a right lower quadrant incision can be made to expose the retroperitoneal right common iliac artery or the distal abdominal aorta. The distal abdominal aorta can be cannulated directly using a pursestring suture. For access to the right common iliac artery, a Dacron graft sewn to the vessel over a partially occluding vascular clamp is appropriate.

Cross-sectional imaging is carefully examined to note which, if any, portion of the aortic wall is intact so that the wire can be directed to that area to traverse the site of injury. The injury is traversed using a directable catheter and a floppy wire. This is exchanged for a stiffer wire and a

pigtail catheter with radiographic markings. The right common femoral artery is accessed with an 8F sheath, and the site of injury traversed in a similar manner. Catheter exchange occurs, and placement of the IVUS catheter is performed. The aorta is interrogated, and the anatomy of the injury, anticipated seal zones, and position of the left subclavian artery are then assessed. Final graft selection is confirmed or modified based on these findings. Wire exchange to the stiff device delivery wire is performed using the IVUS catheter. Using the radiographic markers on the pigtail catheter and the previously measured angles on the CT scan, the gantry of the imaging device is placed orthogonal to the arch to prevent parallax error. Arteriography is then performed to confirm the anatomy. The right-sided access is dilated and the device delivered. After magnifying down to the proximal seal zone, arteriography is performed again, and the area of the proximal sealed zone is confirmed. The proximal seal zone of the device is then delivered. Without moving the imaging head, the view can be unmagnified to show the distal graft as it is deployed. The delivery device can be removed with replacement of an equivalent size sheath maintaining wire access. A balloon can be used to dilate the seal zones if needed. A confirmatory aortogram is obtained to evaluate the repair after recapturing and repositioning the flush catheter.

Future Investigation Although the short-term results of endografts have been quite favorable, there is concern about the long-term results in young patients. As described earlier, studies note that the aorta dilates over time and the behavior of the endografts in the aging patient is being tracked. There have been reports investigating this issue, and a national registry to track these repairs has been suggested.[77,78,80]

Even with potential selection bias in favor of endografts, the low mortality and almost nonexistent paraplegia rate make the use of endografting very compelling. The reported complications of graft migration, infolding, compression, occlusion of the left subclavian artery, and problems at the entry site are all technical and engineering challenges that may potentially be solved by new commercial devices.

THORACIC OUTLET/SUBCLAVIAN ARTERY

Early endovascular approaches to thoracic outlet injuries had variable results.[82] Some early repairs were attempted in the radiology suite where there was limited ability to monitor and treat unstable patients. As surgeons have become more involved in the use of these devices and they are performed in the operating room, they are used more frequently. As previously noted, there has been recognition that a hybrid suite is not always required and that these grafts can be placed with a portable C-arm. This creates flexibility because potentially any well-equipped operating room could be a site for these procedures with a vascular table and a portable vascular C-arm, as described earlier. Thus, an unstable patient can be brought to the operating room with all its benefits and in the care of the trauma team, anesthesiologist, and surgeon. Even unstable patients with complete transections or patients with large hematomas can be treated. In an effort to eliminate the thoracic incisions for proximal control of injuries to the subclavian artery, surgeons have developed the skills to place an endovascular balloon via femoral access for proximal control. The injury can then be managed with a supraclavicular incision.

The development of small, self-expanding, covered stents has facilitated this endovascular approach. A wire placed via femoral access can traverse a partial lateral injury. For transected vessels or thrombosed injuries, through-and-through snare techniques allow complex repairs in unstable patients to occur.[83,84] For thoracic outlet injuries, a CT scan of the chest with vascular contrast in the stable patient defines the injury and allows planning. The patient is positioned supine on a vascular bed, with the appropriate arm available to allow for access. In the operating room, access to the femoral artery is obtained. A wire and catheter are directed into the vessel that is injured, and a balloon can be placed for proximal control. Arteriography can verify the injury and the position of the vertebral artery if the subclavian artery is injured. For the subclavian artery, a cutdown on the ipsilateral brachial artery is performed so that brachial access for a wire snare from the arm can be achieved. The wire from the groin is introduced into the injury or hematoma and grasped by the snare from the arm establishing through-and-through access traversing the injury. A self-expanding covered stent can then be placed. These techniques have been used for transected vessels and for hypotensive patients, as well as for patients with multiple injuries including combined injuries to the carotid and subclavian arteries. These approaches are also extremely helpful for patients who have had previous thoracic operations. In the report by Gilani et al[84] of endovascular management of eight unstable patients or those with transected subclavian arteries, there was 100% survival and only one graft thrombosis at 14 months. Others have reported similar results with endovascular repair, noting improved mortality and lower complication rates.[85,86]

Open Surgical Repair

In the preoperative phase, whenever possible, patients and their families should be made aware of the potential for neurologic complications such as paraplegia, stroke, or injury to the recurrent laryngeal nerve or brachial plexus following surgical reconstruction of thoracic great vessels. Therefore, careful documentation of preoperative neurologic status is helpful. With any suspicion of vascular injury, prophylactic antibiotics are administered preoperatively. In hemodynamically stable patients, fluid administration is limited until vascular control is achieved in the operating room, as noted earlier. An autotransfusion device should be available. During the induction of anesthesia, wide swings in blood pressure should be avoided. Although profound hypotension is clearly undesirable, hypertensive episodes can have equally catastrophic consequences.

The operative approach to great vessel injury depends on the hemodynamic status of the patient and the specific

TABLE 30-7: Recommended Incisions for Injuries to Thoracic Great Vessel

Injured vessel	Incision
Uncertain injury (hemodynamically unstable)	Left anterolateral thoracotomy Transverse sternotomy ± Right anterolateral thoracotomy (clamshell)
Ascending aorta	Median sternotomy
Transverse aortic arch	Median sternotomy ± Cervical extension
Descending thoracic aorta	Left posterolateral thoracotomy (fourth intercostal space)
Innominate artery	Median sternotomy with right cervical extension
Right subclavian artery or vein	Median sternotomy with right cervical extension
Left common carotid artery	Median sternotomy with left cervical extension
Left subclavian artery or vein	Left anterolateral thoracotomy (third or fourth intercostal space) with separate left supraclavicular incision Endovascular balloon occlusion may eliminate need for thoracotomy for proximal control
Pulmonary artery	
Main/intrapericardial	Median sternotomy
Right or left hilar	Ipsilateral thoracotomy
Pulmonary vein	Ipsilateral thoracotomy
Innominate vein	Median sternotomy
Intrathoracic vena cava	Median sternotomy
Azygos vein	Ipsilateral thoracotomy

injury. Patient positioning and selection of incision are particularly important in surgery for great vessel injuries because adequate exposure is needed for proximal and distal control (Table 30-7). Prepping and draping of the patient should provide access from the neck to the knees. For the patient in extremis with an undiagnosed injury, the mainstay of thoracic trauma surgery is the left anterolateral thoracotomy, with the patient in the supine position. In stable patients, CT/CTA may dictate an operative approach by another incision.

Appropriate graft materials should be available, recognizing known limitations. The failure mode of an infected prosthetic graft is a pseudoaneurysm, whereas an infected saphenous vein graft, a devitalized collagen tube susceptible to bacterial collagenase, will dissolve and cause uncontrolled hemorrhage. Therefore, for vessels larger than 5 mm, a prosthetic graft is the conduit of choice, especially in potentially contaminated wounds.

Due to patency considerations, a saphenous vein graft may need to be used when smaller grafts are required. For fragile vessels, such as the subclavian artery and the aorta in young patients, a soft knitted Dacron graft is preferred.

ASCENDING AORTA

Patients with blunt injuries to the ascending aorta rarely survive transport to the hospital. Operative repair requires total cardiopulmonary bypass and insertion of a Dacron graft. If the sinus of Valsalva or the aortic valve is involved, aortic root replacement with reimplantation of the coronary ostia may be required.[63]

Penetrating injuries involving the ascending aorta are uncommon (see Figs. 30-11 and 30-12). Survival rates approach 50% for patients having stable vital signs on arrival at a trauma center.[87] When in extremis, these injuries are found during an exploration through a left anterolateral or clamshell incision. For urgent explorations, these injuries can be approached via a median sternotomy. Although primary repair of anterior lacerations can be accomplished without adjuncts, cardiopulmonary bypass may be required if there is an additional posterior injury. The possibility of a peripheral bullet embolus must be considered in patients with a single gunshot wound to the thoracic aorta.

TRANSVERSE AORTIC ARCH

When approaching an injury to the transverse aortic arch, extension of the median sternotomy to the neck is necessary to obtain exposure of the arch and brachiocephalic branches. If necessary, exposure can be further enhanced by division of the left innominate vein. When hemorrhage limits exposure, balloon tamponade is useful as a temporary measure. Simple lacerations may be repaired by lateral aortorrhaphy using a 4-0 polypropylene suture. With difficult lesions, such as posterior lacerations or those with concomitant injuries to the pulmonary artery, cardiopulmonary bypass may be required. As with injuries to the ascending thoracic aorta, survival rates approaching 50% have been reported.[87] In stable patients, isolated reports of endograft repair with arch vessel debranching have been described.

DESCENDING THORACIC AORTA

Injury to the descending thoracic aorta is often accompanied by other organ injuries. If the patient has a stable thoracic hematoma and concomitant abdominal injury, laparotomy should be the initial procedure. For the patient with a rapidly expanding hematoma, however, repair of the thoracic injury should be the primary therapeutic goal. Sequencing is driven by the lesion that is most likely to cause exsanguination.

Although uncommonly performed now, the standard technique of repair involves *clamping and direct reconstruction* (Table 30-8). The three commonly employed adjuncts to this approach are as follows: (1) pharmacologic agents; (2) temporary, passive bypass shunts; and (3) pump-assisted atriofemoral bypass or cardiopulmonary bypass. In the latter approach, the following two options exist: (1) traditional pump bypass, which requires heparin; and (2) use of a centrifugal (heparinless) pump circuit (see Atlas Figures 36 and 37). The surgeon must choose the approach most appropriate to the specific clinical situation and one that works the best in his or her system.

TABLE 30-8: Current Therapeutic Approaches to the Management of Blunt Injuries to the Thoracic Aorta

1. Endograft repair
   a. With/without coverage of left subclavian artery
   b. With/without restoration of flow to left subclavian artery
2. Surgical (clamp and direct reconstruction with or without an interposition graft)
   a. Pharmacologic control of proximal hypertension
   b. Passive bypass shunts
   c. Pump-assisted bypass
      (1) Traditional cardiopulmonary bypass (with total-body heparinization)
      (2) Left heart bypass using centrifugal pump (with/without heparinization)
3. Nonoperative and/or purposeful delay of operation (with pharmacologic treatment and close radiologic surveillance)

The initial objective is proximal control. Therefore, the transverse aortic arch is exposed, and umbilical tapes are passed around the arch between the left common carotid and left subclavian arteries. Similarly, the left subclavian artery is encircled with an umbilical tape. Care should be taken to avoid injuring the left recurrent laryngeal nerve at this location, although it is often difficult to visualize in the hematoma. If it is suspected that the tear extends to the aortic arch or ascending aorta, cardiopulmonary bypass should be available in the operating room. If the patient has had previous coronary artery bypass surgery with use of the left internal mammary artery as a conduit, repair may require full cardiopulmonary bypass to protect the heart.

Vascular clamps are applied to the transverse arch proximal to the left subclavian artery, distal descending thoracic aorta, and left subclavian artery. Close communication between anesthesiologist and surgeon is essential to maintain stability of hemodynamic parameters before, during, and after clamping, particularly with use of vasodilators to prevent cardiac strain. The hematoma is entered, and back-bleeding from intercostal arteries is controlled with oversewing. Care is taken to avoid indiscriminate ligation of intercostal vessels, and only those required for adequate repair of the aorta should be ligated. After defining the injury, the clamps are moved closer, allowing maximal collateral flow. The proximal and distal ends of the aorta are completely transected and dissected away from the esophagus, allowing full-thickness suturing while minimizing the risk of a secondary aortoesophageal fistula. The injury is then repaired by either end-to-end anastomosis or insertion of an interposition graft, which is performed in more than 85% of reported cases. Prior to clamp removal, blood transfusions and infusion of crystalloid solutions are often needed to avoid hypotension.

For patients undergoing repair of a blunt injury to the descending thoracic aorta, the historic reported mortality has ranged from 0% to 55% (average 13%).[74,88,89] As expected in these victims of major blunt trauma, the mortality is primarily associated with other injuries and is often due to a traumatic brain injury, infection, or multiple organ failure.

The most feared complication of open repair of the descending thoracic aorta is paraplegia. Utilization of protective adjuncts during repair remains a topic of considerable debate. There have been proponents of the use of passive shunts and cardiopulmonary bypass, with and without heparinization. The mortality rate with the use of routine cardiopulmonary bypass is probably secondary to hemorrhage in the brain, abdomen, or at fracture sites. Over the past 35 years, experience using centrifugal pumps for left heart bypass without heparinization has provided an attractive alternative for surgeons who wish to use controlled flow bypass without systemic anticoagulation. This also allows unloading of the left heart during clamping, which can be helpful in patients with cardiac disease. The use of bypass systems, however, is not without complications. In the trauma patient, difficulty inserting cannulae may occur due to patient position, the presence of a periaortic hematoma, and time constraints imposed by an expanding, pulsatile, uncontrolled hematoma. Intraoperative and postoperative complications include bleeding at the cannulation sites and formation of a false aneurysm.

Use of simple clamp-and-repair for injuries to the descending thoracic aorta (without the use of systemic anticoagulation or shunts) is a technique that continues to be used with excellent results. In 1992, Sweeney et al[90] reported using simple clamp-and-repair in 75 patients, only one of whom developed postoperative paraplegia.

Ultimately, the determinants of postoperative paraplegia are multifactorial; therefore, the exact causes cannot be precisely identified in an individual patient (Table 30-9). Paraplegia has been associated with perioperative hypotension, injury or ligation of the intercostal arteries, and duration of clamp occlusion during repair.[90] There are, however, reports of patients surviving surgery without paraplegia, despite having long segments of aorta replaced as well as ligation of multiple intercostal arteries.

The length of aortic cross-clamp time does not *directly* correlate with postrepair paraplegia. A cross-clamp time less than 30 minutes has been argued to provide a safe margin against paraplegia, and shunting techniques have been recommended when longer cross-clamp times are necessary.[91] The use of a shunt, however, does not offer protection for the area of the spinal cord supplied by the arteries between the clamps. Furthermore, patients requiring longer clamp times or interposition grafts have more extensive injuries than those requiring shorter clamp times or end-to-end anastomoses. Thus, it is likely that an increased incidence of paraplegia associated with longer clamp times is secondary to more extensive disruption of intercostal arteries and other flow to the anterior spinal artery caused by the original injury.

Various monitoring techniques are available to assess the effect of occlusion of the descending thoracic aorta on the spinal cord, including the measurement of somatosensory and motor-evoked potentials. Although correlation appears to exist with loss of somatosensory-evoked potentials, duration

TABLE 30-9: Possible Contributing Factors to the Development of Paraplegia Following Operations for Injuries to the Thoracic Great Vessel

Injury factors	Direct segmental/radicular/spinal artery injury
	Spinal cord contusion/concussion
	Spinal canal compartment syndrome
	Severity of aortic injury
	Specific anatomic location of aortic injury
Patient factors	Location of arteria radicularis magna (artery of Adamkiewicz)
	Continuity of anterior spinal artery
	Caliber of individual segmental radicular arteries
	Congenital narrowing of spinal canal
	(?) Increased blood alcohol levels
	Total perispinal collateral blood supply
Operative factors	Required occlusion of segmental arteries
	Pharmacologic agents required
	(?) Declamping hypotension
	(?) Required cross-clamp times (in combination with anatomic and injury factors cited in this table); length of required interposition grafting or required exclusion
	(?) Level of systolic (or mean) proximal aortic blood pressure
	(?) Level of distal aortic mean blood pressure
	(?) "Flow" in the aorta distal to clamp
Postoperative factors	Progressive swelling of the spinal cord
	Spinal canal compartment syndrome
	Delayed or secondary occlusion of injured or contused segmental, radicular, or spinal arteries
	Pharmacologic-induced spasm of spinal cord nutrient arteries

of loss of conduction, and postoperative paraplegia, the use of this modality is not common to all trauma centers. The interpretation of results is still being debated, and actual applicability requires further study. Regardless of the technique used, paraplegia occurs in approximately 10% of these patients (range, 0%–22%).[74,89] No prospective, randomized trial has identified the superiority of any single method. Therefore, the choice of operative technique does not infer legal liability when paraplegia occurs.

INNOMINATE ARTERY (SEE ATLAS FIGURES 30 AND 31)

Median sternotomy is employed for access to injuries to the innominate artery. A right cervical extension can be used when necessary. As previously described, blunt injuries typically involve the proximal innominate artery and, therefore, actually represent aortic injuries and require obtaining proximal control at the transverse aortic arch (Fig. 30-17). In contrast, penetrating injuries of the innominate artery may occur

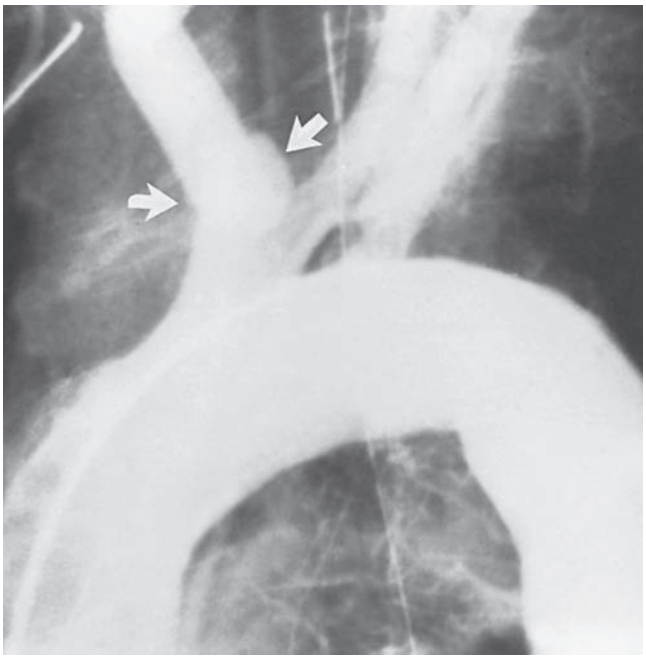


FIGURE 30-17 Aortogram of a patient with blunt innominate injury demonstrating the tear involving the proximal innominate artery.

throughout its course. Once again, exposure is enhanced by division of the crossover left innominate vein.

In selected patients with penetrating injuries, a running lateral arteriorrhaphy using 4-0 polypropylene suture is occasionally possible. More often, injuries to the innominate artery require repair via the bypass exclusion technique developed by Mattox and described in Johnston et al[92] (Fig. 30-18). Bypass grafting is performed from the ascending aorta to the distal innominate artery (immediately proximal to the bifurcation into the subclavian and right common carotid arteries) using a Dacron tube graft. The area of injury is avoided until the sites for insertion of a bypass graft are exposed. A vascular clamp is placed proximal to the bifurcation of the innominate artery to allow collateral flow to the brain via the right subclavian into the right common carotid artery. Hypothermia, systemic anticoagulation, and shunting are not required. After the bypass is completed, the area of hematoma is entered, and the injury controlled with a partial occluding clamp (usually at the origin of the innominate artery) and oversewn. If the right innominate vein is injured as well, it may be ligated if the azygous system is intact.

The treatment of a tracheostomy-induced late tracheal–innominate artery fistula deserves special consideration. These fistulas are usually caused by the concave surface of a low-riding tracheostomy tube eroding into the innominate artery. Arteriography during a "stable interval" is generally not helpful in making a precise diagnosis. Therefore, the possibility of a tracheal–innominate fistula should be evaluated via bronchoscopy through a partially withdrawn endotracheal tube. A rapid chest CT, looking for a violated plane between the trachea and innominate artery, can be obtained if the

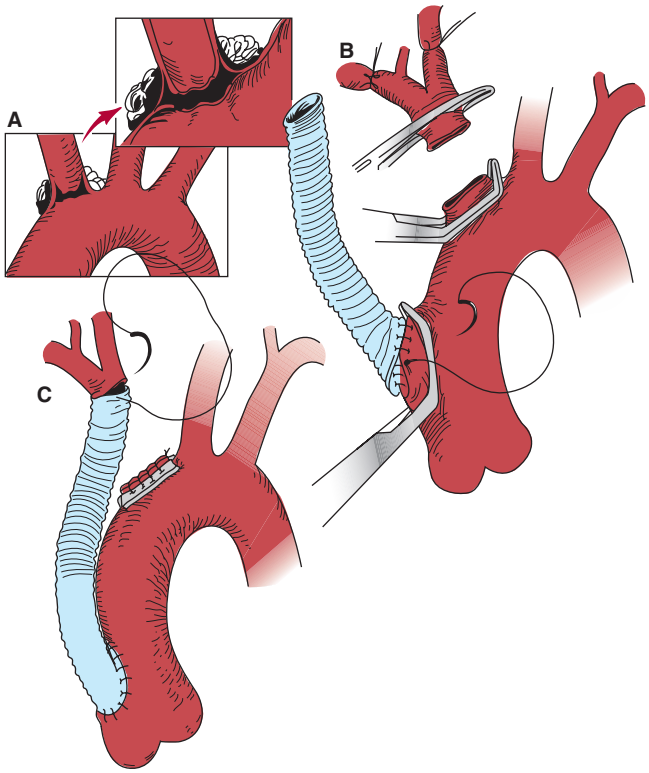

FIGURE 30-18 Drawing depicting the bypass exclusion technique employed in patients with innominate artery injuries. (Copyright © Baylor College of Medicine, 1981.)

bleeding has stopped or been controlled. With massive bleeding, control is achieved by performing orotracheal intubation, removing the tracheostomy tube, and directly tamponading the bleeding digitally through the transverse cervical incision during transport to the operating room. Through a median sternotomy with a right neck extension, the innominate artery is ligated at its origin from the aorta and distally just before the division into the right common carotid and right subclavian arteries. Despite a greater than 25% chance of neurologic complications, no attempt should be made at revascularization, since a delayed graft infection with its dreaded associated complications inevitably occurs. There are sporadic descriptions of the use of endografts to temporize these critical patients. This is occurring with increasing frequency as a damage control approach, accepting a likely infected graft.

SUBCLAVIAN ARTERY (SEE ATLAS FIGURES 17 AND 20)

Subclavian vascular injuries can involve any combination of the intrathoracic, thoracic outlet, cervical (zone I), and axillary/upper extremity areas. In stable patients, a thoracic CTA allows for planning appropriate incision(s) to obtain adequate exposure and control.

For open repair, cervical extension of the median sternotomy is employed for exposure of right-sided subclavian injuries. For injury to the first portion of the left subclavian artery, proximal control is obtained through a left anterolateral thoracotomy above the nipple in the third or fourth intercostal space, whereas a separate supraclavicular incision provides distal control (see Atlas Figure 19). Although these incisions can be connected to create a formal "book" thoracotomy, this results in a high incidence of postoperative "causalgia"-type neurologic complications and its use should be limited. As previously noted, the endovascular placement of a balloon for proximal control is now commonly used to obviate the need for a thoracic incision.

In obtaining exposure, it is important to avoid injuring the phrenic nerve (anterior to the scalenus anticus muscle). This is particularly true because there is also a high associated rate of injury to the brachial plexus. Thus, documentation of preoperative neurologic status is important, as noted.

In most instances, repair consists of either lateral arteriorrhaphy or insertion of an interposition graft. It is unusual that an end-to-end anastomosis can be employed. With an intrathoracic associated injury to the left lung, this can be managed with stapled wedge resection or pulmonary tractotomy.[65] One pitfall in subclavian injuries is failure to anticipate the exposure necessary for proximal control. The guiding principle is to achieve vascular control, either endovascular or open, at a level proximal to the injury hematoma or site of bleeding. As noted earlier, an endovascular balloon may permit proximal control closer to an injury, decreasing collateral bleeding. When approaching the subclavian/axillary artery via the supraclavicular or deltopectoral groove approach without proximal control, exsanguination may occur. Division or resection of the mid-clavicle may aid in proximal control, whereas combination supra- and infraclavicular incisions may be used to avoid clavicular resection. A mortality rate of 4.7% for patients with injuries to the subclavian artery who have vital signs on admission has been reported, but death is often due to associated injuries.

COMMON CAROTID ARTERY

The open operative approach for injuries of either common carotid artery is a median sternotomy with a right or left cervical extension when necessary. With transection at the origin of the left common carotid artery, a bypass graft repair is preferred over end-to-end anastomosis. Intraoperatively, a temporary intraluminal carotid shunt can be inserted by the initial surgeon if needed until resources or assistants can be gathered in the operating room.

PULMONARY ARTERY

The intrapericardial pulmonary arteries are approached via a median sternotomy. Minimal dissection is needed to expose the main and proximal left pulmonary arteries.[93] Exposure of the intrapericardial right pulmonary artery is achieved by dissecting between the superior vena cava and ascending aorta. Although anterior injuries can be repaired primarily without adjuncts, repair of a posterior injury usually requires cardiopulmonary bypass. Mortality rates for injury to the central pulmonary arteries or veins are greater than 70%.[43]

Injuries to the distal main pulmonary artery present with a massive hemothorax. Because these are part of a major hilar injury, a rapid pneumonectomy using en bloc stapling may be a lifesaving maneuver. The use of a hilar clamp can control hemorrhage as well as prevent air embolism while assessment occurs.

INTERNAL MAMMARY ARTERY

The internal mammary artery in a young patient is capable of flows in excess of 300 mL/min. Injuries to this artery can produce an extensive hemothorax or pericardial tamponade, simulating a cardiac or major vascular injury. Such injuries are usually serendipitously discovered at the time of thoracotomy for a suspected injury to the heart or a great vessel.

INTERCOSTAL ARTERIES

Persistent bleeding through a thoracostomy tube can be caused by laceration of an intercostal artery. Because of difficulty in exposure, precise ligation can be difficult. At times, control can only be achieved by circumferential ligatures around the rib on either side of the injury to the intercostal vessel. This is sometimes accomplished via separate stab wounds and a suture passer to loop the suture around the rib. Exposure can sometimes be obtained by extension of the thoracotomy into that interspace.

THORACIC VENA CAVAE

Isolated injury to the intrapericardial inferior or superior vena cava is infrequently reported. Injury at either location has a high incidence of associated organ injuries and a mortality rate greater than 60%. Injury to the intrapericardial inferior vena cava causes a hemopericardium and cardiac tamponade. Exposure of the posterior intrapericardial inferior vena cava is extremely difficult unless the patient is placed on total cardiopulmonary bypass with the inferior cannula inserted via the groin into the abdominal inferior vena cava. The injury is exposed by a right atriotomy and intracaval balloon occlusion to prevent air entering the cannula. Repair is achieved from inside the cava via the right atrium. Injuries to the superior vena cava are repaired by lateral venorrhaphy. At times, an intracaval shunt is necessary before repair can be accomplished. Occasional patients survive following blunt partial transection at the junction of the right atrium and the superior or inferior vena cava. Primary repair can be accomplished after control of the atrium and cava.[94] For complex injuries, a polytetrafluoroethylene (PTFE) patch or Dacron interposition tube graft can be used and is more expedient than the time-consuming construction of panel grafts from a segment of the greater saphenous vein.

PULMONARY VEIN

Injury to a pulmonary vein is difficult to manage through an anterior incision. With major hemorrhage, temporary clamp occlusion of the entire hilum may be necessary. If a lobar pulmonary vein must be ligated, the appropriate lobe needs to be resected. Injury to a pulmonary vein is often associated with concomitant injuries to the heart, pulmonary artery, thoracic aorta, and esophagus.

SUBCLAVIAN VEINS

The operative exposure of the subclavian veins is the same as that described for injuries to the subclavian artery (ie, median sternotomy with cervical extension for right-sided injuries, and left anterolateral thoracotomy with a separate supraclavicular incision for left-sided injuries). In most instances, control of bleeding requires either lateral venorrhaphy or ligation.

AZYGOUS VEIN

The azygous vein is not usually classified as a thoracic great vessel; however, because of its size and high flow, injury to the azygous vein must be considered potentially fatal. Due to its posterior location, an injury is difficult to diagnose and expose through an emergent anterolateral thoracotomy. The key to diagnosis is recognizing ongoing hemorrhage of dark venous blood from a posterior location in the right chest. A penetrating wound of the chest or thoracic outlet causing a combination of injuries involving the azygous vein, innominate artery, trachea, bronchus, and superior vena cava is difficult to control and obviously has a high mortality rate. Combined incisions are frequently needed for successful repair. When injured, the azygous vein is best managed by suture ligature of both sides of the injury (Fig. 30-19). Concomitant injury to the esophagus and bronchus should be considered and ruled out.[95]

Special Problems

MEDIASTINAL TRAVERSE INJURIES

Stab and gunshot wounds that traverse the mediastinum were in the past thought to have a high probability of injury to the heart, a thoracic great vessel, the tracheobronchial tree, or esophagus, and a mandatory exploration was performed.

The evaluation of stable patients using less invasive means such as surgeon-performed FAST and contrast-enhanced CT is now the standard of care. The CT documents the bullet trajectory and guides the need for surgery or additional diagnostic tests.

INJURY TO THE THORACIC DUCT (SEE ATLAS FIGURE 18)

Injury to a thoracic great vessel may be complicated by a concomitant injury to the thoracic duct. If unrecognized, this may produce significant morbidity due to a chyle leak with marked nutritional depletion, especially in children.[96] Diagnosed by chylous material with high triglycerides draining from a thoracostomy tube, this condition is usually treated medically. Continued drainage through a thoracostomy tube coupled with a diet devoid of long-chain fatty acids usually result in spontaneous closure over several weeks. Prolonged

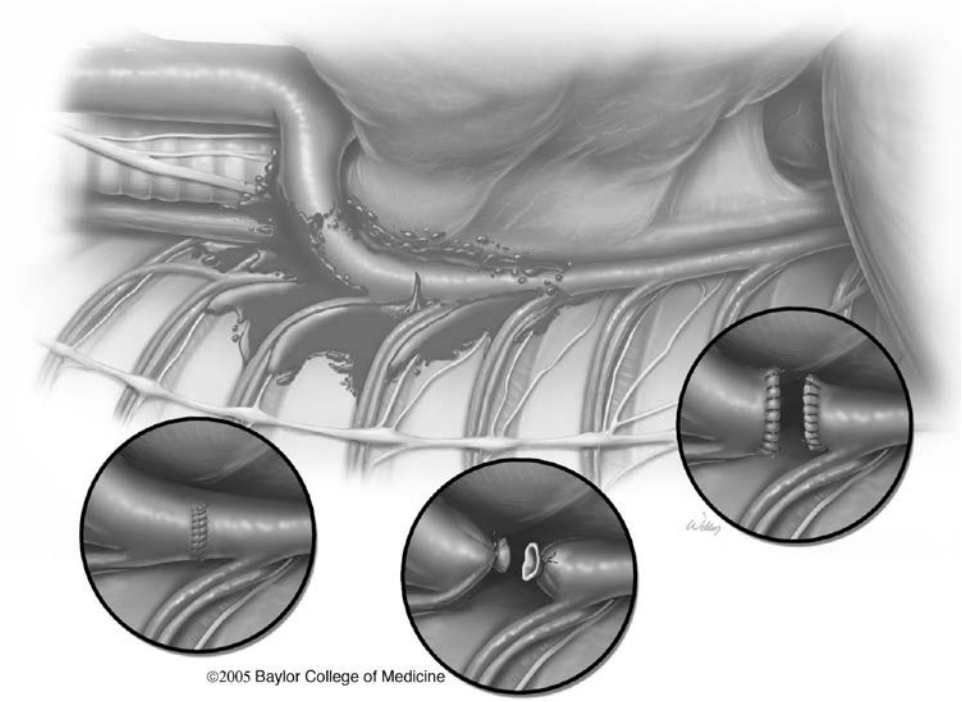

FIGURE 30-19 Injury to the azygous vein with control with lateral repair, ligation and division, and oversewing. (Copyright © Baylor College of Medicine, 2005.)

hyperalimentation beyond 3 weeks, however, has not consistently resulted in spontaneous closure of a fistula from an injured thoracic duct. If a thoracotomy for ligation of duct at the area of injury is required, a fatty meal or heavy cream to increase the chylous flow and facilitate identification of the fistula is given to the patient prior to surgery. The fistula is ligated with 6-0 monofilament suture. Fistulas do recur after ligation, and a reoperation with mass ligation of the thoracic duct at the diaphragm will be necessary. Pleurodesis has also been used as definitive treatment.

SYSTEMIC AIR EMBOLISM

A fistula between a bronchiole and pulmonary vein due to a penetrating wound to the lung may result in a systemic air embolism. The fistula allows air bubbles to enter the left heart and embolize to the coronary arteries, cerebral arteries, and systemic circulation (Fig. 30-20). An intrabronchial pressure above 60 torr increases the incidence of this complication.[97]

Manifestations include seizures and cardiac arrest. Resuscitation requires a left anterolateral thoracotomy, temporary clamping of the hilum of the injured lung to prevent further air embolization, and needle aspiration of air from the left ventricle and ascending aorta. Cardiopulmonary bypass can be considered, but few survivors have been reported.

FOREIGN BODY EMBOLISM

Because of their central location, the thoracic great vessels may serve as both an entry site and final resting place for an intravascular bullet embolus.[98] These migratory foreign bodies present a diagnostic and therapeutic dilemma. As a result of intravascular embolization, bullets may produce infection, ischemia, or injury to organs distant from the site of trauma.

Approximately 25% of migratory bullets finally lodge in the pulmonary arteries (see Fig. 30-5).[98] Although small fragments such as those the size of a BB can be left in place without causing problems, significant catheter emboli and larger bullet emboli should be removed to prevent thrombosis of a pulmonary branch artery, sepsis, or other complications. Percutaneous retrieval of the foreign body using transvenous catheters and fluoroscopic guidance has virtually eliminated the need for thoracotomy.

Postoperative Management

Careful hemodynamic monitoring, with avoidance of both hypertension and hypotension, is critical. Although urinary output is a generally a good indicator of cardiac function, hemodynamic monitoring (surgeon-performed ultrasound of heart and inferior vena cava; Flo Trac system, Edwards Lifesciences, Irvine, CA) is often necessary to optimize hemodynamic parameters and manage fluids, pressors, and vasodilators for the patient with massive injuries (see Chapter 58).

Various pulmonary problems such as atelectasis, respiratory insufficiency, pulmonary contusion, pneumonia, and acute lung injury syndrome represent the primary postoperative complications in this group of patients. The presence

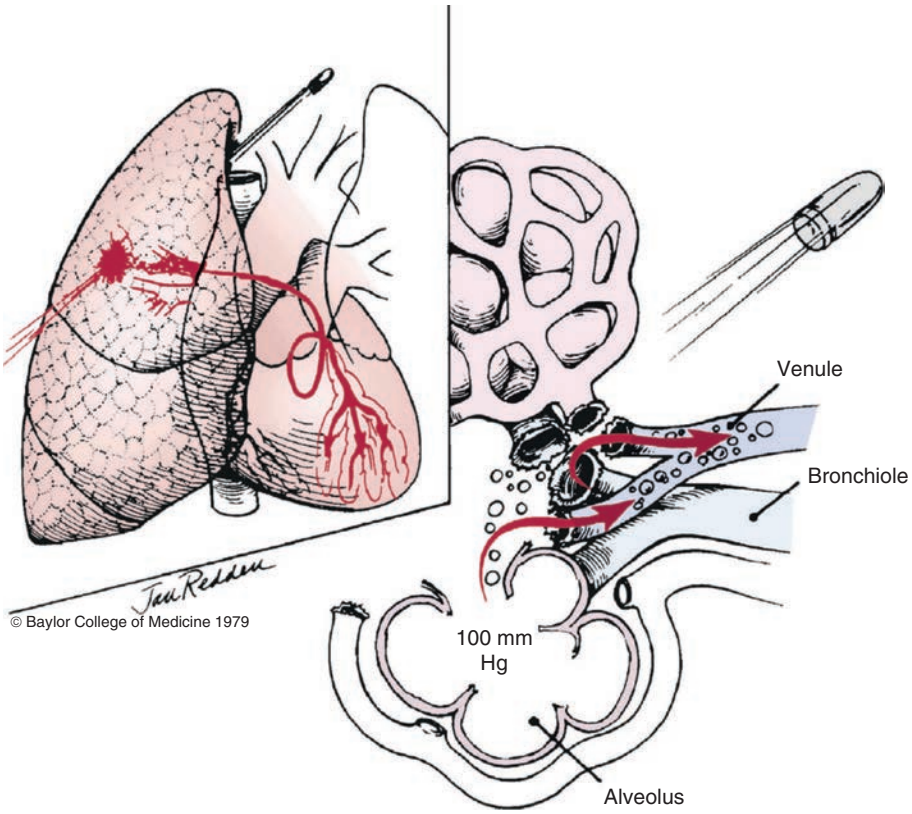

FIGURE 30-20 Drawing depicting the mechanism of systemic air embolism following a penetrating lung injury. (Copyright © Baylor College of Medicine, 1979.)

of pulmonary contusions and the potential for development of adult respiratory distress syndrome mandate that fluid administration be carefully monitored. Special ventilatory strategies to address potential complications of these pulmonary injuries and syndromes can be used (see Chapter 59). Patient mobility is important, and adequate medication for pain relief may decrease atelectasis and pneumonia. For the management of pain related to a thoracotomy or multiple rib fractures, postoperative thoracic epidural anesthesia can be considered in stable patients without spinal injuries. With the advent of long-acting local anesthetic agents, intercostal nerve blocks can be performed shortly after admission or at the completion of a thoracotomy. Multimodal nonopioid pain management strategies are increasingly being employed as well.

Postoperative hemorrhage is often due to a technical problem but may be the result of a coagulopathy related to hypothermia, acidosis, and massive blood transfusion. Coagulation studies, especially thromboelastography or rotational thromboelastometry, can be carefully monitored and corrected with administration of appropriate blood products[99] (see Chapter 16). Blood draining via a thoracostomy tube can be collected and autotransfused. During the initial resuscitation of these critically injured patients, various intravascular lines are often rapidly placed at the expense of strict sterile technique. All such lines should be replaced after the patient has been stabilized in the ICU. Prophylactic antibiotic therapy should be given perioperatively. Patients are counseled regarding the necessity of antibiotic prophylaxis during invasive future procedures, including dental manipulations.

Most late complications are related to infections or sequelae from other injuries. Long-term complications specifically related to the vascular repair include stenosis, thrombosis, arteriovenous fistula, graft infection, and formation of a pseudoaneurysm.

Trauma Laparotomy: Principles and Techniques

Jessica A. Bowman • Gregory J. Jurkovich

KEY POINTS

- Wide prepping and draping allow the surgeon access to the chest and the groin to complete all necessary procedures.
- The trauma laparotomy should be performed in a routine, systematic manner, minimizing the likelihood of missed injuries.
- Damage control laparotomy focuses on immediate control of hemorrhage and contamination, followed by goal-directed resuscitation, reversal of coagulopathy, rewarming, and delayed definitive repair.
- Preperitoneal packing is proving to be a quick, efficient method to control zone III hematomas.
- A quality fascial closure helps prevent future morbidity associated with dehiscence, evisceration, and hernias.
- Surgeons should use laparotomy pads with a radiofrequency detection system or obtain abdominal and pelvic x-rays prior to definitive closure to decrease the risk of retaining foreign bodies.

INTRODUCTION

Performing a complete, efficient emergency exploration of the abdominal cavity is a defining and essential skill of the trauma surgeon. Following penetrating or blunt injury, a laparotomy is indicated for hemodynamic instability, peritonitis, evisceration, positive or questionable radiographic findings of organ injury, a positive diagnostic peritoneal tap (or lavage), and in some cases, a persistent drop in hematocrit. The objectives of a trauma laparotomy include control of hemorrhage, control of contamination from the gastrointestinal tract, and identification of all injuries. The patient's physiology determines whether definitive repair of injuries is accomplished at the initial operation or deferred in a damage control approach. It is the trauma surgeon's responsibility to devise a plan to address all injuries in a comprehensive and time-sensitive manner.

The word *laparotomy* comes from Greek origin, with *lapara* signifying the flank or waist and the suffix "-tomy" from the Greek word *tomoz* meaning to cut. In modern trauma surgery, the word *laparotomy* is used interchangeably with *celiotomy*, which stems from the Greek word *koilia,* meaning belly or bowels. Both words imply opening the peritoneal cavity, although perhaps a laparotomy would more accurately relate to a flank incision.[1,2]

This chapter provides an overview of the trauma laparotomy, including principles of the trauma laparotomy, preparation and team effort, a description of the technical steps and key maneuvers, considerations for the damage control approach, the practical aspects of temporary abdominal closure, and complications.

PRINCIPLES

The Core Mission

In a trauma laparotomy, the core mission is to identify and treat the greatest threat to the patient's life as quickly as possible. Most commonly, this threat is exsanguination, and the primary mission is hemorrhage control. The success of the operation depends on the team's ability to identify, expose, and control hemorrhage, while simultaneously resuscitating the patient with appropriate blood products, fluids, and electrolytes to maintain intravascular volume, correct coagulopathy, and counterbalance physiologic insult. Following hemorrhage control, the mission becomes identifying and addressing contamination from bowel injuries. Lastly, but no less important, is identification and treatment of all other injuries, including injuries to the abdominal wall, the mesentery, the genitourinary tract, and the solid organs of the kidney, pancreas, spleen, and liver.

Indications and Preparation

The patient's mechanism of injury, vital signs, physical exam, and imaging studies all play a role in the decision regarding

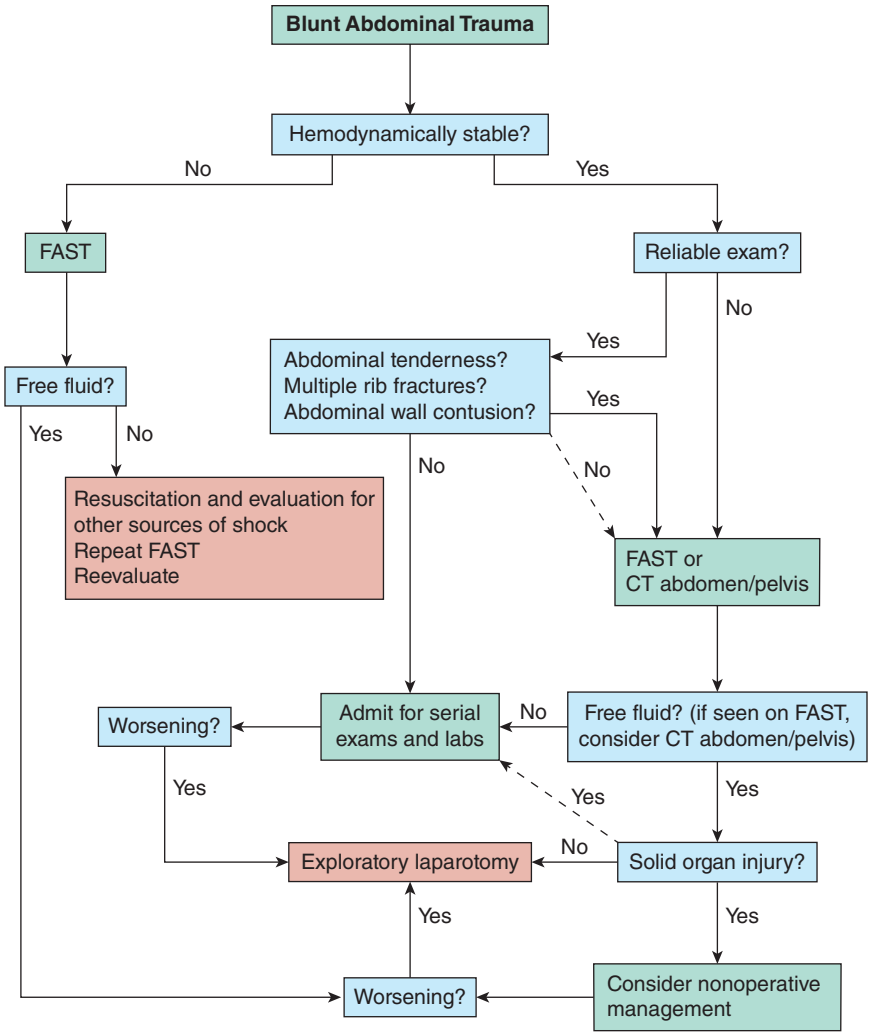

FIGURE 31-1 Indications for trauma laparotomy in a patient with blunt abdominal trauma. The first step is to determine if a patient is hemodynamically normal and stable. If not, suspicion for intra-abdominal injury should be high. These patients should undergo focused assessment with sonography in trauma (FAST) exam and, if positive, laparotomy. A negative FAST in this population is a worrisome and challenging situation. It is difficult to decide when to proceed to the operating room versus continuing resuscitation while evaluating for other sources of blood loss and shock. The surgeon must maintain a high level of suspicion, knowing that a false negative on initial FAST exam is possible.

Among hemodynamically normal and stable patients, assess the reliability of the abdominal exam. If reliable and there are no other high-risk signs of intra-abdominal injury, the patient may be monitored with serial exams and labs. Alternatively (dashed arrow), they may undergo computed tomography (CT) imaging and, if negative, there is assurance there is no intraabdominal injury. Patients without a reliable exam should undergo further imaging. For patients with free fluid and no solid organ injury, we advocate exploratory laparotomy or laparoscopy to evaluate for bowel, bladder, or mesenteric injury, particularly for those who also had high-risk signs of intra-abdominal injury (eg, lap belt sign). If there are no high-risk signs (dashed arrow), patients may be monitored with serial exams and labs, knowing there is a possibility of missed or delayed bowel injury.

whether a patient requires an urgent or emergent laparotomy. Algorithms are a convenient way to organize one's thinking about a clinical scenario, and Figs. 31-1 and 31-2 are presented as standard approaches to determine if a patient requires a trauma laparotomy. The astute clinician needs to be aware of those patients who are not "following the rules," but it is impossible to define an algorithm for every unique patient and situation. Each of the decision branches in these algorithms demands surgical judgment and a careful understanding of the pitfalls and traps of going down the wrong pathway. Continual reassessment of the patient's physiology and the results from any imaging or response to resuscitation are necessary to avoid making a wrong decision.[3,4]

The two management algorithms presented in Figs. 31-1 and 31-2 are simplified guidelines for the many complex decisions that must be made at each of the branching nodes. Assessment of blunt trauma to the abdomen has been greatly aided by the rapid and widespread availability of computed tomography (CT) and the bedside ultrasonography. The benefits and disadvantages of both techniques should always be considered carefully. The penetrating abdominal trauma algorithm includes both gunshot and stab mechanisms and

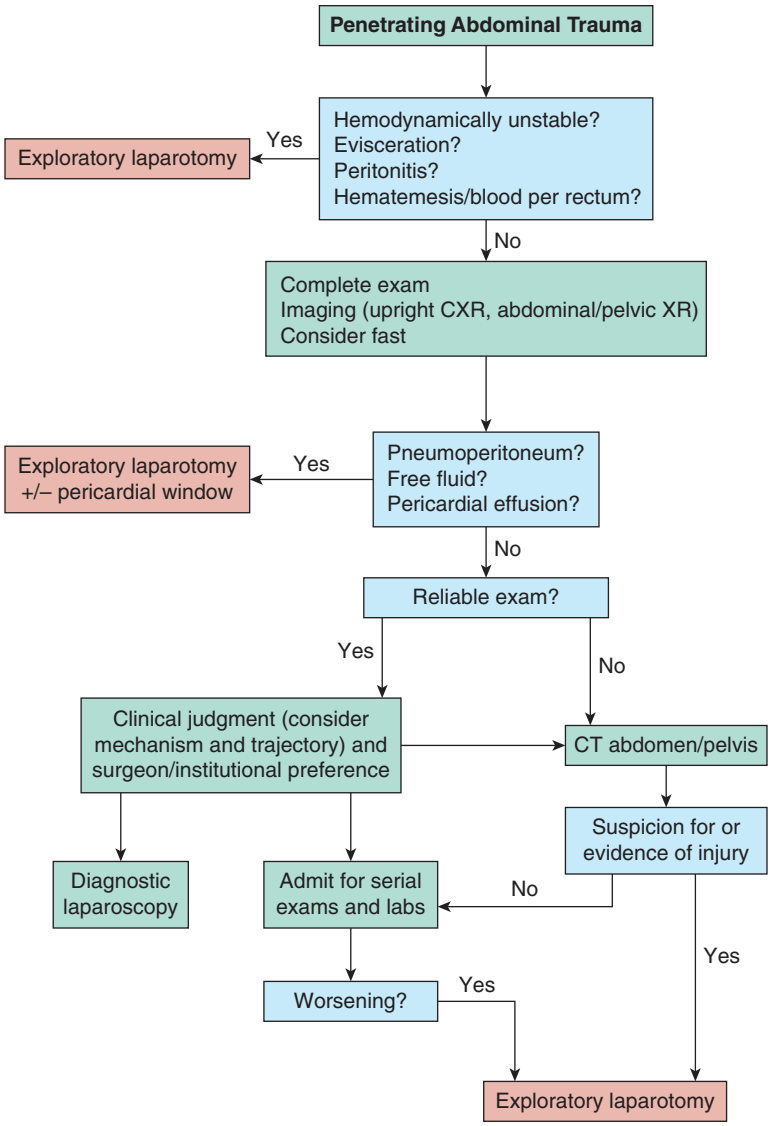

FIGURE 31-2 Indications for trauma laparotomy in a patient with penetrating abdominal trauma. Patients who are hemodynamically unstable and have evidence of peritoneal penetrating injury on physical exam should proceed to laparotomy, as should patients with evidence of intra-abdominal (or cardiac) injury on imaging. Imaging is helpful to evaluate thoracic pathology or bullet trajectory based on residual fragments. The pericardial component of the focused assessment with sonography in trauma (FAST) may identify excessive pericardial fluid and should be carefully performed for patients with penetrating injury to the cardiac box, bounded by the clavicle superiorly and the xiphoid inferiorly, and extending to the midclavicular line laterally. For patients with a reliable exam and no clear evidence of intra-abdominal injury, the surgeon should consider mechanism of injury, trajectory, and institutional/personal preference to determine whether serial exams and labs, computed tomography (CT) imaging, or diagnostic laparoscopy is most appropriate. For example, a patient with a skiving bullet trajectory may be appropriate for observation. This figure is similar to the more detailed Western Trauma Association algorithms for gunshot and stab wounds presented at the 48th Annual Meeting in 2018 (westerntrauma.org/algorithms/AbdominalStabWounds/WTAAbdStabWounds.pdf and westerntrauma.org/algorithms/AbdominalGSW/AbdominalGSWAlgorithmFinal.pdf). CXR, chest x-ray; XR, x-ray.

is perhaps even more fraught with institutional and individual preferences for management. Again, each of the decision branches requires considerable judgment and knowledge of contemporary literature.

For hemodynamically unstable trauma patients, activities in the trauma bay should be limited to interventions that are immediately lifesaving (see also Chapter 13). The surgeon should consider airway control, chest decompression for significant hemopneumothorax, obtaining intravenous access and initiating blood transfusion, placing direct pressure on sites of external hemorrhage, pelvic sheeting (if mechanism dictates), and obtaining a blood specimen for type and cross. In patients who require emergent laparotomy, it is the time from presentation to hemorrhage control that impacts mortality, and obtaining or examining studies should not delay time to incision.

In the operating room (OR), priorities before incision include positioning and prepping the patient, ensuring large-bore intravenous access and Foley catheter placement, obtaining blood products, temperature control of the room and the patient, and the administration of perioperative antibiotics. This requires an organized effort between the surgeon, anesthesiologist, and the nursing team. Communication with the entire OR team regarding objectives, operative plan, anticipated pitfalls, and necessary equipment is essential. Dedicated trauma ORs with ready access to all necessary surgical (eg, staplers) and resuscitation (eg, rapid transfusion devices) equipment should be a standard part of advanced preparation. Ideally, emergency trauma laparotomy trays containing instruments for both abdominal and major vascular procedures are opened prior to the patient arriving in the OR. Chest instruments should also be easily accessible.

Trauma patients should initially be positioned in the supine position with arms fully abducted at a 90° angle (Fig. 31-3). If the patient is unstable, prepping and draping may occur before or simultaneously with intubation. Meanwhile, other members of the team can work on venous and arterial access and the other issues noted earlier. This allows for immediate commencement of the operation should the patient decompensate further with induction of anesthesia.

Antimicrobial skin preparation for trauma surgery remains problematic. Historically, povidone-iodine was the agent of choice, but more recent literature shows povidone-iodine is associated with increased risk of surgical site infections compared to chlorhexidine-based products.[5] On the other hand, chlorhexidine-based products commonly contain alcohol, which increases the risk of an OR fire. In an ex vivo model, Jones et al[6] demonstrated that after alcohol-based skin preparation, immediate use of electrocautery resulted in flash fires 22% of the time. Even after waiting the manufacturer's suggested 3 minutes, electrocautery use still caused fires 10% of the time.[6] In addition to fire risk, critically injured patients do not have 3 minutes to spare.

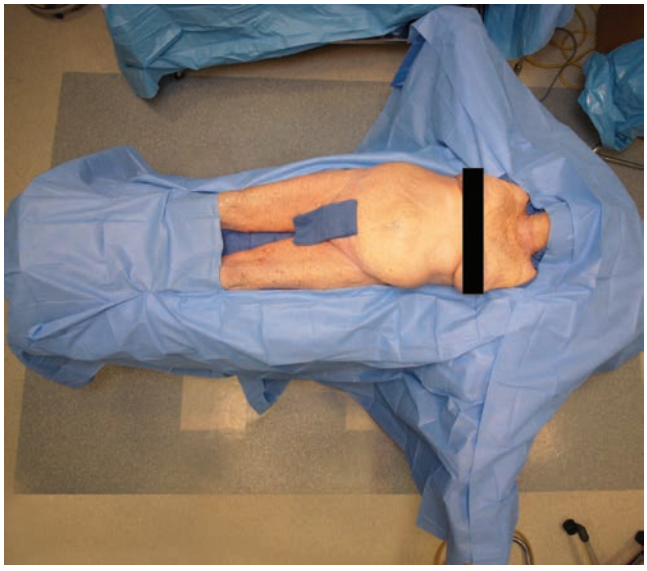

FIGURE 31-3 Prepping from chin to knees: the sterile operative field for trauma provides access to the neck, chest, abdomen, and groins. It allows the surgeon to plan for the unexpected during the procedure, providing access into an adjacent cavity and access to the groins for vein harvest or vascular control.

Typical draping for trauma laparotomy should be performed with exposure from chin to knees, extending to the posterior axillary line laterally. The groin is isolated with a sterile towel, leaving room to access the femoral vessels if needed. Anesthesia is allowed access to the head and arms while the surgeon maintains access to the neck, chest, abdomen, bilateral groins, and saphenous veins. A wide sterile field allows the surgeon to access multiple body cavities and be prepared for any eventuality, such as the gunshot wound to the abdomen that tracks superiorly into the chest or inferiorly to the groins.

In the exsanguinating patient, sterility remains desirable but is not essential. In instances where the patient has been rolled to the OR with a finger holding pressure on a bleeding wound, the assistant's hand may be prepped into the field until surgical control is achieved. In the stable patient, prophylactic antibiotics should be given prior to incision, most commonly in the trauma bay on the way to the OR. Even in unstable patients, antibiotics should be administered as soon as feasible.

Role of the Surgeon

During a trauma laparotomy, the surgeon plays several roles that must be seamlessly integrated. The surgeon must perform the operation in a technically proficient manner while supervising the other members of the team. The surgeon must focus on the specific details of the case while staying attuned to the patient's physiology. Based on the assimilation of these details, the surgeon must decide whether to perform a standard trauma laparotomy with definitive repair or use the damage control approach. Specific considerations will be discussed later in the chapter. The surgeon must anticipate subsequent steps of the operation and communicate effectively with the anesthesiologist and scrub nurse, keeping in mind the end point of the operation (eg, "Next we are going to perform splenectomy, staple off the bowel injuries, and be in the SICU [surgical intensive care unit] in under an hour with a temporary abdominal closure in place. Please let them know we will be coming and have a rapid transfusion device ready.").

The trauma laparotomy is a dynamic process that cannot be performed by the surgeon alone. Continued dialogue among the entire team regarding the patient's condition is of paramount importance. The anesthesiologist should verbally communicate on the patient's hemodynamic and volume status, any dysrhythmias, need for vasopressors, and number of blood transfusions, as well as on the presence of acidosis, coagulopathy, and hypothermia. These variables, reflecting physiologic reserve, guide critical surgical decision making. In patients with thoracoabdominal injuries, anesthesia should ensure that the chest tubes are on suction and that output is

monitored and communicated to the surgeon. In turn, the surgeon must communicate with anesthesia as to the status of the bleeding, the potential release of tamponade, and clamping and unclamping of major vessels, which may alter hemodynamics and arterial pH. Communication with the nursing staff is also vital to ensure availability of needed equipment.

An additional responsibility of the operating surgeon is to acknowledge the need for help. Even the most seasoned surgeons will encounter cases that require an additional experienced trauma surgeon or more specialized assistance. The decision to stop and call for additional help reflects sound judgment and humility and emphasizes patient safety.

TRAUMA LAPAROTOMY

The patient's hemodynamic status dictates the course and urgency of the laparotomy. The standard trauma laparotomy should follow a goal-directed, reproducible sequence of steps that provides a thorough and efficient evaluation of the entire abdomen. These steps include entering the peritoneum, prompt control of bleeding and contamination, complete exploration of the abdominal cavity, and repair of identified injuries. In cases of severe physiologic insult and/or hemodynamic instability, the surgeon may elect an abbreviated version of the standard laparotomy: the damage control approach.

Gaining Access to the Peritoneum

The trauma laparotomy is most commonly performed through a midline incision. In general, the "sicker" the patient (eg, class III/IV shock, multiple torso wounds), the larger the incision should be in order to gain rapid control of the hemorrhage and intestinal spillage. Thus, a classic xiphoid-to-pubis incision is indicated. This incision affords wide exposure of intraperitoneal and retroperitoneal organs and may easily be extended into a sternotomy as needed. In contrast, in patients who are hemodynamically stable from penetrating trauma or those who have undergone preoperative CT scanning, a more directed or limited incision can be used to start, and the surgeon can rapidly extend the incision superiorly or inferiorly based on need and operative findings. Occasionally, subcostal incisions may be appropriate for known isolated injuries of the spleen or liver, and a "transplant" incision can be particularly advantageous for known major liver injuries that require laparotomy. Most general and trauma surgeons are comfortable with this incision and can use the midline to enter the abdomen quickly. Using the scalpel with a size 10 (standard) or 20 or 21 (larger) blade to cut through the skin to the fascia and then again through the linea alba superiorly is more efficient than using electrocautery, but it is also a more difficult skill.

Incising through skin and soft tissue can be done with a few strokes of the knife. In obese patients, a useful technique to get through the pannus in the midline is to apply a significant amount of lateral traction on the skin. The white decussating fibers of the anterior rectus sheath denote the midline. The linea alba from the xiphoid to the umbilicus should be divided sharply, revealing preperitoneal fat and then peritoneum. In patients with significant hemoperitoneum, opening the fascia widely prior to getting into the abdomen prevents the blood from obscuring the rest of the incision and aids in fully opening the incision. The peritoneum may be entered bluntly just cephalad to the umbilicus or entered sharply with a pair of Metzenbaum scissors while lifting the peritoneum to avoid injuring the bowel. This is best performed near the xiphoid with the lateral segments of the liver providing some protection beneath. Once the peritoneum is deemed free of adhesions, it may be freely opened with the scalpel, Mayo scissors, or electrocautery. Of note, in patients with a prior abdominal incision, it is safest to enter the peritoneum away from the preexisting scar in order to avoid underlying adhesions.

Initial Maneuvers

Once the peritoneum is opened, the surgeon should rapidly evacuate any pooled or clotted blood by scooping it out with both hands and laparotomy pads. Note that we do not advocate blind four-quadrant packing as the first step because it is inadequate to tamponade bleeding, may injure delicate structures (splenic ligaments, friable or injured mesentery), and masks ongoing bleeding. The next step is small bowel evisceration, which is accomplished by sweeping the hand around the small bowel from the left upper quadrant toward the pelvis, then up the right side, lifting the entire small bowel up onto the right upper abdominal wall, allowing the mesentery to remain in line and not twisted. Likely sources of bleeding include solid organs, bowel mesentery, and the great blood vessels. The solid organs are quickly inspected and palpated for injury. These maneuvers can be followed by directed packing under vision into the pelvis and other quadrants. These packs will also absorb residual blood and begin to tamponade ongoing bleeding. Liver hemorrhage can be treated with packing, while splenic hemorrhage is typically managed with immediate splenectomy. Mesenteric bleeding is managed by clamps and ligature as the first step, with later evaluation of bowel viability. Retroperitoneal and great vessel injuries are more complex (also see Chapter 38).

If directed packing controls hemorrhage, a pause in the operation can occur, allowing the team to regroup, restore the patient's blood volume, obtain equipment, and mentally prepare for the next portion of the operation. The surgeon's next immediate priorities include locating the injured vessel or organ, exposing the injury, and then deciding on temporary or definitive repair.

If bleeding is not controlled with packing, the surgeon should gain control of the supraceliac aorta with a trained finger or sponge stick. The supraceliac aorta is exposed by retracting the lateral segments (II and III) of the liver toward the patient's right and incising the gastrohepatic ligament. The esophagus can then be laterally displaced, exposing the aorta. The aorta should be dissected anteriorly and laterally to allow for passage of a vascular clamp. Division of the left

crus of the diaphragm will also help to expose the proximal aorta at the hiatus. While suture ligation of most bleeding intra-abdominal vessels is accepted, primary repair of the aorta, vena cava, and very proximal superior mesenteric artery (and rarely the portal vein) should be part of the hemorrhage control plan. Once initial hemorrhage has been controlled, the surgeon should address gastrointestinal spillage to limit contamination.

Hemorrhage Control Techniques

Hemorrhage from the liver is initially treated with manual compression followed by tight packing lateral, superior, and inferior to the liver (see Chapter 33 for further details). If packing controls hemorrhage, packs should be left in place. If bleeding is not controlled, a Pringle maneuver can be performed by placing a finger through the foramen of Winslow and pinching the portal triad (occluding the portal vein and the hepatic artery). A vascular clamp or Rommel occlusive loop can then replace the surgeon's hand. Failure to control bleeding with the Pringle maneuver indicates hepatic vein or retrohepatic vena cava injury.[7]

Bleeding from the spleen is managed by first mobilizing the spleen up into the midline for better exposure, obtaining vascular pedicle control, and then resection (see Chapter 34). For kidney injury, primary vascular control versus initial mobilization of the kidney from the Gerota fascia is more controversial[8] (see Chapter 40).

The decision whether to explore a retroperitoneal hematoma depends on the mechanism of injury, location of the hematoma, and evidence of ongoing bleeding. Zone I is the central zone, extending from the diaphragmatic hiatus to the bifurcation of the vena cava and aorta and bounded by the kidneys laterally. This zone can be further divided by a supramesocolic or inframesocolic location. It is inspected by lifting the transverse colon and gently retracting it either caudally or cranially. Zone I retroperitoneal hematomas require surgical exploration, as they signify great vessel injury, including aorta, vena cava, celiac axis vessel, superior mesenteric artery, superior mesenteric vein, or portal vein injury. Zone II is located laterally from the kidneys to the paracolic gutters, and hematoma in this area usually signifies injury to the kidney, renal artery, or vein. Penetrating injuries to zone II are generally explored, following the trajectory of the bullet or knife to exclude all injuries. Blunt injuries are only explored if the hematoma is expanding, although this decision can be difficult, knowing exploration increases the rate of nephrectomy. Immediate postoperative CT and possible angioembolization of a bleeding renal vessel are options, but not at the expense of hemorrhagic shock and death. Maneuvers to expose zone I and II structures are described in the following section. Zone III includes the pelvis, encompassing the iliac arteries and veins, and should generally only be explored in the case of penetrating injury.

In blunt trauma, management of zone III pelvic retroperitoneal bleeding, which is most commonly caused by venous bleeding, depends on institutional resources, including the availability of interventional radiology for angioembolization, the capability for urgent external fixation, and surgeon comfort with preperitoneal packing (PPP). Opening these hematomas is reserved for cases of exsanguination or critical limb ischemia where a named pelvic arterial injury is expected, as packing the pelvis from the abdominal cavity rarely controls hemorrhage. When confronted by a previously unsuspected expanding zone III hematoma during a laparotomy, the surgeon must decide whether to move to angiography or proceed with PPP. It cannot be overemphasized that this is not simply packing the intraperitoneal part of the pelvis from the celiotomy incision (see Chapter 39). Although routine pelvic x-rays are no longer usually obtained, they still remain indicated in patients with hypotension and/or signs of obvious pelvic instability. In these patients who may be at greater risk of pelvic hemorrhage (eg, known pelvic fracture), we advocate limiting the inferior portion of the initial trauma laparotomy incision sufficiently above the pubis to allow a separate incision for PPP if a major pelvic hematoma is identified.

PPP has come back into favor as a quick, efficient method to control pelvic hemorrhage, especially given that interventional radiology may not be immediately available and prolonged time to hemorrhage control is associated with increased mortality. Additionally, because most pelvic bleeding is due to venous injury, it cannot be controlled with angioembolization.[9] PPP is accomplished by making a separate lower midline incision (10-cm midline incision just above pubis) and dissecting down through the anterior fascia to the preperitoneum without entering or disrupting the anterior peritoneum.

From the lower midline PPP incision, the surgeon can retract the bladder to one side, palpate the pelvic brim, and proceed posteriorly to the sacroiliac joint. Three laparotomy pads are then placed on each side: one posteriorly at the sacroiliac joint, the next just anterior at the middle of the pelvic brim, and the last just posterior and lateral to the pubis. These steps are then repeated on the contralateral side.[10] Ideally, PPP takes place after external fixation, which decreases the volume of the pelvis and also facilitates sterility by removing the sheet/binder.[11] Laparotomy can follow once this cavity is closed, or alternatively, the two procedures can occur simultaneously if necessary. Postoperative angiography can be obtained if suspicion remains high for an arterial injury.

Exposing Retroperitoneal Structures

The medial visceral rotations are maneuvers used to expose key retroperitoneal structures. A right medial visceral rotation, also known as the Cattell-Braasch maneuver, is used to expose the intra-abdominal inferior vena cava, the right renal pedicle, and the right iliac artery and vein (Fig. 31-4). The ureter, head of the pancreas, duodenum, and posterior aspect of the right colon will also be exposed. The Cattell-Braasch begins with mobilization of the hepatic flexure of the right colon and a full Kocher maneuver to mobilize the duodenum and pancreatic head along the peritoneal reflection. This is

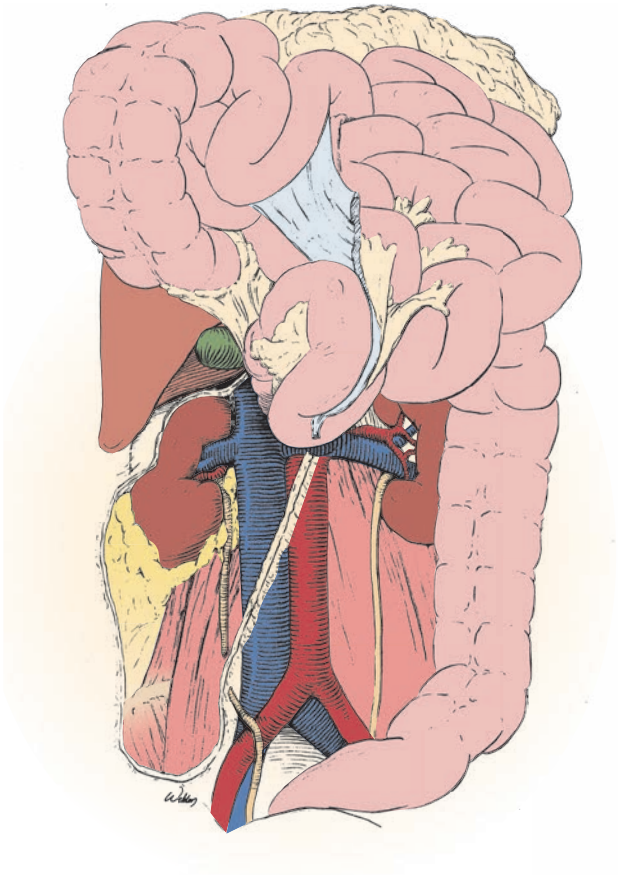

FIGURE 31-4 The full Cattell-Braasch maneuver provides broad exposure of the retroperitoneum. The only two areas of the retroperitoneum that remain inaccessible are the retrohepatic vena cava and the suprarenal aorta. The latter is accessible with the Mattox maneuver.

further carried down the right colon along the paracolic gutter by dividing the white line of Toldt. The exposure ends by dividing the avascular plane, which exists between the root of the mesentery and the peritoneum. The small bowel and right colon are then retracted medially, allowing visualization of the inferior vena cava.

To improve exposure of the retrohepatic vena cava, the surgeon can extend the midline incision across the costal margin into an intercostal space of the right chest. The diaphragm is incised to expose the vena cava and hepatic veins, allowing proximal control of the inferior vena cava from inside the chest.

A left medial visceral rotation, the Mattox maneuver, is used to explore a zone I or a zone II retroperitoneal hematoma on the left (Fig. 31-5). The left-sided organs are mobilized off the aorta, which allows for broad exposure of the aorta from the diaphragmatic hiatus to the iliac vessels, including the celiac axis, superior mesenteric artery and vein, left renal artery and vein, and left iliac artery and vein. Before opening the retroperitoneum, proximal control at the supraceliac aorta should be obtained. A left medial visceral rotation is initiated by dividing the splenorenal ligament. The white line of Toldt is then divided from the splenocolic flexure down the paracolic gutter to the distal sigmoid colon. The left colon, spleen, stomach, and pancreas are mobilized to the midline, just anterior to the Gerota fascia. In the classic Mattox maneuver, the kidney is included in the mobilization, which allows for access to the posterior aspect of the kidney and the aorta below the renal pedicle. Otherwise, the left renal vein restricts access to the anterior aorta. Care must be taken to avoid iatrogenic injury to the spleen when placing traction on the descending colon.

Exploring the Peritoneal Cavity

The peritoneal cavity is explored in a similar manner each time, so as not to overlook any injuries. As previously described, zones I, II, and III of the retroperitoneum are examined for hematoma early in the procedure. The anterior aspect of the stomach is examined in its entirety from the gastroesophageal junction to the pylorus. The lesser sac is then opened by dividing the gastrocolic ligament, and the posterior aspect of the stomach and the anterior aspect of the pancreas are inspected.

From the pylorus, the gastrointestinal tract can be examined from proximal to distal extent. If the duodenum has been mobilized with a Kocher maneuver, the anterior and posterior aspects of the duodenum can be visualized. The small bowel is run in a methodical fashion, examining the circumference of the bowel and identifying any abnormalities. As a segment of small bowel is lifted for examination, the corresponding mesentery is also inspected for hematoma, rents, or other abnormalities.

Serosal injuries or full-thickness perforations of the small bowel may be contained with a Babcock clamp or oversewn with a rapid whipstitch as they are encountered for temporary control of contamination. Definitive management should wait until a complete exploration is accomplished. Once the terminal ileum is encountered, the appendix and ascending, transverse, descending, and sigmoid colon are inspected. It may be necessary to mobilize the colon along the white line of Toldt to examine the retroperitoneal aspect, particularly in cases of penetrating trauma where the trajectory is suspicious. The liver, spleen, kidneys, and gallbladder are palpated for injury. In the pelvis, the genitourinary organs are inspected for injury. Finally, the diaphragm is inspected carefully as a site of potential missed injury. Structures appearing bruised, visceral hematomas, or those located close to a missile trajectory should be fully mobilized and explored carefully to identify all injuries.

Vascular Repair

Treatment options for intra-abdominal vascular injury include vessel ligation, primary repair, vein patch, interposition grafting, and temporary intravascular shunting (see Chapter 38). Shunting is described in further detail later. The decision to ligate or repair a vessel depends on the nature of the vessel and the risk of ischemia with ligation. Ligation of the celiac

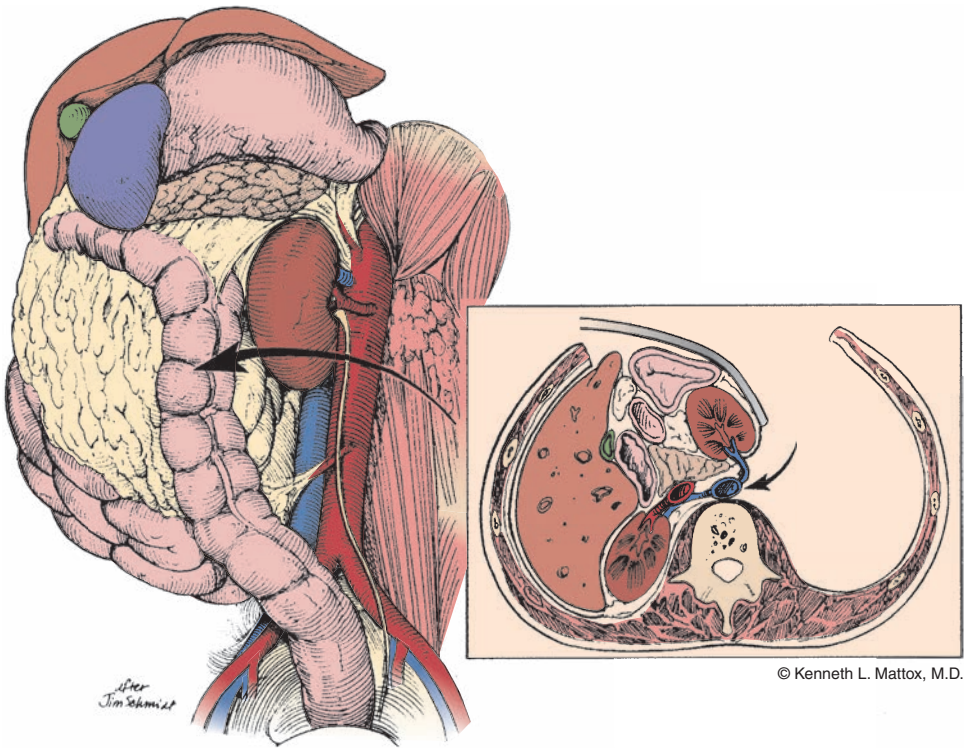

FIGURE 31-5 A full left-sided medial visceral rotation for trauma (Mattox maneuver) provides access to the abdominal aorta and is the only way to rapidly expose the suprarenal aortic segment in the presence of a central retroperitoneal hematoma. The inset shows the correct plane of dissection that is immediately on the muscles of the posterior abdominal wall. The presence of a large retroperitoneal hematoma greatly facilitates the maneuver. (Copyright © Kenneth L. Mattox, MD.)

artery and the internal iliac artery may be done with low risk of morbidity in most patients, as good collateral circulation exists. On the contrary, ligation of the common iliac artery and the external iliac artery carries a high risk of amputation. Primary repair of the vessel should be performed whenever time (and the nature of the wound) permits. Debridement to healthy tissue is performed prior to any repair.

Whenever possible, closure of a vascular injury should be performed in a transverse fashion with a running permanent monofilament suture in a lateral arteriorrhaphy or in an end-to-end anastomosis. Stenosis of the vessel is often accepted in favor of hemorrhage control, but when time permits, stenosis may be avoided with vein patch. In all cases, the tenets of vascular surgery, including proximal and distal control, adequate inflow and outflow, and a tension-free anastomosis, should be followed.

Injuries to the aorta and the suprarenal inferior vena cava mandate repair. Any vein below the renal vein may be ligated if repair is felt to be unsafe. Tying off the external iliac vein, common iliac vein, or even the infrarenal inferior cava is acceptable in critical situations, although lower extremity edema leading to a compartment syndrome may result. In these cases, four-compartment fasciotomy should be performed on the ipsilateral limb. Injuries to the iliac veins may be amenable to a primary repair after proximal control at the bifurcation and distal control in the femoral canal are obtained.

Repair of the portal vein with carefully placed monofilament suture should be attempted when possible, although portal triad vascular injuries remain one of the most lethal of intra-abdominal injuries, typically due to exsanguination.[12] Portal vein ligation should be used as a last resort, as ligation leads to massive intestinal edema. When employed, this strategy should be used in conjunction with an open abdomen and a planned second-look procedure.

The proximal superior mesenteric artery or vein must be repaired to preserve blood flow to the small bowel. Injuries to the superior mesenteric artery beyond the pancreas can be addressed with vessel ligation in conjunction with bypass grafting from the distal aorta, as would be performed for superior mesenteric artery thrombosis. Caution should be used when placing interposition grafts near a major pancreatic injury, as a pancreatic leak could lead to a complete disruption of the anastomosis.[13] Injury to the mesenteric vessels necessitating vascular repair and large mesenteric hematomas may compromise blood flow to the intestine. In these circumstances, a planned second-look laparotomy is prudent.

When segments of critical vessels are destroyed or resected, interposition grafts of polytetrafluoroethylene (PTFE; Gore-Tex, Newark, DE) or Dacron can be used to bridge the deficit in clean or minimally contaminated cases. Tissue coverage with omentum or muscle may be used to protect the graft. Autogenous great saphenous vein can also be harvested as

conduit, particularly in instances of bowel perforation and contamination.

Damage Control Considerations

Over the past few decades, principles of the damage control approach have been widely adopted and applied to both the military and civilian approach to the critically injured trauma patient (see also Chapter 42). The damage control approach refers to an abbreviated laparotomy in an unstable trauma patient with goals of quickly controlling hemorrhage and gastrointestinal spillage with a planned return to the OR for definitive repair of injuries following resuscitation. There are signals in the literature that the techniques of damage control and delayed definitive repair are perhaps overused, recognizing that considerable judgment is needed in this circumstance.[14,15]

The concept of damage control was first introduced to the trauma community in 1908, when Dr. J. Hogarth Pringle described the technique of using suture over gauze to control portal venous bleeding in the trauma patient.[16] In the early 1990s, Dr. Michael F. Rotondo and colleagues at the University of Pennsylvania described the damage control approach in three stages: the first stage of laparotomy with rapid hemostasis and control of contamination with a temporary closure of the abdomen, the second stage of resuscitation and restoration of normal physiology in the intensive care unit, and the third stage of reexploration, definitive repair, and closure. A retrospective review showed the damage control approach improved survival among patients with combined major vascular injury and two or more visceral injuries.[17]

The primary objective of the damage control approach is avoidance of an irrevocable physiologic insult, the "bloody viscous cycle" of trauma—acidosis, coagulopathy, and hypothermia—from which a patient cannot recover. The bloody viscous cycle, also known as the lethal triad, was first described in 1981 by Dr. Gene Moore and the Denver General (now Denver Health) group.[18] Severely injured patients displaying such physiology are at heightened risk of mortality.

The decision to proceed with a damage control approach should be made before the patient develops the lethal triad of physiologic abnormality. Rapid restoration of normal physiology takes precedence over definitive restoration of normal anatomy. For a patient in profound shock or with multisystem/multicavity trauma, the decision to use the damage control approach may be made before going to the OR. Parameters such as pH of <7.20, temperature of 93°F, and blood loss of 10 units or more predict the need for damage control approach.[19] Wound patterns such as combined major vascular injury and gastrointestinal injury may warrant damage control. Intraoperative signs of the bloody viscous cycle, including diffuse oozing from all surfaces, edematous bowel, or dusky-appearing viscera, should guide the surgeon toward the damage control approach.

In the first stage of a damage control approach, the surgeon should (1) pack injuries to solid organs such as the liver and kidney, (2) perform splenectomy as needed, (3) ligate or shunt major vascular injuries, (4) oversew or staple off injuries to the intestines, (5) drain suspected biliary or pancreatic injuries, and (6) place a temporary abdominal closure.

Shunting is a method to temporarily bridge injured vessels with a prosthetic conduit, rapidly controlling hemorrhage and restoring blood flow, while deferring definitive repair. In patients with injury to the common or external iliac arteries, shunting has been shown to reduce the rate of amputations and fasciotomies.[20] Before shunting, thrombectomy with proximal and distal embolectomy should be performed with Fogarty catheters to ensure adequate inflow and outflow. Commercial shunts exist, but surgeons can also employ pediatric feeding tubes, nasogastric tubing, or thoracostomy tubes, depending on the vessel size. The choice of shunt depends mainly on the size of vessel injured, as size match between shunt and vessel is a primary factor in shunt success. Patency and flow through the shunt can be demonstrated with on-table angiography. It is not necessary to systemically anticoagulate patients with temporary intravascular shunts. Complications of shunting include shunt thrombosis, distal embolization, shunt dislodgement, and infection.

If there is concern for ongoing bleeding from solid organs, the surgeon should consider angiography and embolization. Hybrid ORs, which have all the features of a traditional OR plus additional capabilities for angiography, endovascular interventions, and fluoroscopy, are becoming more popular in large centers and allow multiple teams to intervene on a patient at once or to proceed sequentially with endovascular techniques without moving the patient.

The patient should be promptly transported to the surgical intensive care unit for the second stage of resuscitation. Hemodynamics, urine output, and serial lab parameters such as lactate and base deficit are used as quantifiable markers of shock to guide fluid resuscitation. Rewarming with forced-air warmers, radiant heat, and heated fluids is also performed. Coagulation labs and/or thromboelastography should guide transfusions with the goal of correcting underlying coagulopathy. In preparation for the third stage, a thorough head-to-toe tertiary exam should be performed to identify any injuries that may have been overlooked during the primary survey.

Once the patient is fully resuscitated, reexploration with definitive repair can occur. The exact timing is based largely on the patient's response to resuscitation, but a shorter time (<2 days) to the first attempt at definitive closure is associated with greater odds of successful fascial closure.[21] After removing the temporary abdominal closure, copious irrigation is used to soak and rehydrate the packs so they can be removed without disturbing underlying clot. The abdomen is completely explored for other injuries, and then vascular and gastrointestinal injuries can be definitively repaired. If at any point the patient becomes hemodynamically unstable, the damage control sequence can be reinitiated.

When possible, a tension-free fascial closure is performed. In cases of ongoing contamination, bleeding requiring repacking, or concern for bowel viability, a temporary closure may be replaced for subsequent reexploration. Efforts at progressive fascial closure on a daily basis are warranted, since the overall success rate of definitive closure falls dramatically after

TABLE 31-1: Indications for Temporary Abdominal Closure in the Trauma Patient

Damage control approach

Combination of major vascular and gastrointestinal injury
Planned second-look operation
Intra-abdominal packing in place
Unable to achieve tension-free fascial closure
Risk of abdominal compartment syndrome
Treatment of abdominal compartment syndrome

1 week. When the abdomen cannot be fully closed due to loss of domain or unrelenting bowel edema, a sequential abdominal closure with retention sutures may be employed. When all attempts to close the fascia have failed, complex closure methods with component separation or mesh may be used.

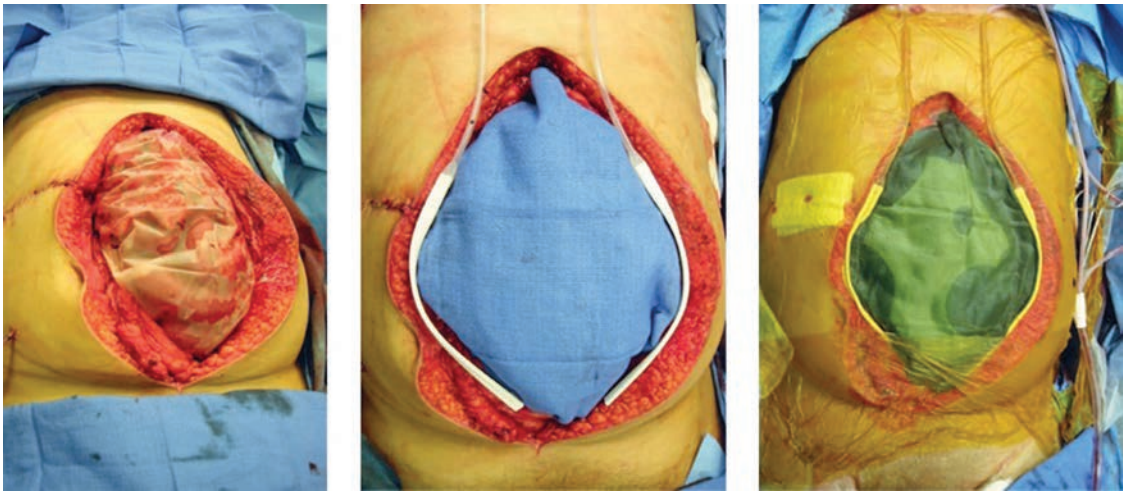
Temporary Abdominal Closure

Temporary abdominal closure allows the surgeon a quick and easy reentry into the abdomen without damaging the fascia, and it can be reapplied as needed before definitive closure. Indications for temporary abdominal closure are listed in Table 31-1. The temporary abdominal closure aims to contain the viscera, protect the bowel, provide early identification of intra-abdominal complications, and preserve healthy fascia for eventual closure. Note that abdominal compartment syndrome (ACS) has been reported with a temporary abdominal closure in place.

FIGURE 31-6 The abdomen has been partially closed with a skin-only closure. (Used by permission from Clay Cothren Burlew, MD.)

There are a variety of techniques used to perform temporary abdominal closure. A running suture in the skin is an easy method to bring the skin together, but drawbacks include injury to the skin and possible evisceration. Skin-only closures do not allow for fascial expansion and have a higher rate of secondary ACS and thus have fallen out of favor (Fig. 31-6). The two most widely accepted techniques for temporary abdominal closure employ either the ABThera Open Abdomen Negative Pressure Therapy (Acelity, San Antonio, TX) device or a homemade vacuum pack device.

Barker et al[22] described their success with the homemade vacuum pack. A similar method uses perforated subfascial 1010 Steri-Drapes (3M Health Care, St. Paul, MN), placed as laterally as possible to prevent adhesions, with two overlying Jackson-Pratt drains, a sterile towel to protect the bowel, and an Ioban drape to close the open abdomen (Fig. 31-7).



A **B** **C**

FIGURE 31-7 One method of temporary abdominal closure. (**A**) The bowel is covered with a sterile 1010 drape. (**B**) A sterile towel is placed to protect the bowel, and two Jackson-Pratt sump drains are placed to remove effluent from the peritoneum. These are placed to bulb or wall suction. (**C**) The closure is completed with a large Ioban drape. (Used by permission from Walter Biffl, MD.)

With any method, the suctioned effluent should be monitored for bloody or bilious drainage. The open abdomen may drain several liters over 1 day, and control of effluent with a vacuum device helps to keep the patient dry. Note that blood clot may collect below the closure, and a patient may have significant blood loss despite minimal effluent.

An open abdomen with a temporary closure does not mandate paralysis or sedation. Rather, patients may be extubated, enterally fed, and mobilized. In patients without bowel injury, enteral feeding has been associated with greater fascial closure rates, decreased complications, and decreased mortality.[23]

Once all packs and foreign bodies have been removed from the abdomen, vascular reconstruction is complete, and the gastrointestinal tract is in continuity, fascial closure can be attempted. Note that the need for enteral access should be addressed at this time.[24] Whenever possible, omentum should be placed between the bowel and the abdominal wall before closure. Several studies have shown that definitive fascial closure should be performed as early as possible to avoid morbidity and mortality. Early abdominal closure shortens hospital and intensive care unit length of stay and diminishes cost. Patients whose abdomens are closed within a week report higher quality of life and improved emotional health and are more likely to return to work than those closed after a week.[25] Factors associated with failure to achieve delayed primary closure include greater number of reexplorations, the development of intra-abdominal infections, bloodstream infections, acute renal failure, enteric fistula, and injury severity score greater than 15.[26]

When the fascia cannot be closed all at once, sequential fascial closure can be employed. Sequential closure may be performed with a sponge "sandwich" (Fig. 31-8). This technique consists of multiple white sponges (Acelity, San Antonio, TX) covering the bowel with the fascia held under tension with full-thickness number 1 polydioxanone (or other similar) sutures. A black sponge is placed over the white sponge with an occlusive dressing, and the vacuum is placed to suction. This addresses the need to keep the fascia under tension to prevent fascial retraction and loss of domain. The patient is returned to the OR at least every other day to perform sequential fascial closure with interrupted sutures. During this period, the surgeon must pay close attention to the patient's fluid status, as forceful diuresis is often required to get the laparotomy incision closed, and wound care, as clean fascial edges and progressive tightening are mandatory.

Despite all efforts, the fascia cannot always be closed. These scenarios present a technical challenge to the surgeon, and the decision and options are complex and not uniformly advocated. When a primary fascial closure is not possible, options include a component separation, direct skin grafting onto slightly granulated bowel, or closure with a variety of meshes (biologic, permanent, absorbable). A component separation, releasing the rectus sheath laterally, may provide up to 10 additional centimeters to bring the fascia together primarily. Biologic meshes, such as a porcine intestinal submucosa (Surgisis; Cook, Bloomington, IN) or a human acellular dermis such as Alloderm (Lifecell, Branchburg, NJ), are often recommended for contaminated wounds as they have no risk of infection, but they are very expensive and have a significant rate of hernia recurrence.

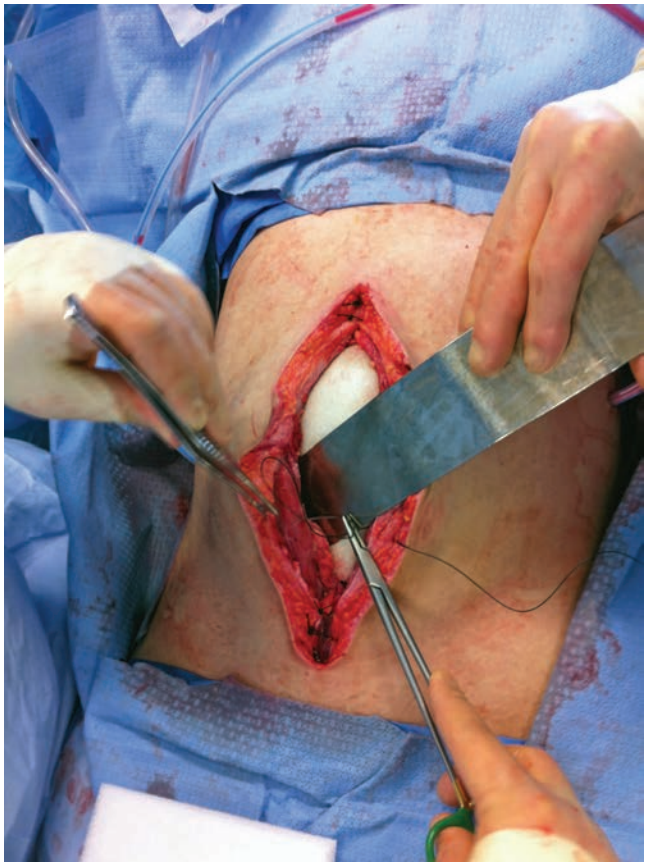


FIGURE 31-8 A sequential closure is performed on the second takeback operation. The lower fascia has been closed in a tension-free manner. A white vacuum-assisted closure sponge is placed over the bowel, and fascial retention sutures are placed. A black sponge will be placed over top and an Ioban drape will seal the closure. (Used by permission from Clay Cothren Burlew, MD.)

In cases of contamination, an absorbable mesh, such as a Vicryl mesh (Ethicon, Somerville, NJ), may be employed in a bridging fashion with an overlying skin graft. Vicryl has a high tensile strength and a very low rate of infection. Negative-pressure dressings can be placed on top of exposed mesh to promote growth of granulation tissue, allowing earlier skin grafting, although there are reports of this being associated with bowel fistula formation. Until grafted, these wounds are similar to full-thickness burns and represent a major catabolic drain for the patient, and the unprotected viscera are susceptible to injury and fistula formation. These patients can eventually undergo planned ventral hernia repair.[27]

A permanent prosthetic, such as a Marlex mesh (Davol, Cranston, RI) or a Prolene mesh (Ethicon, Somerville, NJ), may be employed to bridge a fascial defect, although they are much more commonly used for definitive repair of a long-standing hernia and not the closure of an open

abdomen. They become well-incorporated into the body but carry a risk of infection, adhesion formation, seroma, and fistula formation. Permanent prosthetics should not be used in a contaminated abdomen, as they will stay infected and eventually require removal. Composite meshes use a combination of materials in order to take advantage of their various properties. They have improved tissue incorporation and create less inflammatory reaction, but they are more expensive.

In complex cases where there is a lack of intact skin to cover the defect, the surgeon should consider autologous tissue transfer in the form of either pedicled or free flaps.

COMPLICATIONS OF TRAUMA LAPAROTOMY

This section will focus on four potentially devastating complications after trauma laparotomy: fascial dehiscence and evisceration, enterocutaneous fistula, missed injury, and retained foreign body.

Fascial Dehiscence and Evisceration

Dehiscence occurs when previously closed fascia pulls apart. Evisceration occurs when intra-abdominal contents leave the peritoneal cavity through an opening in the fascia. Among trauma patients, predictors of dehiscence include technical error, wound infection, and intra-abdominal infection.[28] Additional risk factors for dehiscence include obesity, pulmonary disease, hemodynamic instability, sepsis, poor nutritional status, malignancy, ascites, and steroid use. Mortality among patients with dehiscence reaches nearly 30%.[29] The best treatment of dehiscence is prevention—namely, a quality fascial closure. The evidence for running versus interrupted sutures remains equivocal. In a retrospective review of trauma patients, there was no difference in the rate of dehiscence, incisional hernia, or surgical site infection based on closure with interrupted or running suture.[28,30] A recent prospective study demonstrated decreased dehiscence and mortality in an emergency laparotomy cohort with the use of slowly absorbable monofilament suture, the "small step" technique, and a suture-to-wound ratio of 4:1. This means the length of the suture used is at least four times the length of the incision. Exact placement of sutures is 5 to 6 mm from the edge of the fascia, with 4 to 5 mm between sutures.[31]

Unfortunately, dehiscence may complicate any exploratory laparotomy. Dehiscence with evisceration mandates urgent return to the OR. Principles of operative management include debridement to healthy fascia, control of any intra-abdominal sepsis, and a tension-free fascial closure. More complex methods of abdominal closure, as described earlier, may be employed when tension-free closure cannot be obtained. Prophylactic abdominal retention sutures may be useful in decreasing evisceration rates, but ultimately, their benefit remains debatable within the literature.

Enterocutaneous and Enteroatmospheric Fistulae

A fistula is an abnormal connection between two epithelialized organs. Factors contributing to the formation of enterocutaneous fistulas (ECFs) include damage to the serosal lining, erosion of the bowel against a prosthetic mesh, missed traumatic or iatrogenic injury to the bowel, and anastomotic breakdown. In the patient with an open abdomen, bowel ischemia and inflammation, bowel obstruction, increased manipulation of the bowel, desiccation of the bowel, and the presence of intra-abdominal infection can also contribute to fistula formation, known as enteroatmospheric fistula (EAF) in this setting. Prevention of a fistula can be attempted by placing omentum over the bowel, minimizing injury to the serosal layer of the bowel, keeping the bowel moist when the abdomen is open, and obtaining fascial closure as early as possible.

Unlike an ECF, an EAF has no vascularized tissue over the fistula tract. Although the majority of ECFs heal spontaneously, 50% to 80% of EAFs require surgical repair.[32] ECFs and EAFs require patience, during which time nutrition and wound care are of the utmost importance. When the patient has an open abdomen, early intervention has been recommended. If the surgeon misses the critical window before the abdomen becomes "frozen" with dense adhesions, operative intervention is delayed several months, which can lead to persistent electrolyte imbalance, malnutrition, prolonged intensive care unit and hospital stays, and increased mortality.

Missed Injury and Retained Foreign Bodies

Missed injuries and retained foreign bodies contribute to increased morbidity and mortality. While injuries may be missed during the primary or secondary survey, the majority of missed injuries are caused by incomplete surgical exploration.

Injuries to the colon, diaphragm, and genitourinary tract are the most commonly missed intra-abdominal injuries. Errors in technique and judgment can contribute to an imperfect exploration, as may hemodynamic instability and distracting injuries. Typically, missed injuries occur in proximity to another identified injury, potentially even in the same organ. Surgeons must be vigilant with regard to complete exposure of an injured area, including visceral rotations to explore retroperitoneal structures as needed. Additionally, surgeons should be aware of injury trajectory and number of bullet holes through the digestive tract.[33]

After trauma laparotomy, there are various factors that may contribute to a retained foreign body. Although quite rare, estimated at 0.14% by Teixeira et al[34] in a retrospective review of their 7-year experience at University of California, Los Angeles, retained foreign body can have devastating effects. The emergent nature of the procedure precludes the routine counting of instruments. During the initial entry and packing of the abdomen, it is easy and common to lose track

of the number of laparotomy pads placed in the abdomen when the focus is on lifesaving hemorrhage control. The presence of multiple teams operating in multiple body cavities may also contribute to the potential for instruments to be left behind. In one retrospective analysis, emergency surgery, unplanned change in procedure, and body mass index of the patient were found to be significantly associated with risk of foreign body retention.[35]

When a patient's abdomen is left open and packed, it is helpful to include the location, and ideally the number, of packs left within the abdomen in the operative note. This is especially important when a different team completes the subsequent case, as is common in trauma. Before preparing to close fascia, the surgeon should perform a thorough search of the peritoneum for remaining laparotomy pads and instruments. Prior to definitive closure of the abdomen, even when the instrument and sponge counts are correct, plain films should be performed and assessed by both the surgeon and a radiologist to look for retained foreign bodies.[34] Another option is the use of laparotomy pads embedded with a radiofrequency detection system, which has been shown to detect retained laparotomy pads even when x-rays were normal.[36]

Paramount to the management of any missed injury or retained foreign body is prompt identification, notification, and intervention. Once the missed injury has become evident to the team, full disclosure to the patient and family must occur. A hospital's risk management team may help to manage and mitigate this difficult situation.

NEGATIVE AND NONTHERAPEUTIC LAPAROTOMIES

A negative laparotomy is a laparotomy in which there is no evidence of injury. A nontherapeutic laparotomy is a laparotomy in which there is an injury that does not require further surgical intervention. A retrospective review of over 1800 trauma laparotomies at an urban, Level I trauma center demonstrated a negative laparotomy rate of 4%. Peritonitis, hypotension, and suspicious CT findings were the most common indications cited for laparotomy.[37] Another population-based study focusing on splenic and hepatic injuries identified a negative laparotomy rate of 5% and a nontherapeutic laparotomy rate of 9%.[38]

Despite the highly accurate radiographic imaging available, the decision to perform laparotomy for trauma is not always straightforward. On occasions where imaging or physical examination is equivocal or when the imaging does not correlate with the patient's clinical state, there is not always a clear decision algorithm. In these instances, the risk of a nontherapeutic laparotomy must be weighed against the risk of a delay in diagnosis.

There is controversy about the relative morbidity of a nontherapeutic laparotomy. Potential complications include, but are not limited to, cellulitis, wound infection, dehiscence, ileus, deep vein thrombosis, and myocardial infarction. Among patients with splenic and hepatic injuries who had a laparotomy, 6% developed subsequent small bowel obstruction (80% of those resolving with nonoperative management) and 9% developed an incisional hernia. In contrast, less than 1% of patients managed nonoperatively had a small bowel obstruction.[38]

The greater acceptance of minimally invasive techniques for trauma has reduced the negative laparotomy rate. Thoracoscopy or laparoscopy for penetrating trauma can be used in select hemodynamically stable patients with thoracoabdominal stab wounds to rule out diaphragm injury. Laparoscopy is a useful tool in the evaluation of left-sided thoracoabdominal gunshot wounds, gunshot wounds with suspected extraperitoneal trajectory, and for assessment of peritoneal violation after stab wounds to the flank and anterior abdomen.[39]

RELAPAROTOMY

Relaparotomy for Hemorrhage

The decision to return to the OR for postoperative bleeding, especially when using the damage control approach, is complex. The surgeon must weigh the risks of worsening coagulopathy and hypothermia associated with return to the OR against the likelihood of identifying surgically correctable bleeding. There is minimal benefit to returning a patient to the OR for coagulopathic, nonsurgical bleeding. The decision is often an interplay of factors including what was found and done during the original laparotomy, the patient's coagulopathic profile, physiologic status including core temperature, and transfusion requirements. In patients with a temporary abdominal closure, large volumes of sanguineous drainage may be used as a trigger to return to the OR.

Intraoperatively, hemostasis should focus on surgically correctable causes followed by appropriate packing to control coagulopathic bleeding. These patients almost always require temporary closure because they have a high rate of ACS after massive transfusion.

Relaparotomy for Intra-Abdominal Infection

In a patient who underwent a trauma laparotomy in which no injury to the gastrointestinal tract was identified and who then develops an intra-abdominal infection, the surgeon must consider a missed injury. As mentioned before, missed injuries require prompt patient notification and intervention. In a patient who had repair of an injury to the gastrointestinal tract and then develops an intra-abdominal infection, the surgeon must consider a leak. A septic clinical picture warrants further intervention—either return to the OR or urgent cross-sectional imaging to identify fluid collections that might be amenable to percutaneous drain placement. Infected biloma, hematoma, or abscess cavities that are multiloculated or not amenable to percutaneous drainage necessitate return to the OR.

If returning to the OR, the surgeon should be prepared for a challenging reoperation. After a few days, the abdominal cavity becomes entrapped and immobile secondary to

TABLE 31-2: Technical Options for Source Control During Relaparotomy for Uncontrolled Abdominal Infection

Technical option	Comment
Resection and anastomosis	Rarely feasible for early leaks
Resection and exteriorization	Almost never feasible due to foreshortened mesentery
Proximal diversion	Occasionally lifesaving (edematous abdominal wall is obstacle)
Tube drainage	Contraindicated
Vacuum-assisted management	Useful option for exposed fistula (caution if unprotected suture lines)

adhesions and contamination. The bowel is hard to free and is often highly edematous and easily injured. A variety of treatment options exist, but repairs are fraught with potential complications, and often the best strategy is wide drainage of the infected fluid collections and controlled drainage of a bowel fistula to air. Simple suture closure of a bowel leak or perforation often puts part of the bowel under tension. Secondary to the inflamed nature of the bowel surrounding the leak, this simple method has a high likelihood of failure. Resection and anastomosis is a better option when enough bowel can be mobilized, although any new anastomosis remains at high risk for failure in this situation. Tube drainage directly into a fistula site is controversial, and although it may help control the drainage, one can also expect continued leak around the tube, and the tube can serve to enlarge the enterotomy and maintain patency.

Proximal diversion is another treatment option. Injuries to the duodenum and proximal jejunum may be addressed with pyloric exclusion and a gastrojejunostomy. A loop ileostomy would permit more distal repairs in the ileum and large bowel to heal while diverting enteric contents. The technical options for reoperation for sepsis are outlined in Table 31-2.

BEDSIDE LAPAROTOMY

Resuscitative laparotomy may be performed at the bedside in the intensive care unit for patients requiring high levels of ventilatory support or escalating vasopressor requirements that preclude safe transport to the OR. One of the most common indications is decompressive laparotomy for ACS.

ACS is usually defined as intra-abdominal pressures greater than 20 mm Hg in the presence of elevated airway pressures or renal impairment. Primary ACS is often the result of injury, typically due to hemorrhage. Secondary ACS is caused by increased bowel edema and ascites from resuscitation in a closed abdomen; there is no primary intra-abdominal injury. Tertiary ACS, also called open abdomen ACS, occurs after treatment of primary or secondary ACS.

On physical examination, the abdomen will be distended and tight. The increased intra-abdominal pressure can directly compress of the inferior vena cava and, as a result, increase central venous pressure, increase pulmonary wedge pressure, decrease cardiac preload, and increase afterload. Lung expansion is difficult against a tense abdomen, elevating peak airway. Compression of the renal veins leads to an oliguria that is unresponsive to fluid resuscitation.

Diagnosis should be based on clinical findings in conjunction with a measurement of a bladder pressure. The trend of the bladder pressure may be more helpful than the absolute number. More importantly, the patient's physiologic profile and degree of organ dysfunction should hold more value in assessing ACS than the absolute bladder pressure measurement. It is commonly accepted that bladder pressures greater than 26 to 30 mm Hg should prompt decompression, but the absolute intra-abdominal pressure leading to a compartment syndrome is not definitively known and may vary by patient. Treatment for ACS is emergent decompression of the abdomen via midline laparotomy incision with placement of a temporary abdominal closure.

Cooperation and coordination between the surgical team, anesthesia, and nursing staff are essential for success of the bedside laparotomy. Essentially you are transporting the OR to the patient instead of vice versa. All potentially necessary personnel (eg, OR staff) and instruments and equipment (eg, sutures, staplers, electrocautery) need to be readily available. Most intensive care units have insufficient lighting, and one or more headlights are an absolute necessity. Despite these disadvantages and high associated mortality, laparotomy at the bedside can be lifesaving and the only option for a critically ill trauma patient.

Diaphragm

Walter L. Biffl • William G. Cioffi

KEY POINTS

- Traumatic diaphragm injury is rare (<1%) following blunt trauma, whereas penetrating thoracoabdominal trauma has an incidence of 24% to 38%.
- Most traumatic diaphragm injuries are identified at surgical exploration.
- The overall accuracy of chest x-ray is quite poor; the only direct sign of diaphragmatic injury is the visualization of herniated abdominal viscera into the chest.
- Laparoscopy is recommended over computed tomography for the diagnosis of left-sided thoracoabdominal stab wounds.
- The two principles of repairing acute diaphragmatic hernias are complete reduction of the herniated organs back into the abdominal cavity and watertight closure of the defect.
- Repair of the acutely blunt-injured diaphragm is best performed via laparotomy, although laparoscopic or thoracoscopic repair is feasible.

INTRODUCTION

The diaphragm, the most important muscle of respiration, separates the thoracic and abdominal cavities. It can be injured in isolation or involved with injury in either body cavity. The most challenging aspect of management is the identification of injury. Penetrating injuries in particular may be initially asymptomatic but later develop herniation and strangulation of the stomach or other abdominal viscera.

HISTORY

Traumatic diaphragmatic rupture was first reported by Sennertus in 1541, and Ambroise Paré was the first to report a series of diaphragmatic perforations found at autopsy.[1] Paré also described the consequences of gastric and colonic incarceration in a ruptured diaphragm.[2] The first documented antemortem diagnosis was by Bowditch in 1853,[3] and it was not until 1886 that Riolfi was credited with the first successful repair.[4] The first acute repair was by Walker in 1899, in a patient who had been struck by a falling tree.[5] The largest early review of 378 diaphragmatic hernias was by Hedblom in 1925.[4]

ANATOMY

The diaphragm is a dome-shaped musculofibrous septum separating the abdomen and thorax. It is bounded above by both pleural spaces and the pericardium, which is attached to the central tendon. Structures immediately adjacent to the inferior side of the diaphragm include the liver, spleen, stomach, and to varying degrees the colon, omentum, and small bowel. The origin of the diaphragm includes the lower sternum, lower six costal cartilages and adjacent ribs, and medial and lateral lumbocostal arches. The crura, two tendinous pillars, arise from the lumbar vertebrae. The insertion of the diaphragm is into the central tendon, an aponeurosis, located at the top of the dome, oriented transversely and separated into three segments. At rest, the diaphragm rises to the level of the fourth intercostal space on the right and the fifth intercostal space on the left. At maximal contraction, the diaphragm descends two rib spaces bilaterally. The aorta passes behind the diaphragm and between the crura, where it has no attachments. Along with the aorta, the thoracic duct and azygous vein pass through this opening. The esophagus traverses the esophageal hiatus, which is mostly composed of the right crus along with the vagus nerves. The inferior vena cava passes through its hiatus at the junction of the right and middle leaflets of the central tendon to which it may be adherent (Fig. 32-1).

The blood supply to the diaphragm is redundant, making necrosis rare.[6] The major blood supply to the abdominal aspect of the diaphragm arises from the inferior phrenic arteries, which are branches of the abdominal aorta or celiac trunk. Additional blood supply is from the superior phrenic, pericardiophrenic, musculophrenic, and intercostal arteries. Lymphatic drainage is rich on both sides of the diaphragm

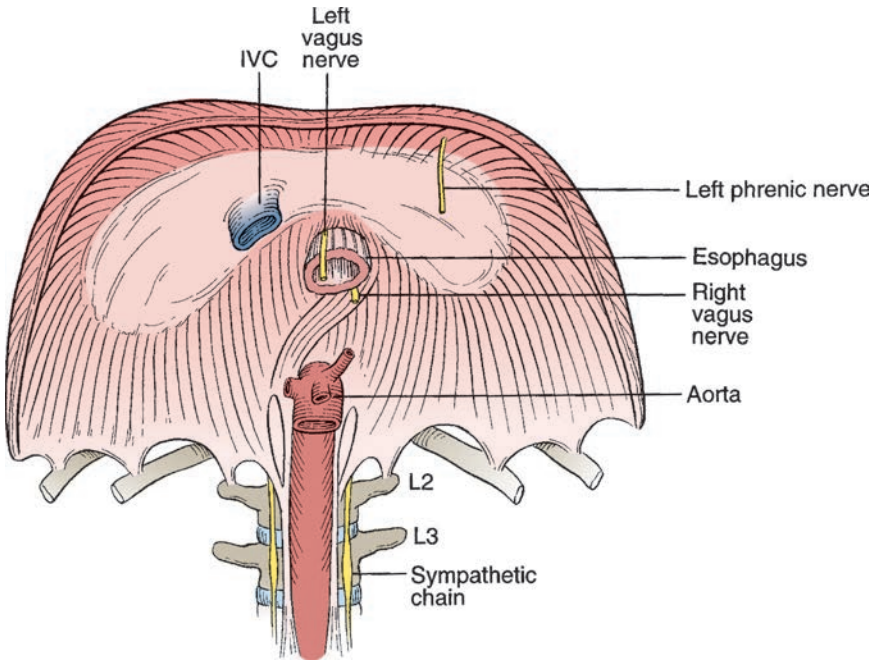

FIGURE 32-1 View of the diaphragm from the abdomen including the aortic, esophageal, and caval hiatuses. IVC, inferior vena cava.

with the peritoneal surface the major contributor to peritoneal lymphatic drainage. Innervation is principally through the phrenic nerves, with additional contribution of the sixth or seventh intercostal nerves to the costal region of the diaphragm. Both phrenic nerves enter the diaphragm near the anterior border of the central tendon. These nerves branch along the thoracic surface of the diaphragm before penetrating it and spreading branches in anterior, posterior, and lateral directions. The nerves are often buried deep in the muscle, and one should not rely on visualizing the nerves in order to choose incisions in the diaphragm. Safe diaphragmatic incisions that protect the phrenic nerves are depicted in Fig. 32-2.

PHYSIOLOGY

The diaphragm is a vital muscle involved in the function of both the digestive and respiratory systems. It participates in breathing, swallowing, coughing, defecation, emesis, micturition, parturition, sneezing, and vocalization.[7] In humans, it is the most important muscle of inspiration and can independently generate negative intrapleural pressure sufficient for respiration.[8] The innervation of the diaphragm is centrally unified in the spinal cord, and the entire diaphragm from the crura to the lateral margins has motor neuron origins intermingled within the spinal cord.[9] The crural components, however, may have their function overridden through peripheral or central mechanisms related to function of the gastrointestinal tract.

Perforation of the diaphragm can lead to acute changes in physiology. A normal pressure gradient between the abdomen and the chest leads to displacement of abdominal viscera into the chest, which may compromise both cardiac and respiratory function. Cardiac dysfunction due to reduced ventricular filling can lead to decreased cardiac output. Significant compression of the pulmonary parenchyma can lead to impaired ventilation on the ipsilateral side and, if more severe, mediastinal shift and compression of the contralateral lung. As with any herniation of portions of the gastrointestinal tract, sequelae such as ischemia, necrosis, and perforation may develop. There are no long-term outcome data that describe diaphragmatic function after repair for trauma, but it appears that normal physiologic pulmonary and gastrointestinal function is generally attained and is durable.

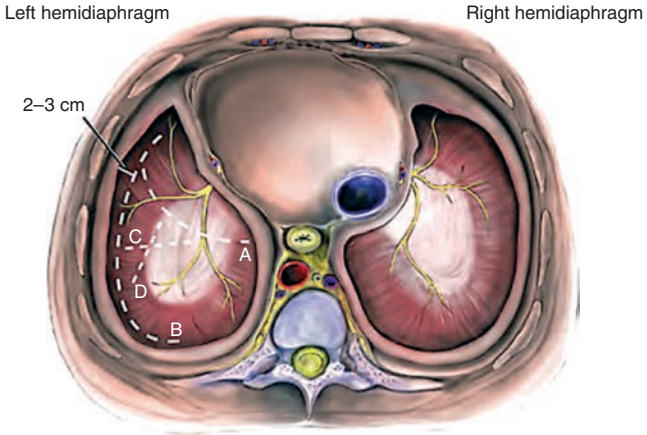

FIGURE 32-2 Surgical incisions on the diaphragm. (**A**) An incision with a risk of total paralysis of the diaphragm. (**B**) A preferred incision with minimal risk of nerve injury. (**C**, **D**) Incisions in safe areas, but with small risk of nerve injury. (Reprinted with permission from Anraku M, Shargall Y. Surgical conditions of the diaphragm: anatomy and physiology. *Thorac Surg Clin.* 2009;29:419-429. Copyright © 2009 Elsevier.)

INCIDENCE

The incidence of traumatic diaphragm injury (TDI) has been reported to range from less than 1% to 7% after blunt trauma and from 10% to 15% after penetrating trauma.[10-12] This wide range stems from an inability to identify injuries treated at nontrauma centers, deaths prior to hospital admission, and missed injuries after admission to a trauma center. The largest source of variability is the denominator in question. An analysis of the National Trauma Data Bank (NTDB) for the admission year 2012 identified 3873 TDIs among 833,309 patients, for an overall incidence of 0.46%.[13] Based on 2016 NTDB data, TDIs are rare among overall blunt trauma patients, with an incidence of 0.17%.[12] In contrast, the highest reported rate of injury occurs in patients sustaining thoracoabdominal gunshot wounds. Berg et al[14] reported TDI in 63% of such patients. Among patients with penetrating thoracoabdominal trauma, 24% to 38% have been found to have TDI when laparoscopy is performed.[15-18]

MECHANISM OF INJURY AND PATHOPHYSIOLOGY

A recent 16-year review from three regional trauma centers in Wisconsin found that 75% of TDIs were caused by penetrating mechanisms.[19] A 15-year review from the R. Adams Cowley Shock Trauma Center in Baltimore similarly reported 73% of injuries resulting from penetrating mechanisms.[20] These centers' data are consistent with the 2012 NTDB data, in which 67% of TDIs resulted from penetrating mechanisms of injury.[13] Most blunt TDIs are reported on the left side: 67% in the Wisconsin series[19] and 69% in the Baltimore series.[20] It is hypothesized that the left posterolateral diaphragm is the weakest area and thus predisposed to injury.[11] It is likely, however, that the liver affords protection to the right hemidiaphragm by mitigating the effects of blunt kinetic energy applied to the abdomen.[21] Similarly, penetrating injury to the diaphragm has had a left-sided predilection. This has been suggested, but not proven, to be related to the prevalence of right-handed assailants. In fact, recent data indicate a more even distribution. In the Baltimore series,[20] 45% of penetrating TDIs were on the right. Interestingly, in the Wisconsin series,[19] in the first half of the study period, the right:left distribution was 27%:70%; however, in the second half, it was 49%:49%.

Penetrating wounds typically result in a smaller injury, but the defects may enlarge over time and eventually lead to acute incarceration and/or strangulation of abdominal viscera if not promptly recognized and repaired.

PRESENTATION

Grimes[22] classified diaphragmatic injuries into the following three phases of presentation: acute, or during the period of recovery from injury; latent, following an asymptomatic period; and obstructive, during which time herniation leads to cardiovascular compromise or gastrointestinal obstruction or perforation. In the acute phase, patients may have minimal signs of external injury or be experiencing severe shock and respiratory compromise that may or may not be directly related to the diaphragmatic injury. In the less severely injured, possible signs and symptoms include shoulder pain, epigastric pain, vomiting, dyspnea, absent breath sounds, or bowel sounds heard during auscultation of the chest.[23] It is difficult to glean from the literature how many patients present with symptoms directly related to a TDI. Some are identified on imaging, and most are identified at surgical exploration.[19,20]

In the latent phase, TDI or visceral herniation is often asymptomatic and may be discovered incidentally on radiographic studies performed for other reasons. Although the majority of injuries are diagnosed acutely, case series have reported 3% to 15% of cases presenting in the late or obstructive phase.[24,25] Patients presenting in the obstructive phase often experience nausea, vomiting, early satiety, pain, dyspnea, postprandial pain, or generalized chest and abdominal pain. Patients may also present in extremis with signs and symptoms of septic shock due to ischemia or perforation related to strangulation or gangrene of incarcerated viscera or with cardiovascular collapse due to compression.[26] In the series by Murray et al,[27] 14 (50%) of 28 patients with posttraumatic diaphragmatic hernia presented as surgical emergencies, with an associated mortality of 11%.

ASSOCIATED INJURIES

Blunt diaphragmatic injury typically involves high-energy compression-type mechanisms, and associated injuries are common (Table 32-1). Not surprisingly, liver and lung injuries are most commonly associated with TDI. As seen in the

TABLE 32-1: Injuries Associated with Diaphragmatic Injury and the Mortality Rate Among Patients with Those Injuries in a Large Single-Center Series[20]

Associated injury	Number (%)	Mortality rate
Total patients	773	21%
Lung	592 (77%)	23%
Hemothorax	414 (54%)	24%
Liver	402 (52%)	25%
Pneumothorax	372 (48%)	15%
Rib fractures	257 (33%)	23%
Spleen	248 (32%)	13%
Bowel	153 (20%)	27%
Stomach	144 (19%)	19%
Kidney	133 (17%)	18%
Head	123 (16%)	35%
Pancreas	57 (7%)	23%
Heart	54 (7%)	63%
Pericardium	37 (5%)	60%

large series from Maryland,[20] traumatic brain injury and injuries to the heart and pericardium are less common, but their presence indicates a higher risk of death.

DIAGNOSIS AND DIAGNOSTIC TESTS

Diaphragmatic injury is often asymptomatic, or the presentation is dominated by other injuries. Consequently, the clinical diagnosis is very challenging. Information about the mechanism of injury should always be obtained from prehospital personnel, as it may direct the diagnostic evaluation. Blunt diaphragmatic injuries generally result from a sudden increase in abdominal pressure, with motor vehicle crashes being the most common blunt injury mechanism.[13] In penetrating trauma, any injury to the thoracoabdominal area should raise suspicion for a potential diaphragmatic injury.[14,18] Although most stab wounds that result in diaphragmatic injury will be in this region, gunshot wounds that injure the diaphragm may occur anywhere on the trunk.[26] Injuries are graded according to the American Association for the Surgery of Trauma Organ Injury Scale for Diaphragmatic Injuries (Table 32-2).[28]

Plain chest x-ray (CXR) is regarded as a key initial diagnostic study in any patient in whom there is a possibility of significant torso injury and especially those with thoracic or thoracoabdominal penetrating injury. Unfortunately, the overall accuracy of CXR is quite poor; the sensitivity has been reported to be in the range of 27% to 62% for left-sided injuries and 18% to 33% for right-sided injuries.[29] Most patients with TDI have a normal CXR or only nonspecific findings, such as loss of a smooth, diaphragmatic contour, ipsilateral pleural effusion, ipsilateral elevated hemidiaphragm, or mediastinal shift.[30] The only direct sign of diaphragmatic injury is the visualization of herniated abdominal viscera into the chest. A nasogastric or orogastric tube may help determine that a hyperlucency is the herniated stomach rather than a pneumothorax (Fig. 32-3A and B). In the Wisconsin series,[19] only 50 (11%) of 454 patients had TDI diagnosed based on CXR, and the authors report that none of them were identified by nasogastric tube position. Contrast swallow studies and enemas, as well as fluoroscopy, have been used in the past and may be potentially helpful but are rarely employed today (Fig. 32-4).

TABLE 32-2: Grading of Diaphragmatic Injuries

Grade	Description of injury
I	Contusion
II	Laceration ≤2 cm
III	Laceration 2–10 cm
IV	Laceration >10 cm with tissue loss ≤25 cm^2
V	Laceration with tissue loss >25 cm^2

Ultrasonography is employed frequently during trauma resuscitation, and evaluation for hemoperitoneum, hemopericardium, pneumothorax, and hemothorax is routine in trauma centers. The diaphragm can be recognized as a curved hyperechoic structure, and its movement can be observed with respiration. Signs of TDI include the presence of floating diaphragm edges, intrathoracic visceral herniation, and absence of diaphragmatic excursion.[31-34] Rip's absent organ sign, referring to the nonvisualization of the spleen or heart, has also been identified as a sign of TDI,[34] and in patients with right-sided ruptures, a finding of liver sliding against the chest wall has been reported.[33] There are inadequate data to evaluate the sensitivity or specificity of these findings.

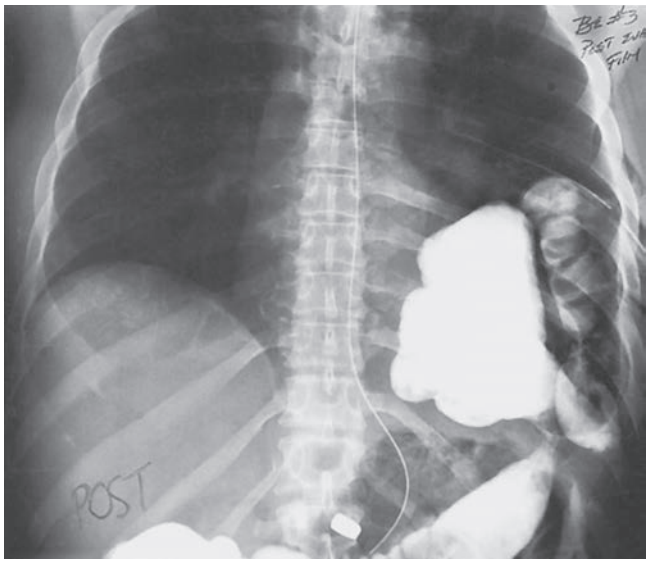

FIGURE 32-4 Contrast enema with splenic flexure identified above the diaphragm.

It is likely that the advent of routine helical computed tomography (CT) scanning has decreased the incidence of missed diaphragmatic injuries after blunt trauma.[35] Helical CT for the detection of blunt TDI has a reported sensitivity of 71% to 100% and specificity of 75% to 100%; sensitivity improves to 78% to 100% if only left-sided injuries are included.[36] Findings consistent with diaphragmatic disruption include the following: direct visualization of the defect; segmental nonvisualization of the diaphragm; herniation of viscera; constriction of a herniated viscus or a "collar sign"; dependent viscera sign or contact of intra-abdominal organs with the posterior chest wall; thickening of the diaphragm; and active extravasation of contrast at the level of the diaphragm (Fig. 32-5A and B). Multidetector CT scanning has been evaluated in patients with penetrating trauma with a reported sensitivity and specificity of 87% and 72%, respectively.[37] In addition to the signs listed earlier, contiguous visceral injuries on both sides of the diaphragm are an important potential finding in penetrating trauma.

Magnetic resonance imaging (MRI) provides excellent resolution of the diaphragm and separates it from surrounding structures including the liver and atelectatic lung.[36] In general, the signs seen on MRI are the same as those seen on CT (Fig. 32-6). The utility of MRI is limited due to availability, time, and other issues. In the hemodynamically normal patient with equivocal CT findings, MRI may have a role, although there have not been any large studies examining its accuracy to date.

Despite the imaging options, most patients are diagnosed intraoperatively. Over the 16-year study period in Wisconsin trauma centers,[19] 29% of blunt and 71% of penetrating TDIs were diagnosed intraoperatively. This is in part due to patients being taken directly to the operating room due to physiologic condition, but it has also been recognized that the diagnosis of penetrating injuries in particular can be very

difficult. Diagnostic peritoneal lavage was employed liberally in the 1970s to 1990s and is currently advocated as an option in a few specific circumstances,[38] but it has all but disappeared from the trauma surgeon's armamentarium. Currently, laparoscopy and thoracoscopy are considered the best diagnostic tests for TDI.

Uribe et al[15] performed routine thoracoscopy in patients with penetrating thoracoabdominal injuries and found diaphragmatic injuries in 32%. Of note, the authors performed laparotomy on all patients with diaphragmatic injuries and found that 89% of them had intra-abdominal injuries that required surgical repair. In the 1990s, a number of investigators attempted to clarify the role of laparoscopy. Murray et al[16] prospectively studied 110 patients with penetrating injuries to the left lower chest and found occult diaphragmatic injuries in 26 (24%) of them. Friese et al[17] confirmed these results, also finding diaphragmatic injuries in 24% (8 of 34) of patients with penetrating thoracoabdominal injuries. They further evaluated the accuracy of laparoscopy by following it with laparotomy and found one (11%) missed injury. In more contemporary experience, among 595 patients with thoracoabdominal stab wounds who arrived to the hospital alive, 38% were found to have TDI.[18] Of note, the authors reported that CT scan did not show evidence of diaphragmatic injury in 32% of patients. The same group, analyzing their experience with 984 thoracoabdominal gunshot victims, found that 63% had diaphragmatic injuries.[14] The authors cautioned that preoperative diagnosis of TDI is inaccurate and that there is limited role for nonoperative management in this subgroup of patients.

A recent practice management guideline from the Eastern Association for the Surgery of Trauma conditionally recommends laparoscopy over CT for the diagnosis of left-sided thoracoabdominal stab wounds.[39] The superior accuracy of laparoscopy is weighed against procedural risks, which are few. A diagnostic algorithm for identifying diaphragmatic injury is presented in Fig. 32-7.

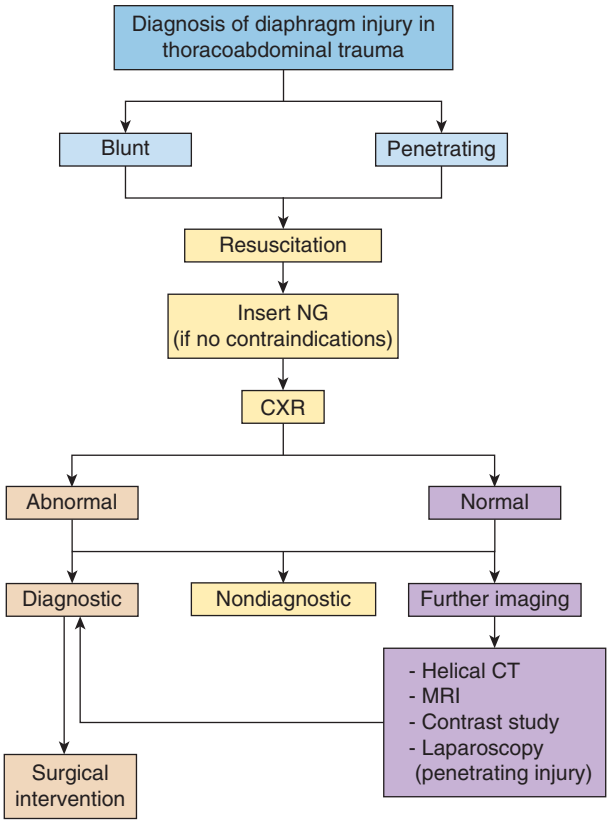

FIGURE 32-7 Diagnostic algorithm for identification of diaphragmatic injury. CT, computed tomography; CXR, chest x-ray; MRI, magnetic resonance imaging; NG, nasogastric.

REPAIR OF ACUTE DIAPHRAGMATIC INJURIES

The two principles of repairing acute diaphragmatic hernias are complete reduction of the herniated organs back into the abdominal cavity and watertight closure of the defect to prevent recurrence. Given the high rate of associated abdominal injuries following blunt TDI, on average 1.6 intra-abdominal injuries per patient, repair of the acutely blunt-injured diaphragm is best performed via an exploratory laparotomy. Similarly, unstable patients with penetrating injuries require laparotomy. Stable patients with penetrating injuries may undergo diagnostic laparoscopy, with laparoscopic repair of injuries or conversion to laparotomy depending on the laparoscopic skills of the surgeon. Although there are limited data, it appears that nonoperative management of stable patients with right-sided penetrating wounds is safe.[39] The ligamentous attachments of the liver prevent its herniation through relatively small penetrating wounds, and the liver itself prevents intestinal herniation into the right chest. Only in the setting of large defects or leakage of bile into the chest is repair required.

The right hemidiaphragm is best inspected after transection of the falciform ligament and downward traction of the liver. The left hemidiaphragm can be inspected by applying gentle downward retraction of the spleen and greater curvature of the stomach. The central tendon of the diaphragm should also be examined, along with the esophageal hiatus. Reduction of the intra-abdominal contents is generally not difficult in the period immediately following injury. If the herniated contents are difficult to reduce, the phrenotomy can be partially extended to facilitate reduction, with care taken to avoid injury to the phrenic nerve.

It may be necessary to carefully debride the edges of a laceration if devitalized tissue is found, as with a high-velocity missile or close-range shotgun wound. The edges of the diaphragmatic laceration should then be grasped with Allis clamps and the laceration spread apart to inspect the ipsilateral pleural cavity. This allows for evaluation of ongoing hemorrhage from within the thoracic cavity, as well as the determination of the degree of contamination between the abdominal and thoracic cavities. Small diaphragmatic disruptions, commonly seen after penetrating trauma, can generally be repaired using interrupted nonabsorbable sutures. Larger defects, more likely associated with blunt trauma, may be repaired in a number of different ways, including interrupted figure of eight, horizontal mattress sutures, a running hemostatic suture line, or a two-layer repair (Fig. 32-8). Generally, a #0 or #1 monofilament or braided nonabsorbable suture is used. The authors prefer a #1 nonabsorbable monofilament running suture for the repair of traumatic diaphragmatic defects. In patients in whom a laceration through the central tendon exposes the inferior aspect of the heart, meticulous attention is given to the placement of the sutures to prevent inadvertent puncture or laceration of the myocardium. At the completion of the repair, the integrity of the suture line may be tested by increasing intrathoracic pressure with the administration of large tidal volumes and assessment of diaphragmatic motion. This maneuver is repeated with the field flooded with sterile saline to determine if there is escape of air through the suture line.

In cases where there is concomitant injury to a hollow viscus in the abdomen, contamination of the chest will have occurred due to the pressure gradient between the positive pressure in the abdomen and the negative pressure in the thoracic cavity. In this event, careful irrigation of the thoracic cavity through the diaphragmatic disruption is advised prior to diaphragmatic repair, as empyema is three times more prevalent when there is an associated injury to the bowel.[25,40] Zellweger et al[41] studied the management of patients with

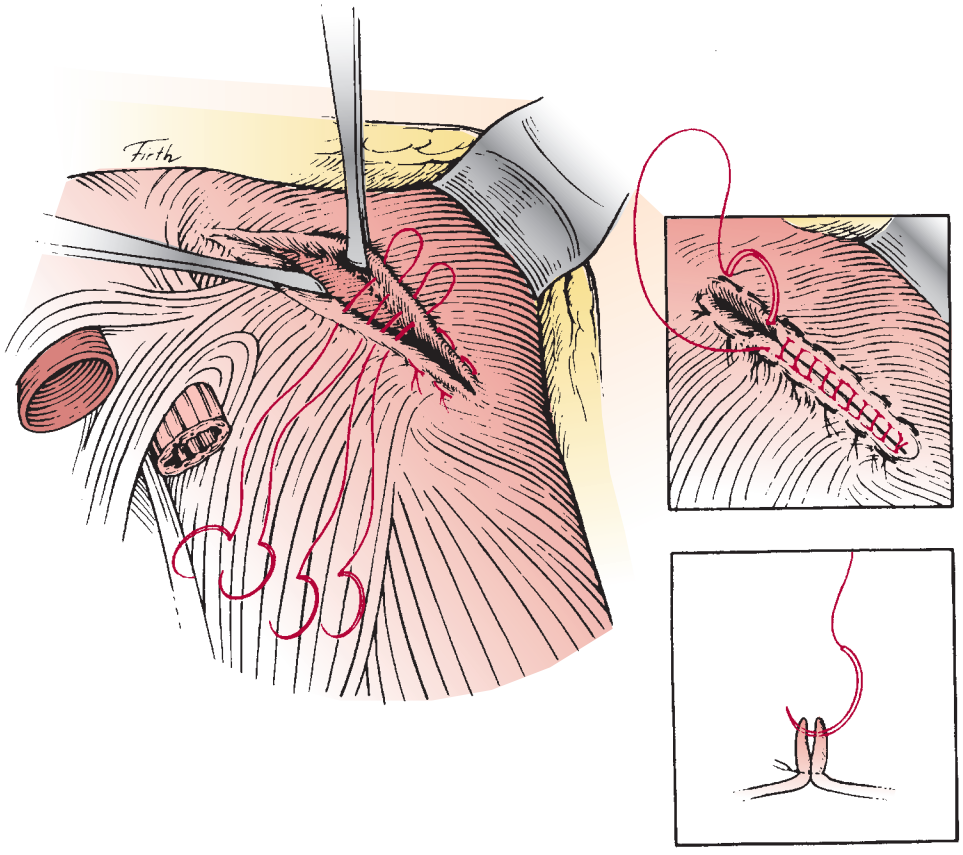

FIGURE 32-8 Technique for two-layer repair of diaphragmatic defect. (Reproduced with permission from Juan A. Asensio, MD, FACS, FCCM, and Demetrios Demetriades, MD, PhD, FACS.)

penetrating thoracoabdominal wounds that injured the diaphragm and gastrointestinal tract and/or liver. They demonstrated that a transdiaphragmatic washout of the pleural cavity was an effective strategy to decrease thoracic contamination.

Laparoscopic repair of diaphragmatic injuries is feasible.[39] A diaphragmatic injury diagnosed by laparoscopy in the absence of other injuries mandating laparotomy or thoracotomy can be repaired with this approach.[42] Laparoscopic repairs of diaphragmatic injuries can be performed with sutures or staples.[13] The decision to proceed laparoscopically should be solely dependent on the skill of the operating surgeon. For laparoscopic explorations to rule out a left-sided diaphragmatic injury, port placement is important. The initial port should be at the level of the umbilicus or just above depending on the patient's body habitus. A subxiphoid port is placed for retraction of the liver, and a port is placed laterally on the left side just below the costal margin. This port is used to maintain traction on the stomach or other cranially herniated abdominal organs. The umbilical port is used for the 30° laparoscopic camera. Two additional ports in the bilateral mid-clavicular lines are used as working ports. These two ports are also placed in a subcostal location. After placing the patient in steep reverse Trendelenburg position and careful reduction of the abdominal contents back into the abdomen, the defect is repaired. Techniques of repair are identical to the open methods. For right-sided injuries, port placement is similar, moving the left lateral subcostal port to the right. The right lobe of the liver is retracted medially or caudally. The falciform ligament and the right triangular ligament may require division for adequate retraction and exposure of the injury. During repair, air will be introduced into the pleural cavity. Tube thoracostomy is recommended if there was a significant hemo- or pneumothorax preceding repair. In the absence of either, air may be removed from the pleural space via a catheter just as the diaphragmatic repair sutures are tied down; this may be assisted by a Valsalva maneuver and may obviate the need for tube thoracostomy. A postoperative CXR is recommended.

At times, a thoracotomy is required for the management of a massive hemothorax, generally defined as greater than 1500 mL of blood on insertion of a chest tube or in the first 15 to 30 minutes or more than 200 mL of blood per hour for the first 4 hours after trauma.[43] A laceration of the right hemidiaphragm with an associated laceration of the liver may present as a massive hemothorax, with the diagnosis made at the time of thoracotomy. In this scenario, the diaphragm may be repaired through the chest, but a formal laparotomy will be necessary for the operative management of the hepatic injury and to rule out other associated intra-abdominal injuries.

For thoracoscopic management of a known diaphragmatic injury, the patient is placed in the lateral decubitus position with the arm abducted to allow maximal superior displacement of the scapula. The initial 2-cm incision should be placed just below the tip of the scapula. Two further incisions are then placed to complete a triangle based on the patient's intrathoracic anatomy. The principles of visceral reduction and the technique of repair remain similar to those used in open surgery.

Disruption of the diaphragm following high-energy crushing injuries or major deceleration can result in avulsion of the diaphragm from its attachments to the chest wall. Repair of this injury may require an ipsilateral thoracotomy, which allows horizontal mattress sutures to be placed around the ribs and secures the diaphragm into its normal anatomic position. In the presence of a flail segment of the ipsilateral chest wall, formal fixation of the ribs may be required to facilitate this complex repair of the diaphragm.[23] Prosthetic material for diaphragmatic reconstruction in the acute setting is rarely indicated, because tissue retraction and loss have not occurred and concomitant gastrointestinal injuries may lead to an increased rate of postoperative infection.

Massive diaphragmatic destruction such as that caused by thoracoabdominal shotgun injuries merits special mention. Bender and Lucas[44] described the immediate reconstruction of the chest wall following this type of injury by first detaching the affected hemidiaphragm anteriorly, laterally, and posteriorly. The diaphragm was then translocated to a position above the full-thickness chest wall defect, which converted the defect functionally into an abdominal wall defect. This is performed by suturing the ribs at a higher intercostal space, while the abdominal wall defect is managed with local wound care in anticipation of reconstruction with either split-thickness skin grafts or myocutaneous flaps at a later date.

REPAIR OF CHRONIC DIAPHRAGMATIC INJURIES

Patients who initially sustain small, undetected diaphragmatic lacerations may remain asymptomatic or may experience a progressive increase in visceral herniation of the omentum or of a hollow viscus.[45,46] The diaphragm as a muscle is quick to retract and atrophy. Therefore, tissue that could be approximated easily early after injury retracts in the latent or obstructive phase to the point where approximation is impossible at a late reoperation.

Chronic diaphragmatic hernias can be repaired either transabdominally or transthoracically, with the choice generally determined by the surgeon's preference.[47,48] The classical teaching, however, is that large chronic posttraumatic diaphragmatic hernias should be approached using a thoracotomy to allow for lysis of intrathoracic adhesions. On occasion, a combined approach may be indicated to complete the procedure safely and effectively. The transthoracic approach offers several benefits including the direct visualization of intrathoracic adhesions, which may extend all the way to the apex of the pleural cavity, and avoidance of abdominal adhesions from the prior trauma.[27,49-51] The thoracic approach has been performed successfully using both open and thoracoscopic techniques.[52-54] The open procedure is generally performed through the seventh or eighth intercostal space using a posterolateral approach. On rare occasions, an extension along the costal arch into a thoracoabdominal incision may be needed to allow access to the abdominal cavity.

As noted earlier, the transabdominal approach is often considered less attractive due to the inherent difficulty of visualizing adhesions to the lung and other intrathoracic structures and dealing with potential dense intra-abdominal adhesions from prior trauma and/or surgery. Additionally, if the procedure cannot be completed at laparotomy, the incision will need to be closed and the patient repositioned for a posterolateral thoracotomy. This is because it is difficult to visualize the posterior diaphragm from an anterolateral approach. Laparoscopy has been described for the reduction of chronic diaphragmatic hernias as well, although problems with an iatrogenic pneumothorax have mandated insertion of a thoracostomy tube.[27,55-58] No matter which approach is used, current recommendations support the role of open surgery for patients with defects greater than 10 cm and for those whose hernia extends to or through the esophageal hiatus.[39]

Careful dissection is required to free the entire diaphragm from its adhesions to surrounding tissues. Once mobilized, the edges should be brought together to evaluate for tension. If the edges can be approximated easily, the repair should be performed primarily as described in the section on acute diaphragmatic injuries. Generally, defects up to 8 cm can be closed primarily.[59] Primary repair of larger defects in the diaphragm will cause unacceptable flattening of the diaphragm, and prosthetic material will be needed to reconstruct the diaphragm. Many different prostheses have been used, including Mersilene, polytetrafluoroethylene (PTFE), polypropylene, and polydioxanone meshes.[50,55,60-63] Recently, a 2-mm-thick PTFE patch has been advocated as an excellent material for reconstructing the diaphragm because it provides the necessary strength and is watertight.[59] Generally, the patch is sutured using a running 0 nonabsorbable suture around the edges of the defect, often starting medially (Fig. 32-9). The patch must be tailored to minimize laxity in the diaphragm. Full-thickness bites in the diaphragm are necessary, with care taken to avoid injury to underlying structures. Other alternatives to synthetic mesh include a bovine pericardial patch, which in case series has proven to be an effective alternative to prosthetic materials.[64]

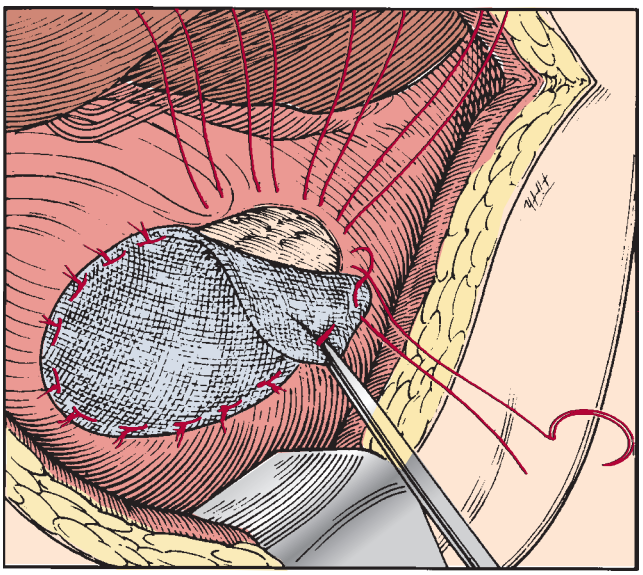

FIGURE 32-9 Technique for repair of the diaphragm using a prosthetic. (Reproduced with permission from Juan A. Asensio, MD, FACS, FCCM, and Demetrios Demetriades, MD, PhD, FACS.)

For injuries extending laterally to the chest wall without adequate tissue for fixation, the prosthetic can be secured with interrupted sutures placed around the ribs, following the natural course of the native diaphragm. Medially, the mesh can be secured either to pericardium or to the posterior crus if inadequate native diaphragmatic tissue exists.[59] In contaminated fields, autologous tissue may be used instead of PTFE to reconstruct large diaphragmatic defects. Latissimus dorsi, rectus abdominis, external oblique, and transversus abdominis flaps have been described, mainly in pediatric populations.[65-69] The benefit of autologous tissue in the pediatric population is that it allows for growth of the child. A surgical algorithm to approach diaphragmatic injuries is presented in Fig. 32-10.

OUTCOMES

Mortality following diaphragmatic injury is dependent on the severity of the associated injuries.[20] Mortality rates vary between 4% and 9% in penetrating injuries and 15% and 24% after blunt diaphragm injuries.[19,20] Recurrence rates of diaphragmatic hernias following repair are difficult to ascertain; however, it appears that the recurrence rate is higher when absorbable suture is used for the initial repair.[25]

Postoperative morbidity directly related to the acute surgical repair includes suture line dehiscence or failure of the diaphragmatic repair, paralysis of the hemidiaphragm secondary to an iatrogenic injury to the phrenic nerve, respiratory insufficiency, empyema, and subphrenic abscess. The complication rate after repair of a diaphragmatic injury has ranged from 30% to 68%.[70,71] Atelectasis has been documented in 11% to 68% of patients, with pneumonia and pleural effusions reported in another 10% to 23%. Sepsis, multiorgan system failure, hepatic abscess, and empyema have been reported in 2% to 10% of patients.[70,71]

When complication rates were compared in blunt versus penetrating injuries of the diaphragm in one review, patients with blunt trauma had a 60% complication rate versus a 40% complication rate in those with penetrating trauma.[72] Most of the morbidity reported in these studies is clearly the result of the large number of associated injuries present in association with diaphragmatic injuries.[70,72] Mortality following repair of a chronic diaphragmatic hernia depends entirely on the presence or absence of obstructive symptoms at the time of presentation. A mortality of less than 10% is expected in patients with asymptomatic diaphragmatic hernias, and this is related to the patient's comorbidities and not to the repair.[26,73] Patients presenting with gastrointestinal obstruction have a significantly higher morbidity (>60%) and mortality (25%–80%). This reinforces the need to pursue the diagnosis and surgical

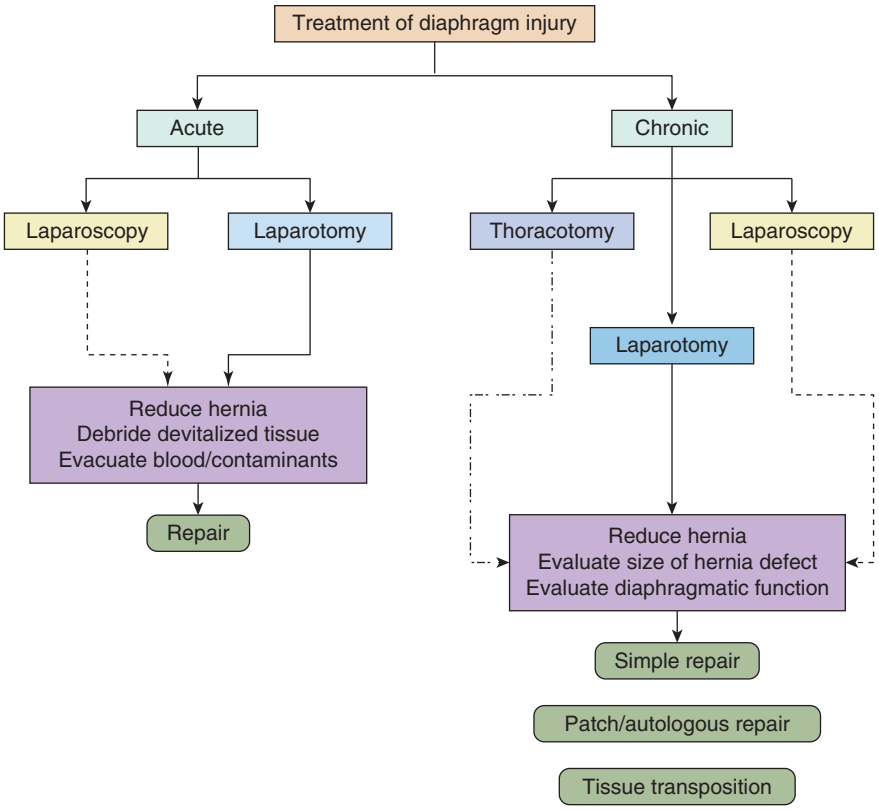

FIGURE 32-10 Algorithm for repair of an acute or chronic diaphragmatic defect.

management of diaphragmatic injuries prior to the onset of obstructive symptoms with chronic hernias.

PERICARDIODIAPHRAGMATIC RUPTURE

Blunt ruptures of the central tendon of the diaphragm involving the pericardium are rare and may present as acute injuries or as chronic hernias following missed injuries. Most are caused by combined blunt trauma to the chest and abdomen; however, isolated trauma to either one of the cavities can also cause this entity. Simultaneous rupture of the pericardium into the left and the right pleural spaces has also been described, as has herniation of the heart inferiorly into the peritoneal cavity.[74] There is a high incidence of associated injuries including musculoskeletal injuries that occur predominantly on the left side of the body. The organs most frequently involved in pericardial herniation are the transverse colon, stomach, omentum, liver, and small bowel. Exploratory laparotomy is recommended as the preferred approach for the acute repair of these injuries.[74]

CONCLUSION

Diaphragmatic injuries may be associated with other severe life-threatening injuries as after blunt trauma or may be subtle in their presentation in following penetrating trauma. In either situation, a high index of suspicion is necessary to make the diagnosis. As modern imaging techniques improve, diagnostic accuracy similarly improves but can still miss injuries, thus the reliance on diagnostic laparoscopy in patients with a high suspicion for injury. Once the diagnosis is made, repair in the acute phase can usually be accomplished using the surgical techniques described. In the latent or obstructive phases of presentation, repair or reconstruction of the diaphragm can be a surgical challenge. If gastrointestinal obstruction, perforation, or ischemia occurs with a chronic posttraumatic diaphragmatic hernia, postoperative morbidity and mortality are significant.

Liver and Biliary Tract

Brandon Bruns • Rosemary Kozar

KEY POINTS

- Sixty to ninety percent of hepatic injuries are treated nonoperatively.
- A contrast-enhanced computed tomography scan documenting extravasation in the liver may require angioembolization or operation.
- Organ Injury Scale grade I or II hepatic injuries do not require drains at laparotomy; for higher grade injuries with evidence of biliary leak at laparotomy, drainage should be considered.
- Partial disruption of hepatic segments II/III or VI/VII are managed with resectional debridement at the time of laparotomy.
- Perihepatic packing is useful in selected patients with intraoperative coagulopathies or ongoing bleeding.

INTRODUCTION

Due to its large size, the liver is one of the most commonly injured organs after trauma.[1] The size of the organ and its position under the right costal margin make the liver susceptible to both blunt and penetrating trauma to the right thoracoabdomen and right upper quadrant of the abdomen. The management of hepatic injuries continues to evolve with improved modes of diagnosis and nonoperative and operative management. The most severe hepatic parenchymal and retrohepatic venous injuries, as well as those involving the portal triad, continue to have a high mortality; therefore, despite progress, the opportunity for further improvements in management exists.

ANATOMY (SEE ATLAS FIGURE 41)

A comprehensive knowledge of hepatic anatomy is essential to the proper treatment of trauma to the liver. An understanding of the ligamentous attachments, parenchyma, and intraparenchymal and extraparenchymal vascularity of the liver is key to the effective application of methods for control and repair of hepatic injuries (Fig. 33-1).

Lobes

The liver is divided into two lobes by a 75° angle line traversing from the gallbladder fossa inferiorly to the left side of the inferior vena cava superiorly. The left lobe includes the hepatic tissue to the left of the falciform ligament along with the quadrate and caudate lobes, whereas the right lobe consists of the remaining parenchyma.

Functional Anatomy (See Atlas Figure 42)

The functional anatomy of the liver separates the liver into segments pertinent to resection. Couinaud provided the basis of modern resection planes by dividing the liver into eight segments (I–VIII) based on the distribution of the portal vein (horizontal plane) and hepatic veins (vertical planes).[2] The horizontal plane divides the sections of the liver into superior and inferior segments, as follows:

- Right anterior (or medial) section: Segment V below the portal plane and segment VIII above
- Right posterior or lateral section: Segment VI below the portal plane and segment VII above
- Left medial section: Segment IVb below the portal plane and segment IVa above
- Left lateral section: Segment III below the portal plane and segment II above

The right hepatic vein traverses between the right posterolateral (segments VI and VII) and right anteromedial (segments V and VIII) segments. On the left, the left hepatic vein delineates the anterior (segments III and IV) and posterior

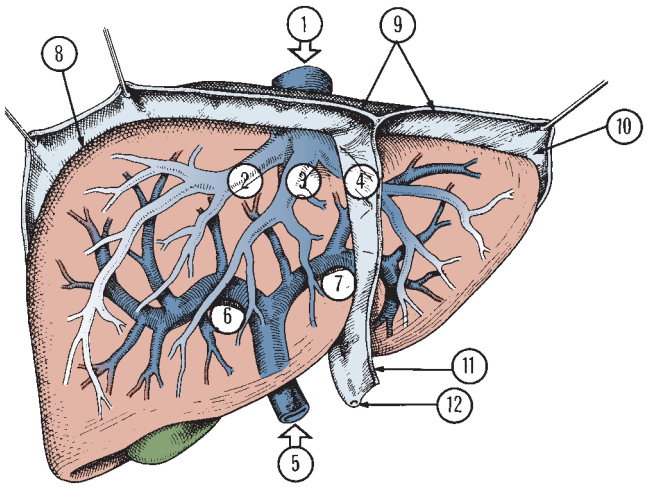

FIGURE 33-1 Surgical anatomy of the liver: (1) inferior vena cava; (2) right hepatic vein; (3) middle hepatic vein; (4) left hepatic vein; (5) portal vein; (6) right branch portal vein; (7) left branch portal vein; (8) right triangular ligament; (9) coronary ligament; (10) left triangular ligament; (11) falciform ligament; (12) ligamentum teres.

(segment II) segments. The caudate lobe (segment I) drains directly into the inferior vena cava (Fig. 33-2).

Common Hepatic Artery

The common hepatic artery is one of the three main branches of the celiac axis in the visceral portion of the abdominal aorta. It becomes the proper hepatic artery beyond the gastroduodenal artery and is found in the porta hepatis, typically to the left of the common bile duct and anterior to the portal vein. Transversely incising the peritoneum overlying the hepatoduodenal ligament exposes the proper hepatic artery, a maneuver facilitated by mobilization of the hepatic flexure

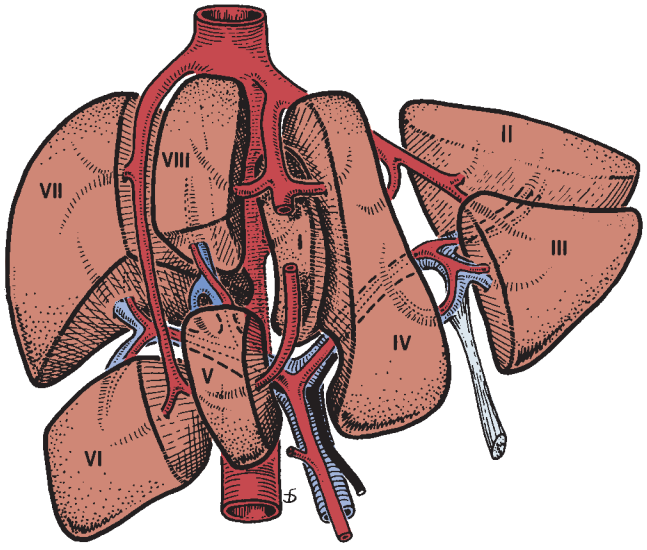

FIGURE 33-2 Functional division of the liver, according to Couinaud's nomenclature. (Reproduced with permission from Blumgart LH, ed. *Surgery of the Liver and Biliary Tract.* New York, NY: Churchill Livingstone; 1988. © Elsevier.)

of the colon toward the midline. At the hilum of the liver, the proper hepatic artery bifurcates into a right (the longer branch) and a left branch. These furnish approximately 25% to 30% of all hepatic blood flow (overall, 1.5 L/min) and 50% of hepatic oxygenation.

There are a number of anatomic variants. The most frequent (11%) is the aberrant origin of the right hepatic artery from the superior mesenteric artery traversing behind the duodenum. Other variants include a left hepatic artery origin from the left gastric artery (8%) and the left and right hepatic arteries arising from the superior mesenteric artery (9%). Given these multiple variants, great care is taken when controlling traumatic hemorrhage in this region.

Hepatic Veins

The hepatic veins develop from the hepatocytes' central lobar veins. The superior, middle, and inferior vein branches originating from the right lobe form the right hepatic vein. The two veins arising from segments IV and V combine to form the middle hepatic vein, frequently including a branch from the posterior portion of segment VIII. In 90% of patients, the middle hepatic vein joins the left hepatic vein just before draining into the inferior vena cava. The left hepatic vein is more variable in its segmental origin. Most important is the posterior positioning of the left hepatic vein when dissecting the left coronary ligament, so care must be taken in this area to avoid inadvertent injury. The liver must be fully mobilized for visualization of the hepatic veins, which are notoriously fragile and can be easily torn. The retrohepatic vena cava is about 8 to 10 cm in length and receives the blood of the hepatic veins in addition to multiple small direct hepatic vessels.

Portal Vein

The portal vein is formed from the confluence of the splenic and superior mesenteric veins directly behind the head of the pancreas. It provides about 75% of hepatic blood flow and 50% of hepatic oxygen. The portal vein lies posterior to the hepatic artery and common bile duct as it ascends toward the liver. At the parenchyma, the portal vein divides into a short right and a longer left extrahepatic branch. Surgically, the portal vein can be approached by division of the pancreas at its neck or with a generous Kocher maneuver of the duodenum toward the midline.

Ligaments

When operating on the liver, it is crucial to understand the orientation of its ligamentous attachments. The coronary ligaments attach the diaphragm to the superior parietal surface of the liver. The triangular ligaments are at the lateral extensions of the right and left coronary ligaments. The falciform ligament, with the underlying ligamentum teres, attaches to the anterior peritoneal cavity. The medial portion of the coronary ligaments is where the hepatic veins traverse; therefore,

TABLE 33-1: Liver Injury Scale (2018 Revision)

AAST grade	AIS severity	Imaging criteria (CT findings)	Operative criteria	Pathologic criteria
I	1	• Subcapsular hematoma <10% surface area • Parenchymal laceration <1 cm in depth	• Subcapsular hematoma <10% surface area • Parenchymal laceration <1 cm in depth • Capsular tear	• Subcapsular hematoma <10% surface area • Parenchymal laceration <1 cm • Capsular tear
II	2	• Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <10 cm in diameter • Laceration 1–3 cm in depth and ≤10 cm length	• Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <10 cm in diameter • Laceration 1–3 cm in depth and ≤10 cm length	• Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <10 cm in diameter • Laceration 1–3 cm depth and ≤10 cm length
III	3	• Subcapsular hematoma >50% surface area; ruptured subcapsular or parenchymal hematoma • Intraparenchymal hematoma >10 cm • Laceration >3 cm in depth • Any injury in the presence of a liver vascular injury or active bleeding contained within liver parenchyma	• Subcapsular hematoma >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma • Intraparenchymal hematoma >10 cm • Laceration >3 cm in depth	• Subcapsular hematoma >50% surface area; ruptured subcapsular or intraparenchymal hematoma • Intraparenchymal hematoma >10 cm • Laceration >3 cm in depth
IV	4	• Parenchymal disruption involving 25%–75% of a hepatic lobe • Active bleeding extending beyond the liver parenchyma into the peritoneum	• Parenchymal disruption involving 25%–75% of a hepatic lobe • Intraparenchymal hematoma	• Parenchymal disruption involving 25%–75% of a hepatic lobe
V	5	• Parenchymal disruption >75% of hepatic lobe • Juxtahepatic venous injury to include retrohepatic vena cava and central major hepatic veins	• Parenchymal disruption >75% of hepatic lobe • Juxtahepatic venous injury to include retrohepatic vena cava and central major hepatic veins	• Parenchymal disruption >75% of hepatic lobe • Juxtahepatic venous injury to include retrohepatic vena cava and central major hepatic veins

- Vascular injury is defined as a pseudoaneurysm or arteriovenous fistula and appears as a focal collection of vascular contrast that decreases in attenuation with delayed imaging. Active bleeding from a vascular injury presents as vascular contrast, focal or diffuse, that increases in size or attenuation in delayed phase. Vascular thrombosis can lead to organ infarction.
- Grade based on highest grade assessment made on imaging, at operation, or on pathologic specimen.
- More than one grade of liver injury may be present and should be classified by the higher grade of injury.
- Advance one grade for multiple injuries up to a grade III.

dissection in this area is done cautiously. In order to effectively visualize the liver during operative therapy, these ligaments must be divided and the liver fully mobilized into the field of view.

ORGAN INJURY SCALE

The American Association for the Surgery of Trauma recently revised the Organ Injury Scale for the liver.[3] The new scale includes the following three sets of criteria to assign grade: imaging, operative, and pathologic. For the first time, the scale incorporates findings from computed tomography (CT) scans (Table 33-1). Additionally, vascular injuries, defined as pseudoaneurysms or arteriovenous fistulae, are included. This classification provides for uniform comparisons of hepatic injuries managed both operatively and nonoperatively. An example of a grade IV hepatic laceration with involvement of 25% to 75% of a hepatic lobe is shown in Fig. 33-3.

INITIAL MANAGEMENT

Care for the patient with a possible hepatic injury should proceed by the tenets of Advanced Trauma Life Support (ATLS). After performing a primary survey, the search for ongoing hemorrhage ensues. Given its size, the liver is a likely source of active bleeding in the hypotensive patient after truncal trauma. Resuscitation strategies continue to focus on early transfusion of blood products and the establishment of a ratio of packed red cells to plasma to platelets that is more similar to whole blood and is reliant on a viscoelastic assay.

Plain radiographs and surgeon-performed ultrasound obtained in the trauma resuscitation unit may give clues

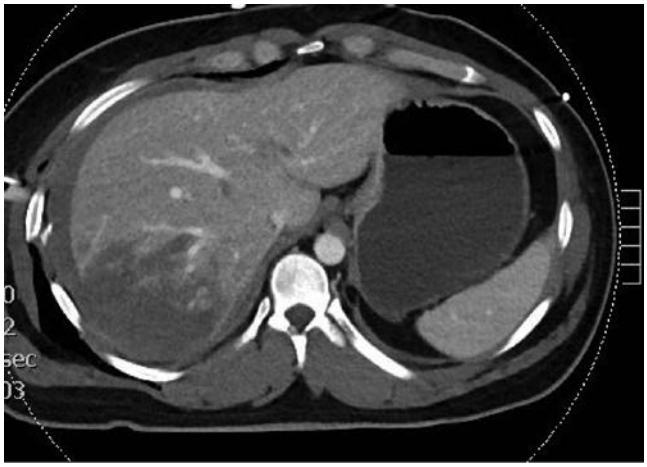

FIGURE 33-3 Computed tomography showing a grade IV liver laceration in a patient sustaining blunt injury to the right thoracoabdominal region.

to a possible hepatic injury. The presence of right-sided rib fractures and/or a hemothorax on chest radiograph or hemoperitoneum on ultrasound may raise suspicion. Although nonoperative management of hepatic injuries has become routine, a patient exhibiting clear-cut peritoneal signs and/or hemodynamic instability likely requires operative exploration. Often overlooked is the detrimental effect that hypothermia can have on coagulation, particularly for the patient with a significant hepatic injury. Type and crossmatch and measurement of hemoglobin levels, coagulation parameters, and a viscoelastic assay (thromboelastography/rotational thromboelastometry) should all be performed early in the resuscitation and repeated as necessary.

DIAGNOSIS OF HEPATIC INJURY

Hemodynamically Unstable Patient

If after the primary survey and initial resuscitation the patient remains hemodynamically unstable, determining the possible causes of the continued shock state is necessary. This can be difficult in patients with injuries involving multiple organ systems, but the correct body cavity that harbors the ongoing hemorrhage must be identified and treated. An intra-abdominal injury can be an obvious cause of instability, especially if the physical exam reveals peritoneal signs or a penetrating injury or if fluid is noted on the focused abdominal sonography for trauma (FAST). Similarly, chest and pelvic x-rays are mandatory to ensure the ongoing blood loss is not from a hemothorax or a rapidly expanding pelvic hematoma.

Focused Abdominal Sonography for Trauma

The FAST exam is the primary modality for the determination of hemoperitoneum in the unstable patient. Richards et al[4] reported a 98% sensitivity of ultrasound for hemoperitoneum in grades III and higher hepatic injury; however, they were not able to identify the anatomic location of the hepatic parenchymal injury in 67% of these severely damaged livers. A multi-institutional study by Rozycki et al[5] concluded that the right upper quadrant is the most common site where a hemoperitoneum accumulates in blunt abdominal trauma. Diagnostic peritoneal aspirate is also a method for determining the presence of intraperitoneal blood, although it has been largely replaced by ultrasound for the diagnosis of hemoperitoneum.

Hemodynamically Normal Patient

The FAST examination has proven to be a very good diagnostic tool in the diagnosis of hemoperitoneum in the blunt trauma patient, but a negative FAST does not preclude the presence of a hepatic injury.[6]

Since the first use of CT to diagnose intra-abdominal injuries in the early 1980s, it has become a routine part of the management of trauma patients.[7,8] In recent years, the availability of the helical CT scan has improved resolution and speed of scanning. Being able to grade the extent of visceral injury and to follow the evolution of an existing injury can determine if nonoperative management is possible and successful. A contrast-enhanced helical CT scan provides information on injury grade, amount of hemoperitoneum, active extravasation of contrast (Fig. 33-4), and the presence of vascular injuries.

Additionally, triple-contrast CT has long been used in penetrating wounds to the back and flank with excellent sensitivity; however, the sensitivity for injuries to the diaphragm and small bowel is less.[9] Because of the risk of hollow viscus injury, minor hepatic lacerations can be evaluated and nonoperatively managed with CT guidance, but continued frequent abdominal exams must also be performed.

Laparoscopy has been successfully used to diagnose peritoneal penetration in penetrating trauma, thus saving the patient from a nontherapeutic exploratory laparotomy.[10] Repair of a hepatic injury found at laparoscopy has been reported in hemodynamically stable patients as well.[11]

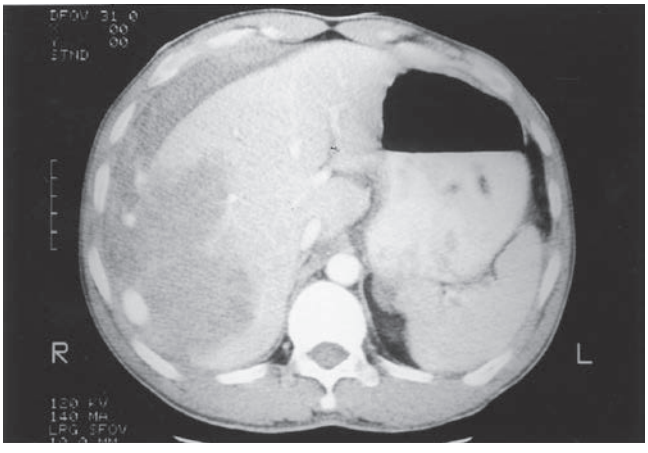

FIGURE 33-4 Computed tomography scan demonstrating a "contrast blush," indicative of active arterial bleeding in a patient with a grade IV blunt hepatic injury.

MANAGEMENT OF HEPATIC TRAUMA

Blunt hepatic injury traverses almost exclusively along the lines dividing the segments of the liver. This most likely occurs due to the strength of the fibrous covering around the portal triad preventing injury from transecting these structures. The hepatic veins do not have a similar fibrous structure and, therefore, are the primary vascular structures injured in blunt trauma. On the other hand, penetrating trauma involves both venous and arterial injury with direct transection of any structure in the trajectory. These anatomic principles are key to understanding the rationale for making decisions in the management of liver trauma.

Hemodynamically Normal Patient with Blunt Injury

The Western Trauma Association has recently proposed an algorithm for the management of nonoperative blunt hepatic trauma (Fig. 33-5).[12] As noted earlier, most blunt hepatic trauma causes venous injuries that are low pressure (3–5 cm H_2O); therefore, hemorrhage usually stops once a clot forms on the area of disruption. Such an injury can be managed nonoperatively, which leads to lower transfusion requirements, decreased abdominal infections, and decreased hospital lengths of stay. Hurtuk et al[13] found no effect on mortality after solid organ injury with increased use of nonoperative management. With grade III and IV hepatic injuries, Coimbra et al[14] documented a reduced mortality with nonoperative management. Richardson[15] has recommended that hemodynamically stable patients who have received less than 4 units of blood can be safely managed nonoperatively. Unlike the spleen, which can be easily removed, liver-related bleeding can be made worse by operative intervention.[16]

A study by Tinkoff et al[17] showed that the need for operative intervention increases with grade of hepatic injury, but grade alone is not an indication for operation. These data from the National Trauma Data Bank demonstrated that 73% of grade IV and 63% of grade V liver injuries could be successfully managed nonoperatively.[17] A more recent retrospective study by the research consortium of New England Centers for Trauma examined nonoperative management of only grade IV and V injuries and reported an 8.8% failure rate for nonoperative management. Risk factors for failure were a presenting systolic blood pressure of less than 100 mm Hg and the presence of associated abdominal injuries.[18] Importantly, they

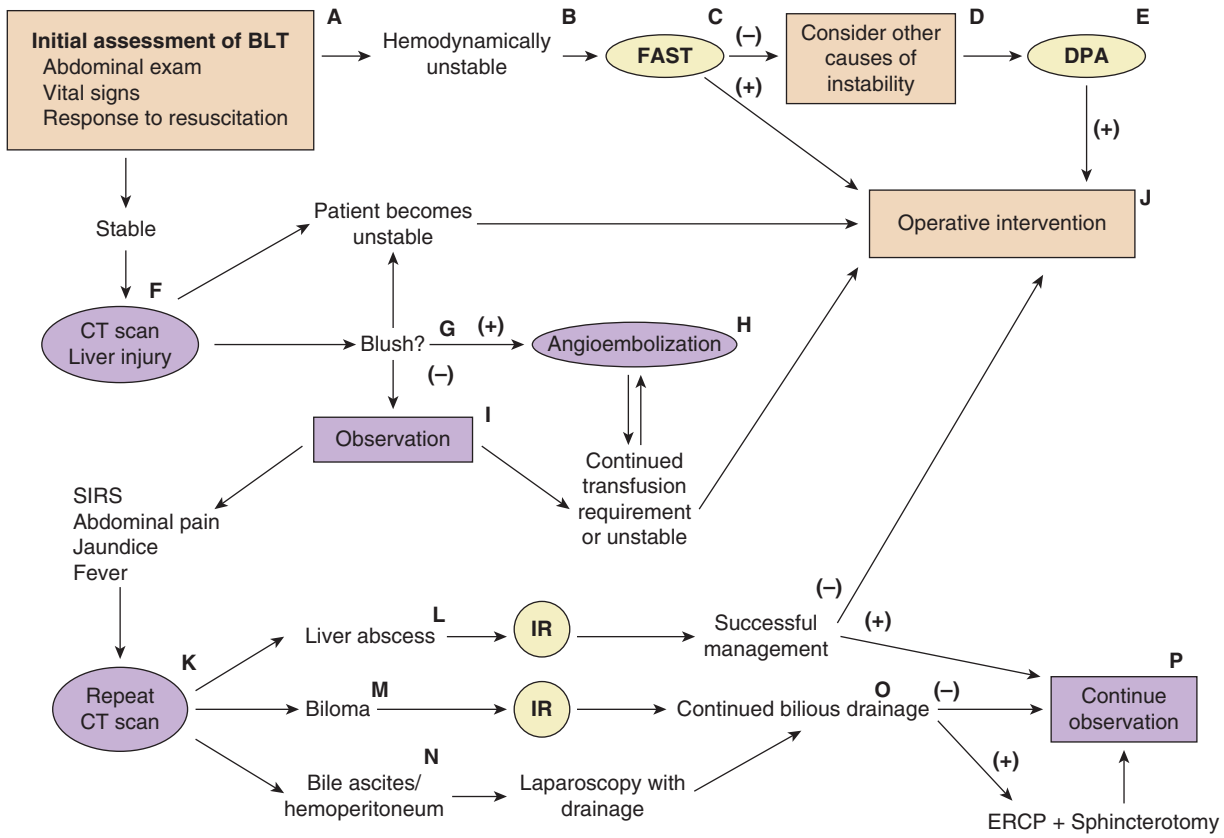

FIGURE 33-5 Western Trauma Association algorithm for nonoperative management of adult blunt hepatic trauma. BLT, blunt liver trauma; CT, computed tomography; DPA, diagnostic peritoneal aspirate; ERCP, endoscopic retrograde cholangiopancreatography; FAST, focused abdominal sonogram for trauma; IR, interventional radiology; SIRS, systemic inflammatory response syndrome. Western Trauma Association critical decisions in trauma: nonoperative management of adult blunt hepatic trauma. *J Trauma.* 2009;67(6):1144.)

found no increase in mortality in patients who failed initial nonoperative management.

In contrast, Polanco et al[19] used the National Trauma Data Bank data to examine patients with liver Abbreviated Injury Scale scores of 4 or higher and asked the question, "Has the pendulum swung too far?" In this study, there was a rather alarming trend in the percentage of hypotensive patients who underwent attempted nonoperative management.[19] Although only 7% of the patients failed, those patients had a statistically significant increase in mortality. Age, sex, Injury Severity Score, Glasgow Coma Scale, and hypotension were predictors of unsuccessful nonoperative management. An additional factor to consider in review of nonoperative management of high-grade hepatic injuries is the type of resuscitation strategy that was implemented. As shown by Shrestha et al,[20] damage control resuscitation strategies increased successful nonoperative management and decreased mortality in a retrospective review of over 200 patients with grade IV and V hepatic injuries who received blood products. In addition to more nonoperative management of hepatic injuries, there was no increase in liver-related complications.

The extent of hemoperitoneum and the presence of contrast extravasation and/or a pseudoaneurysm are not contraindications for nonoperative management; however, patients with these entities are at higher risk for failure. A patient with a CT finding of a contrast blush or extravasation (active hemorrhage) may benefit from catheter-directed intravascular angioembolization. Misselbeck et al[21] reviewed their 8-year experience with hepatic angioembolization and found that hemodynamically stable patients with contrast extravasation on a CT scan were 20 times more likely to require embolization than those without extravasation. Sivrikoz et al[22] have shown that angiography in severe blunt hepatic injury is associated with improved survival in both operatively and nonoperatively managed patients; however, patients managed with angiography did have more complications. Finally, Letoublon et al[23] employed angioembolization for either contrast extravasation seen on a CT scan in hemodynamically stable patients or as an adjunctive technique to control arterial bleeding despite laparotomy. They report a complication rate of 70% in their retrospective review.[23]

Complications of Nonoperative Management of Blunt Hepatic Injury

Most patients undergoing nonoperative management of blunt hepatic injuries heal without complication.[24] In a retrospective multi-institutional study of 553 patients with grade III to V hepatic injury, 12.6% developed hepatic complications. Significant coagulopathy and grade V injury were found to be predictors of a complication.[25]

BILE LEAKS

Bilomas from a bile leak have occurred in 3% to 36% of patients managed nonoperatively.[26] Either a hepatobiliary hydroxyl-iminodiacetic acid (HIDA) radioisotope scan or magnetic resonance cholangiopancreatography has been used to localize bile leaks.[27] Hyperbilirubinemia, abdominal distention, and intolerance to feeding may all indicate a bile leak. Percutaneous drainage directed by ultrasound or CT is the primary treatment used for symptomatic biliary leaks.

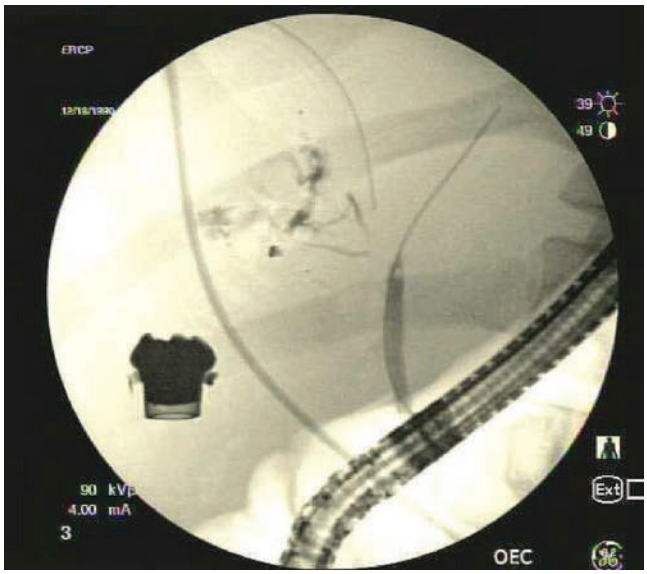

FIGURE 33-6 Endoscopic retrograde cholangiogram demonstrating leak and placement of stent with large bullet fragment visible.

The majority of bile leaks, however, occur after operative management. Anand et al[28] found that 8% of high-grade hepatic injuries managed nonoperatively developed a bile leak. For patients presenting with bile peritonitis and/or with large leaks not responsive to percutaneous drainage alone, the addition of endoscopic retrograde cholangiography (ERC) (Fig. 33-6) with sphincterotomy and biliary stent placement can be effective. Griffen et al[29] have reported success with a combined laparoscopic and ERC approach. They described patients with biliary ascites taken to the operating room for laparoscopic bile drainage and drain placement near the site of injury with postoperative ERC and bile duct stenting. They reported no septic complications and healing of the substantial biliary leaks.[29] In their prospective observational study, Hommes et al[30] classified bile leaks as minor or major, with major defined as greater than 400 mL/d or leaks lasting greater than 14 days. Patients with major leaks underwent ERC and stenting, whereas minor bile leaks nearly always resolved without ERC or other decompressive maneuvers.[30]

PERIHEPATIC ABSCESS

Although rare after nonoperative management, a patient with a perihepatic abscess may exhibit signs of sepsis, abnormal liver function tests, abdominal pain, or food intolerance (Fig. 33-7). Similar to biliary collections, an abscess can often be managed by CT-guided drainage catheters; however, if the patient fails to improve with drainage and antibiotics, wide surgical drainage should be performed. Operative therapy may involve merely incision and adequate drainage of the cavity, or it may involve extensive debridement of necrotic hepatic parenchyma.

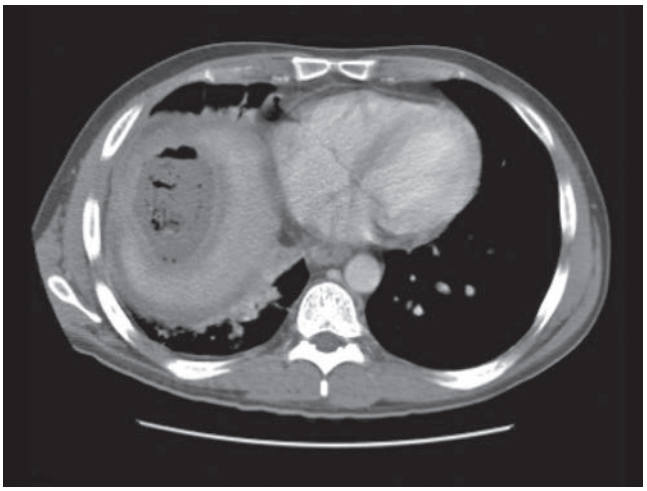

FIGURE 33-7 Computed tomography scan demonstrating a hepatic abscess from a patient who had sustained a blunt hepatic injury.

HEMORRHAGE

Delayed hemorrhage after nonoperative management is rare. Kozar et al[25] reported a 13% overall incidence of liver-related complications in patients managed nonoperatively after grade III to V injuries, with bleeding accounting for 8% of the complications. Bleeding occurred almost equally between early (<24 hours) and late (>24 hours) time periods after injury. Late bleeds occurred only in patients with grade IV and V injuries, the majority of which were managed with angioembolization.[25]

DEVASCULARIZATION AND HEPATIC NECROSIS

Disruption of vascular inflow to a hepatic segment following trauma or after angioembolization can lead to ischemia and subsequent necrosis of that segment of the liver. The consequences of necrosis may include elevation of liver transaminases, coagulopathy, bile leaks, abdominal pain, feeding intolerance, respiratory compromise, renal failure, and sepsis. Devascularization can be differentiated from intraparenchymal hemorrhage when follow-up CT scans reveal segments of liver that remain hypoperfused or have foci of air within the devascularized area.[31]

HEMOBILIA

Hemobilia can occur after blunt hepatic injury when abnormal connections between the vasculature and biliary tree form. The classic triad of right upper quadrant pain, jaundice, and upper gastrointestinal bleeding is present in most, but not all, trauma patients with hemobilia.[32] Selective arterial embolization is the initial treatment of choice with a substantial rate of success and a low incidence of serious complications.[33]

SYSTEMIC INFLAMMATORY RESPONSE

Patients with inadequately drained bile collections or hematomas may be susceptible to the development of the systemic inflammatory response syndrome. Franklin et al[34] and Letoublon et al[35] have recommended laparoscopic evacuation of undrained bile or hemoperitoneum at postinjury days 3 to 5. Early evacuation of these collections can markedly decrease this inflammatory response.

UNUSUAL COMPLICATIONS

A subcapsular hematoma may increase hepatic intraparenchymal pressure high enough to cause segmental portal hypertension and hepatofugal flow. This "compartment syndrome of the liver" was described in a patient managed nonoperatively who had a decreasing hematocrit and abnormal liver function tests. These findings prompted an angiographic examination documenting hepatofugal flow in the right portal vein. After operative drainage of the tense hematoma, the patient did well with return of hepatopetal flow and viability of the right lobe.[36] This type of compressive complication has also caused Budd-Chiari syndrome when the hematoma led to compression of the inferior vena cava or hepatic veins.[37]

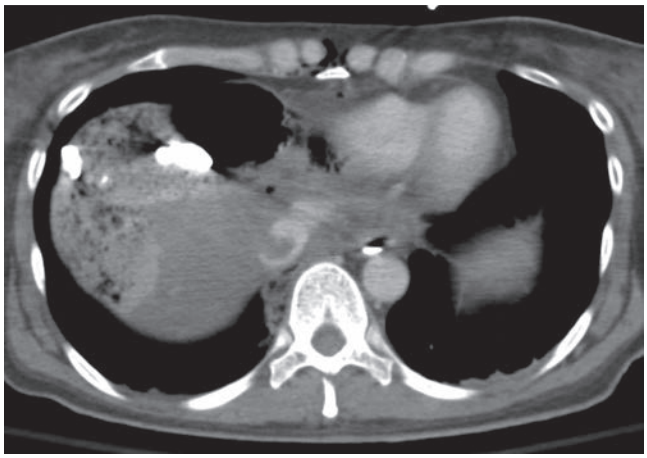
With the frequent use of CT scanning, previously unidentified complications of a hepatic injury may be seen. Fig. 33-8 shows a series of CT images of a patient who underwent operative control of parenchymal bleeding with packing followed immediately by CT scanning. Thrombosis of the retrohepatic vena cava was seen, with clot extending up to the right atrium. Approximately 24 hours after packs were removed, therapeutic anticoagulation was started.

Follow-Up CT Scanning After Blunt Hepatic Injury

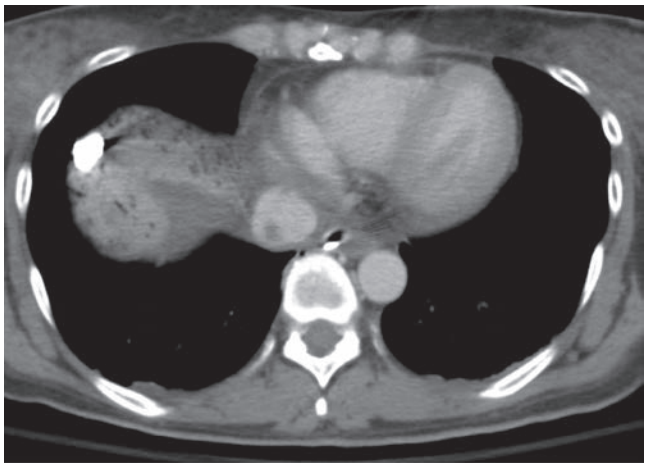
Definitive data on the value of follow-up CT scanning for blunt hepatic injury are not available. Some published reports suggest utility of postobservation CT scans for patients with more severe (grade III–V) injuries. Cuff et al[38] reported that of the 31 patients who had follow-up CT scans 3 to 8 days after injury, only three scans changed management. Additionally, the three scans that affected management were obtained due to a change in clinical picture and were not merely routine.[38] Cox et al[39] concluded from their follow-up of 530 patients, including 89 with grade IV or V injuries, that follow-up CT scans are not indicated as part of the nonoperative management of blunt hepatic injuries. Unfortunately, the time to onset of biliary complications can range from days to weeks, making a recommendation difficult.[12] Currently, follow-up CT scans are generally indicated only for patients who develop signs or symptoms suggestive of a hepatic abnormality.

Length of Observation, Prophylaxis for Venous Thromboembolism, and Resumption of Activity

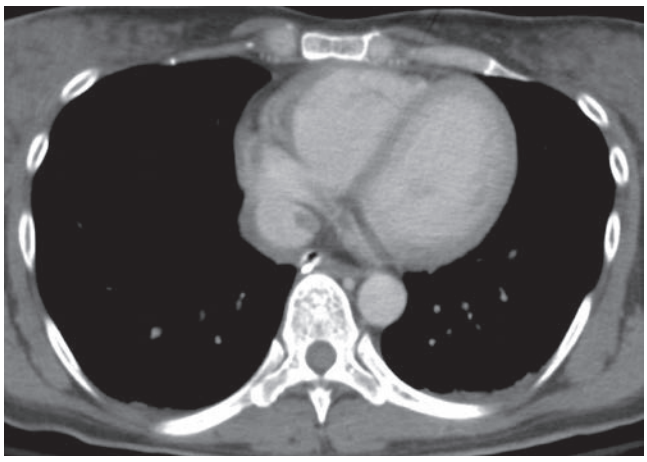
Bed rest and prolonged periods of in-hospital observation are no longer advocated after nonoperative management of hepatic trauma. In their retrospective study of 591 patients with blunt hepatic injuries, Parks et al[40] concluded that the



A



B



C

FIGURE 33-8 Computed tomography scans from a patient who underwent perihepatic packing then immediate postoperative scanning. Images reveal a retrohepatic caval thrombus that extends proximally to the atrial caval junction.

length of in-hospital observation should be based solely on clinical criteria. The authors recommended discharge of patients with a normal abdominal examination and stable hemoglobin.[40]

Although data are retrospective and studies are small, existing data suggest that early (defined as ≤48 hours) institution of chemical prophylaxis against thromboembolism is safe.[41,42] Resumption of normal activity also seems safe, but the period of time needed to refrain from high-risk activities such as contact sports remains unclear. Most hepatic injuries resolve by CT in 4 months, but whether this period of time is optimal is unknown. Dulchavsky et al[43] found, in animal studies, that hepatic wound burst strength at 3 weeks was as great or greater than uninjured hepatic parenchyma. This is most likely a result of fibrosis throughout the injured parenchyma and Glisson capsule. This study suggests that activity can be resumed about 1 month after injury, although human studies have not been performed.

Hemodynamically Normal Patient with Penetrating Injury

NONOPERATIVE MANAGEMENT OF PENETRATING INJURY

Peritoneal penetration had traditionally mandated operative exploration; however, selective nonoperative management of stab wounds is common.[44] Reports of successful nonoperative management of gunshot wounds (GSWs) to the liver have also been published. Renz and Feliciano[45] prospectively treated 13 patients with right thoracoabdominal GSWs nonoperatively. The rationale behind this management is that the wounds caused by small-caliber weapons may cause modest injury to diaphragm and liver only, sparing any hollow viscus injury. The authors stressed the importance of serial abdominal exams and contrast CT scanning in their successful nonoperative management of penetrating injury.[45] Other centers concur with this selective nonoperative management.[46,47] Demetriades et al[48] even reported successful nonoperative management of penetrating grade III to IV hepatic injuries that required angioembolization. The criteria for nonoperative management include the following: (1) patient is hemodynamically normal; (2) patient does not have peritoneal signs; and (3) patient is able to cooperate with serial abdominal examinations. Before nonoperative management is decided upon, the patient has a contrast-enhanced CT scan to rule out other abdominal visceral or vascular injury. As reported by Shanmuganathan et al,[49] triple-contrast CT of 86 abdominal GSWs had a sensitivity and specificity of 97% and 98%, respectively, in the detection of organ injury and peritoneal violation. Velmahos et al[50] used a single intravenous dose of contrast in lieu of triple contrast and reported a sensitivity and specificity of 90.5% and 96%, respectively, in diagnosing intra-abdominal organ injuries requiring surgical intervention.

Missed or deliberate nonrepair of small penetrating diaphragmatic injuries may lead to long-term adverse sequelae,

not only of diaphragmatic herniation, but also of possible biliopleural fistula.[51] Late intervention for other missed injury (eg, duodenal injury) may also lead to substantial morbidity.

Operative Management of Patients with Minor Hepatic Injury

The decision to operate on a patient with hepatic injury may be made due to a penetrating mechanism with secondary peritonitis, hemodynamic instability, or evidence of a concomitant organ injury. The incision of choice remains the midline incision from the xiphoid to the pubis with full surgical preparation and draping of the chest, abdomen, and thighs. On opening the peritoneal cavity, initial attention is on the rapid evacuation of old blood and halting ongoing hemorrhage. The peritoneal cavity is cleared of clot using hands or laparotomy pads. When a minor hepatic injury is present, bleeding is managed with packing and pressure applied to the injured area. While packs are in place, inspection of the remainder of the abdomen for other injuries is performed. Nonbleeding injuries should not be probed or otherwise manipulated, as this may cause dislodgement of clot. Small wounds of the hepatic parenchyma with minimal bleeding can be controlled with electrocautery, argon beam coagulation, or topical hemostatic agents. Small to moderate-sized bleeding cavities are first inspected for any obvious bleeding vessels that can be ligated. In 1975, Stone and Lamb[52] first described the technique of packing a tongue of vascularized omentum into the wound in an effort to stop venous bleeding. Wrapping a column of absorbable gelatin sponge with oxidized regenerated cellulose that can be plugged into deeper bleeding cavities is another option.

Operative Management of Patients with Major Liver Injury

In 2009, Lucas and Ledgerwood[53] reported that a surgical resident would perform a hemostatic technique on the liver only 1.2 times during his or her training. With the increasing utilization of nonoperative management, gaining and maintaining the necessary skills to control major hepatic bleeding is a challenge. The Western Trauma Association has published a useful algorithm for operative management of adult blunt hepatic trauma (Fig. 33-9).[54]

INITIAL MANAGEMENT

Once the peritoneum is entered in these patients, the natural tamponade provided by hemoperitoneum is released, and

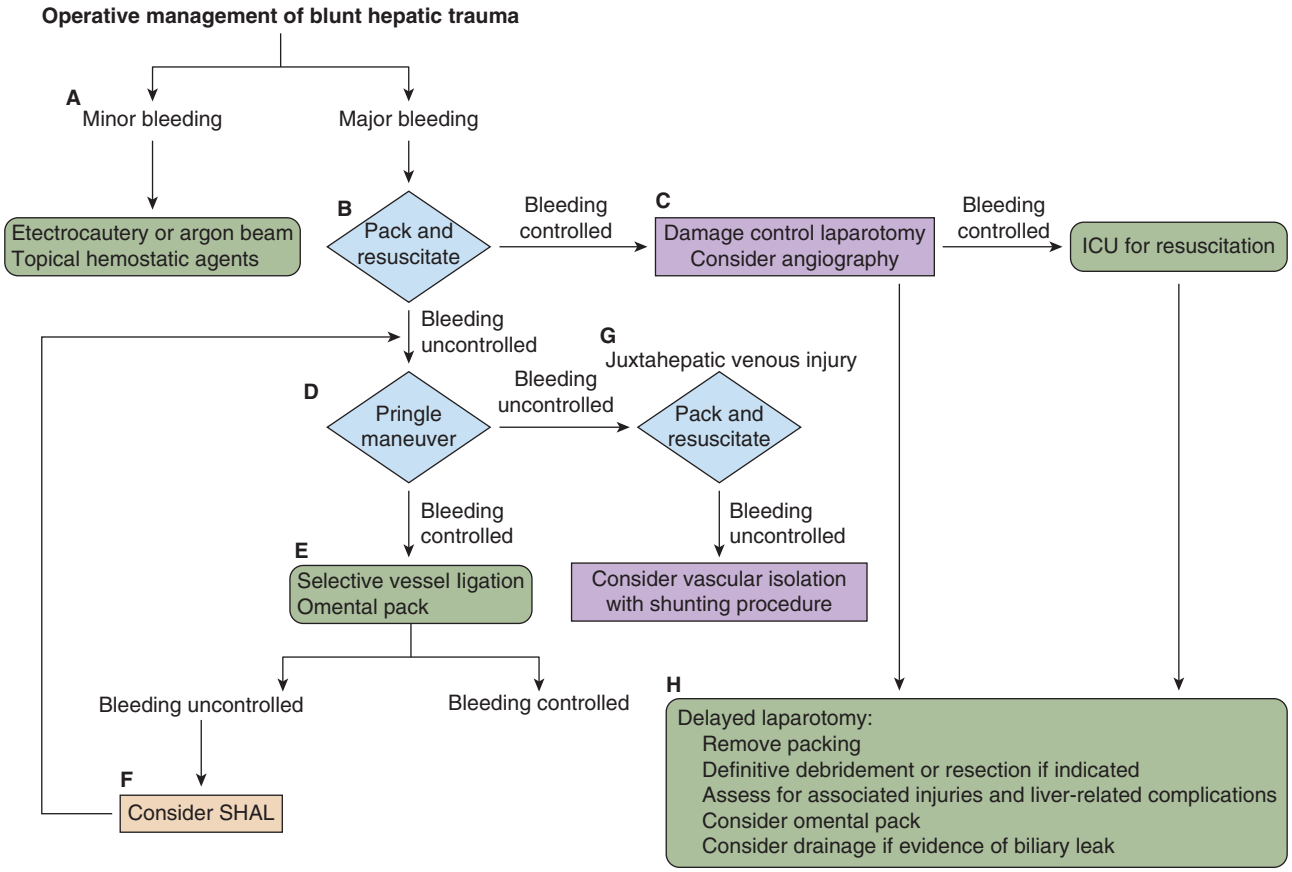


FIGURE 33-9 Western Trauma Association algorithm for operative management of adult blunt hepatic trauma. ICU, intensive care unit; SHAL, selective hepatic arterial ligation. (Reproduced with permission from Kozar RA, Feliciano DV, Moore EE, et al. Western Trauma Association critical decisions in trauma: operative management of adult hepatic trauma. *J Trauma*. 2011;71(1):1-5.)

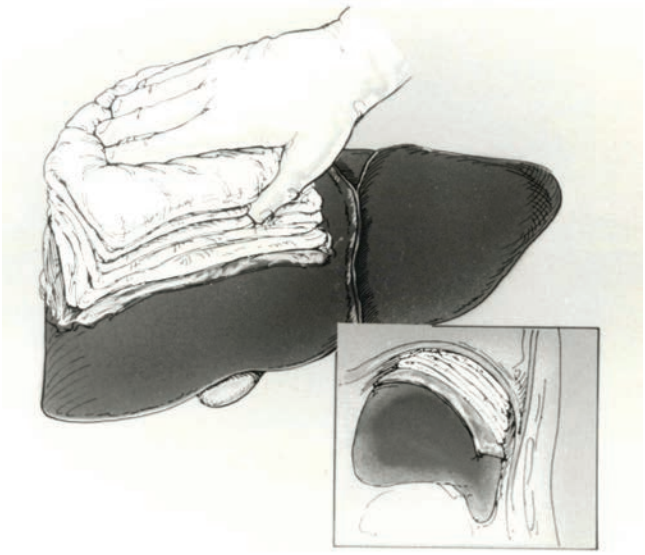

FIGURE 33-10 Manual compression of a hepatic injury. Sagittal view (inset) of packs placed above the liver to assist with compression of hepatic bleeding. (Reproduced with permission from Feliciano DV, Pachter HL. Hepatic trauma revisited. *Curr Probl Surg*. 1989;26:453.)

this may exacerbate bleeding. Manual compression of obvious injury will decrease bleeding (Fig. 33-10) and allow the anesthesia team some time to initiate a massive transfusion protocol and "catch up" with blood loss prior to proceeding. Any resuscitative products should be warmed and coagulopathy corrected, keeping in mind current recommendations for blood products in ratios approaching 1:1:1 (packed red cells to fresh frozen plasma to platelets) or viscoelastic assay-directed resuscitation while minimizing the administration of crystalloids. Once the patient has been adequately resuscitated, a more thorough examination of the peritoneal cavity is completed. If the bleeding source is localized to the liver and bleeding continues after manual compression is released, then the portal triad should be identified and a Pringle maneuver performed (Fig. 33-11) (see Atlas Figure 43).

Much controversy has centered on the ischemic time produced by the use of the Pringle maneuver. Multiple studies have documented that long duration (60 minutes) portal triad occlusion is well tolerated in the absence of cirrhosis.[55,56] In one study describing the operative management of 1000 patients with hepatic trauma, the Pringle maneuver was used routinely for between 30 and 60 minutes without adverse sequelae.[57] Pachter et al[58] managed 81 patients with the assistance of the Pringle maneuver for up to 75 minutes without any apparent morbidity. Given these data, it seems that longer normothermic, or hypothermic, ischemic times can be used without added morbidity. The Pringle maneuver often does not control all bleeding. It will control the inflow bleeding from the hepatic artery and portal vein, but not retrograde bleeding from the inferior vena cava and hepatic veins; therefore, if bleeding persists with the portal triad clamped, injury to the retrohepatic vena cava and/or hepatic veins should be suspected.

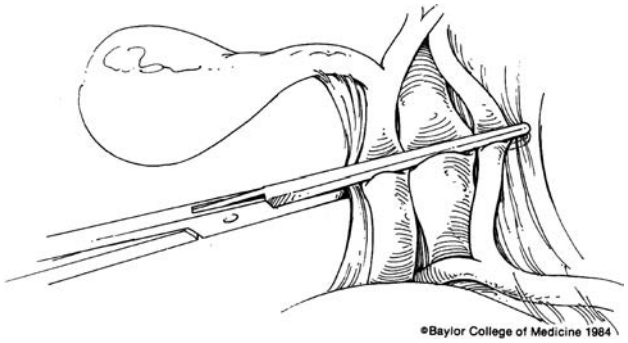

FIGURE 33-11 The Pringle maneuver places a vascular clamp across the common bile duct, portal vein, and common hepatic artery. Any residual hemorrhage is likely the result of bleeding hepatic veins. (Reproduced with permission from Feliciano DV, Pachter HL. Hepatic trauma revisited. *Curr Probl Surg*. 1989;26:453.)

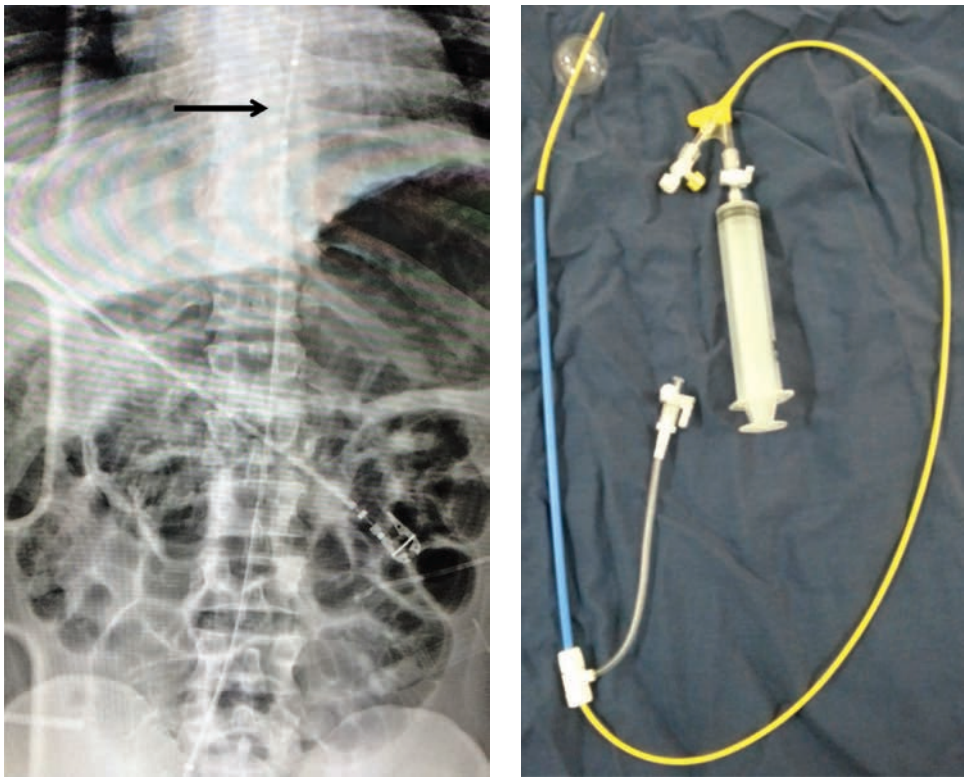
Clinical experience and animal data suggest that resuscitative endovascular balloon occlusion of the aorta (REBOA) is useful for partially controlling bleeding from intra-abdominal visceral and vascular injuries.[59,60] It is becoming increasingly common to place femoral arterial access in patients presenting in shock and, if needed, a REBOA catheter if the patient does not respond to resuscitation (Fig. 33-12). Matsurmura et al[61] demonstrated that quicker femoral access was significantly associated with a decrease in mortality in patients undergoing REBOA placement with occlusion. A new smaller diameter sheath (7F) is now available and reduces the time to balloon inflation as well as frequently obviating the need for repair of the puncture site in the femoral artery.[62]

Hemostatic Maneuvers for Severe Parenchymal Injury

PACKING (SEE ATLAS FIGURE 44)

Perihepatic packing has become the most widely used "bailout" method for damage control of a severe hepatic injury. Packing laparotomy pads around the liver compresses the bleeding wound between the anterior chest wall, diaphragm, and retroperitoneum and stops venous bleeding. Beal[63] reported an 86% survival rate in 35 patients in whom perihepatic packing was used. In order to provide the tamponade necessary for effective packing, it is sometimes necessary to mobilize the liver by taking down the falciform ligament and right and left coronary and triangular ligaments. If, however, there is obvious hematoma in a ligament, this mobilization should be avoided, as it may indicate an injury to the hepatic veins or retrohepatic vena cava and mobilization may lead to rapid exsanguination. The decision to pack should be made early in the operation in order to provide the best chances for patient survival.[64,65] Also, it is important to remember that packing will not control major arterial hemorrhage. The major refinement in the technique of perihepatic packing has been the placement of separate posterior paracaval, lateral, anterior, and posteroinferior packs as described by Baldoni et al.[66]



A B

FIGURE 33-12 (**A**) Plain abdominal radiograph from a patient with a grade V blunt hepatic injury that had a resuscitative endovascular balloon occlusion of the aorta (REBOA) catheter deployed in zone I (arrow) in the emergency room prior to operaexploration. (**B**) Photo of a REBOA catheter.

One of the challenges with perihepatic packing is the removal of the pads. Often, the bare liver area that has become hemostatic is now adherent to the packs, and bleeding will occur with removal. Different solutions to this problem have been described, from wetting the gauze with saline on removal to more innovative techniques. Feliciano and Pachter[67] suggest placing a nonadherent plastic drape directly on top of the hepatic surface, followed by laparotomy pads above this plastic interface, thus preventing adherence of the packs to the parenchyma.

Abdominal hypertension can be minimized in packed patients by leaving the fascia and skin edges open over the inferior two-thirds of the midline incision and placing a temporary closure device over the open abdomen, remembering that abdominal compartment syndrome can still arise.

The timing of pack removal continues to be the subject of debate. With damage control resuscitation, correction of perioperative hypothermia, acidosis, and coagulopathy can almost always be accomplished within 24 hours of packing. Intraabdominal sepsis is a theoretical risk of prolonged packing, but an obvious risk of continued bleeding exists with premature removal. Krige et al[68] found that packs that remained for more than 3 days had an 83% incidence of developing perihepatic sepsis, whereas those left less than 3 days had a 27% chance of sepsis. Caruso et al[64] advocate the removal of packs at 36 to 72 hours, because they have experienced a higher rate of repacking for recurrent hemorrhage in the group of patients who had their packs removed earlier. Nicol et al[69] reported a significantly higher repacking rate in hemodynamically stable patients whose packs were removed at 24 hours, compared to patients whose packs were removed after 48 hours.

DIRECT SUTURE (SEE ATLAS FIGURE 45)

Grade III and IV hepatic lacerations often do not respond to the superficial procedures described for minor injury control. One of the oldest reported techniques to control deep parenchymal bleeding is direct suturing of the tissue with a large, blunt-tipped 0 chromic suture. The sutures can be continuous, or if a deeper laceration is encountered, a mattress configuration is useful. This technique is most appropriate for lacerations less than 3 cm in depth. It is best to avoid deep suture placement as blind passage of these large blunt needles may injure bile ducts and vascular structures, leading to possible intrahepatic hematomas or hemobilia. Of note, hepatic necrosis can occur with the use of liver sutures, especially if tied too tightly.

FINGER FRACTURE OR HEPATOTOMY (SEE ATLAS FIGURE 46)

More severe parenchymal lacerations may involve larger branches of the hepatic artery or portal vein and will not

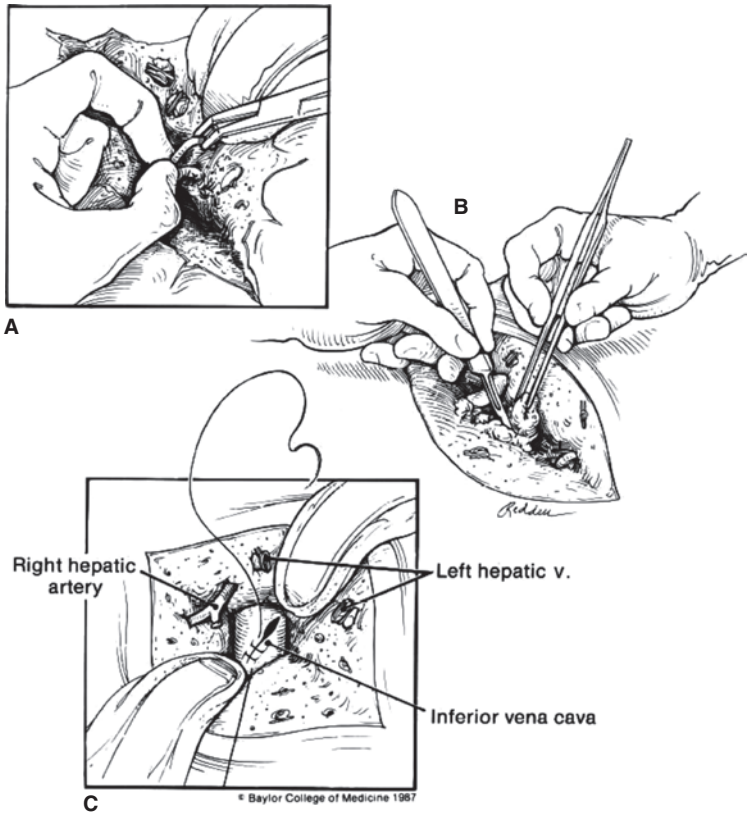


FIGURE 33-13 Hepatotomy with selective ligation is an important technique for controlling hemorrhage from deep (typically penetrating) lacerations. This technique includes finger fracture to extend the length and depth of the wound (**A**), clipping of visible ducts and vessels after fracture through the hepatic parenchyma (**B**), utilization of sponge stick and knife to fracture the parenchyma (**C**), and repair of any injuries to major veins and/or arteries. (Reproduced with permission from Feliciano DV, Pachter HL. Hepatic trauma revisited. *Curr Probl Surg*. 1989;26:453.)

respond to packing or parenchymal suturing. In these cases, finger fracture has been described (Fig. 33-13). The utilization of this technique involves careful extension of the laceration using finger fracture or clamping of the hepatic parenchyma as dissection proceeds through the liver. The fracture continues until bleeding vessels are identified and controlled with clips, ligation, or direct repair.[70] Ordoñez et al[71] published a series of penetrating hepatic injuries with 20.8% mortality for grade IV injuries and 70% for grade V. The authors concluded that intraparenchymal exploration and selective vessel ligation are useful in patients who fail packing and the Pringle maneuver. More recently, the use of stapling devices has been advocated.[72]

OMENTAL PACKING (SEE ATLAS FIGURE 47)

Omental packing can be used as the primary technique or in conjunction with other methods of hemorrhage control. Omental packing can fill a hepatic laceration or hepatotomy site with viable tissue that also is a source of macrophage activity. Stone and Lamb's original work[52] was reinforced by Fabian and Stone[73] when they managed to stop venous hemorrhage in severe parenchymal lacerations in 95% of patients with an 8% mortality. The greater omentum is first mobilized from the transverse mesocolon in the avascular plane and then freed from the greater curvature of the stomach, preserving a gastroepiploic (usually the right) vascular pedicle. The tongue of omentum is then placed into the injury defect (Fig. 33-14). It is then fixated in place by placing 0 chromic sutures from one side of the laceration or hepatotomy site to the other over the omentum and tying the knots firmly.

TRACT OF A PENETRATING WOUND (SEE ATLAS FIGURE 48)

Penetrating tracts through the hepatic parenchyma may be of great depth and length, making visualization of the entire injury impossible. Management of these injuries has included packing of the tract with an omental pedicle or a self-assembled device such as the rolled cellulose-covered gelatin sponge. Poggetti et al[74] advocate the use of balloon tamponade of the tract using a Penrose drain placed over a red Robinson catheter and tied on both ends. The "balloon" over Robinson catheter is then placed into the tract and inflated with a contrast agent (Fig. 33-15). If successful tamponade is achieved, the balloon is left in the abdomen and removed 24 to 48 hours later at a second laparotomy. A similar technique using a Foley catheter has been described after inflation of the balloon to obtain tamponade. If there is continued active bleeding, the catheter is moved back or forward and inflated again.

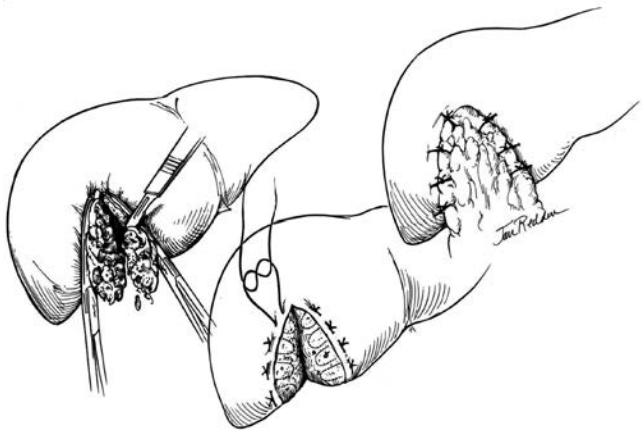

FIGURE 33-14 Major hepatic laceration controlled with clamps and sharply debrided. The edges of the laceration are oversewn with heavy silk or chromic suture to obtain some degree of hemostasis. A well-vascularized pedicle of omentum is mobilized and secured to the denuded section of liver. (Reproduced with permission from Feliciano DV, Pachter HL. Hepatic trauma revisited. *Curr Probl Surg*. 1989;26:453.)

If bleeding continues through the catheter but not out of the tract, the balloon is proximal to the bleeder and needs to be repositioned deeper. If the bleeding continues from the tract orifice, then the balloon must be repositioned further out of the tract.[75] Once the catheter is positioned, drains are placed in the area and brought out through the skin along with the end of the catheter. The Foley can be removed after deflation produces no further signs of bleeding or at the time of the next planned reexploration. Sengstaken-Blakemore tubes have been used in these situations as well.[76]

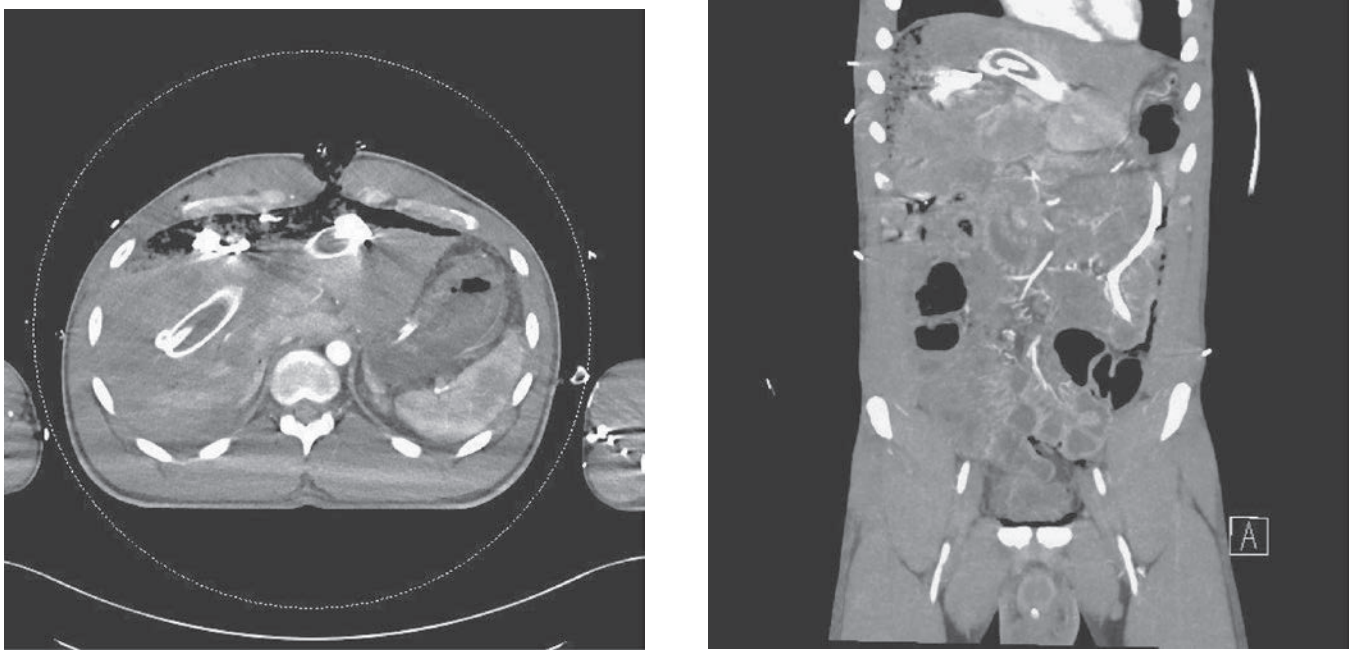
When a hepatotomy with selective vascular ligation, insertion of an omental pack, or balloon catheter tamponade is ineffective, angioembolization is another option for these lesions, if the patient can be stabilized for the procedure.

RESECTION

Anatomic resections for severe hepatic trauma were often performed in the late 1960s and early 1970s. In most series, mortality was high[77]; thus, resection fell out of favor until recently, when several groups reported improved outcomes. Polanco et al[78] reported on their experience of patients who underwent hepatic resection during their initial operation, with a morbidity of 30% and a mortality of 17.8%. Based on these data, the authors recommended hepatic resection in patients with massive bleeding related to a hepatic venous injury that must be repaired directly, in patients with massive destruction of hepatic tissue, and in patients with a major bile leak from a proximal main intrahepatic bile duct. Of the 56 patients undergoing resection, 42 had some type of resection performed during the initial surgical procedure.[78]

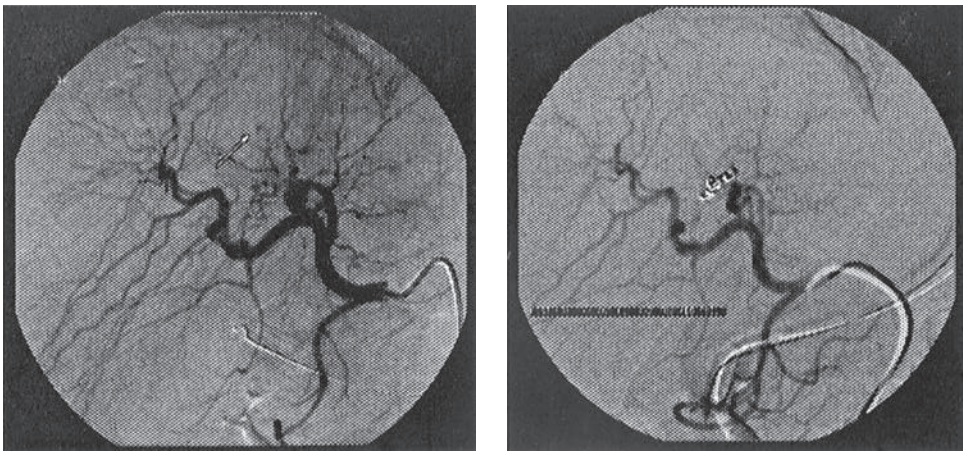
SELECTIVE HEPATIC ARTERY LIGATION OR ANGIOEMBOLIZATION

Although hepatic artery ligation can be a useful maneuver, it has largely been supplanted by angioembolization. In the



A B

FIGURE 33-15 Computed tomography of a patient with a transhepatic gunshot wound trajectory managed with a handmade balloon fashioned from a Penrose drain to control hemorrhage. (**A**) Axial views show the patient with an open abdomen and packing anterior to the liver. (**B**) Coronal views.



A B

FIGURE 33-16 (**A**) Hepatic pseudoaneurysm. (**B**) Coiled hepatic pseudoaneurysm.

operating room, if a patient has a noticeable decrease in bleeding after the right or left hepatic artery is clamped, hepatic artery ligation can be considered. This would usually be after attempts at direct vessel ligation or control, and bleeding cannot be controlled sufficiently to permit time for angioembolization. When the portal vein remains patent, the chance for severe hepatic dysfunction after hepatic artery ligation is minimal[79,80]; however, with patients in traumatic shock, hepatic artery ligation may lead to further ischemia with later development of necrosis or sepsis.[81]

Currently, most centers are advocating a multimodality approach to hepatic arterial bleeding, with a special emphasis on angioembolization. In 1984, Sclafani et al[82] reported successful selective arterial embolization to control bleeding from a severely injured liver after packing. Angiography has since become an important step in the management algorithm for a severe hepatic injury (Fig. 33-16). In a recent systematic review of angiography for hepatic trauma, angioembolization was successful in 77% to 100% of cases. The most common indication for angioembolization was a contrast blush seen on CT, followed by failure of nonoperative therapy and continued bleeding after damage control laparotomy.[83] Although this review was unable to draw a definitive conclusion regarding mortality, Matsumoto et al,[84] using data from the National Trauma Data Bank, reported that the use of postoperative hepatic angiography was associated with decreased mortality.

HEPATIC TRANSPLANTATION

Hepatic transplantation after trauma has been successfully reported. The patient must have an overall excellent chance of survival with minimal other injuries, especially in the abdomen or to the brain. In a review of over 1500 liver transplants by Heuer et al,[85] six were done following trauma with a 33% survival rate. In a 2013 report from Kaltenborn et al,[86] 12 patients undergoing liver transplantation for trauma had an overall mortality rate of 42%. In the survivors, retransplantation was necessary in 25%.

Juxtahepatic Liver Injuries

In an article by Buckman et al,[87] the authors divide injuries to the retrohepatic vena cava or hepatic veins into two categories: intraparenchymal and extraparenchymal. *Intraparenchymal* injuries include those to hepatic veins within the body of the liver; therefore, bleeding occurs through the injured liver. *Extraparenchymal* injuries include those to the hepatic veins outside the liver and to the retrohepatic vena cava. Life-threatening bleeding from these injuries occurs if the supporting structures, mainly the suspensory ligaments and diaphragm, are disrupted. Thus, inadvertent exposure of a major venous injury will release the tamponade and result in free bleeding and possible exsanguination. As Buckman et al[87] outlined, there are three main strategies to deal with these mortal injuries. The first is to directly repair the venous injury with or without vascular isolation. The second is to perform a formal lobectomy. The third is by using a strategy of tamponade and containment of the venous bleeding.[87] Once a juxtahepatic injury is identified, manual compression should be maintained on the liver while plans for repair are being carried out. These should include activation of a massive transfusion protocol, active warming, a call for additional help to the operating room, and on rare occasions, a call to a perfusion team if the need for venovenous bypass is likely.

DIRECT VENOUS REPAIR

Direct venous repair without shunting has been advocated by Pachter and Feliciano.[88] They described occlusion of the portal triad for a significant time, mobilization of the liver with medial rotation, and efficient finger fracture to the site of injury. With these methods, they reported a 43% survival rate (6 of 14 patients). Chen et al[89] have published similar results with a 50% survival rate.

Various shunting maneuvers of the retrohepatic cava have been described. Schrock et al[90] first introduced the atriocaval shunt in 1968 (Fig. 33-17) (see Atlas Figure 49). The goal is to shunt all venous blood from the infrahepatic vena cava

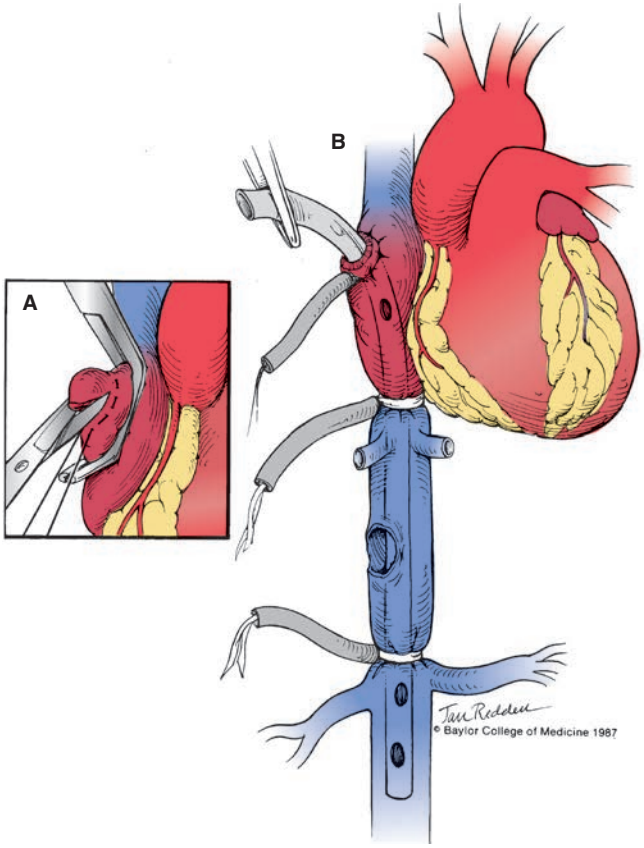


FIGURE 33-17 (**A**) A hole is cut in the right atrial appendage above a 2-0 silk pursestring suture. A Satinsky clamp maintains vascular control. (**B**) Final position of No. 36 chest tube acting as an atriocaval shunt. Note the extra hole cut in the chest tube at the level of the right atrium. All holes in the chest tube are outside the umbilical tapes, thereby forcing blood from the lower half of the body and the kidneys through the shunt. (Reproduced with permission from Feliciano DV, Pachter HL. Hepatic trauma revisited. *Curr Probl Surg*. 1989;26:499.)

thorough the shunt in the retrohepatic vena cava and into the right atrium.[90] Unfortunately, of the approximately 200 cases published using atriocaval shunting, at best 10% to 30% of patients have survived their injury.[15] For the Shrock atriocaval shunt to be performed in a timely manner, all required equipment must be ready, and the addition of a median sternotomy is necessary. Shunting a patient will not be successful if the patient has arrested, had major blood loss, or has become coagulopathic.

Additional shunting techniques exist. In 1977, Pilcher et al[91] reported on a balloon shunt introduced through the saphenofemoral junction. This method has had some anecdotal success and avoids an emergent median sternotomy without destruction of the surrounding ligamentous tamponade.[92] A 1988 multi-institutional trial, however, did not show any survival benefit of the balloon shunt versus the atriocaval shunt.[93]

Total vascular occlusion has been successfully employed in a small number of patients.[94,95] Vascular clamps are placed on the porta hepatis, suprarenal inferior vena cava, and suprahepatic inferior vena cava usually via a sternotomy. If clamping is tolerated, a direct vessel repair can be accomplished; however, hypovolemic patients will not tolerate total vascular occlusion. If this technique is to be used, it is best performed at the time of a delayed laparotomy for those patients who responded to initial packing.

Venovenous bypass has been used successfully in some institutions as well[96,97] (see Atlas Figure 50). Again, this method requires considerable planning and equipment but obviates the hemodynamic instability of occlusion of the inferior vena cava. It allows for active rewarming of the patient and may be a better option for hemodynamically unstable patients who do not respond to packing. In general, direct approaches to vein repair are difficult and can result in uncontrollable hemorrhage.

ANATOMIC RESECTION

Anatomic resection of the overlying injured hepatic lobe was described as a way to access injuries to the retrohepatic vena cava in the past. In certain circumstances, when the dissection has already been done by the injury itself, further resectional debridement for exposure may still be indicated.

ADJUNCTIVE TECHNIQUES

In a swine model of retrohepatic caval injury, Reynolds et al[98] used a Coda balloon to gain rapid control of the suprahepatic inferior vena cava. The resuscitative balloon occlusion of the inferior vena cava (REBOVC) reduced blood loss and decreased time to death.[98] The Coda balloon, however, is not intended for use in veins. There is a balloon catheter specifically designed for the venous system that was developed to provide temporary control to the superior vena cava due to hemorrhage occurring during extraction of cardiac leads. The system has a low-pressure compliant balloon that is 8 cm in length and covers the length of the superior vena cava.[99] Although there are no reports using this balloon for trauma, it seems suited to provide rapid control of the suprahepatic inferior vena cava.

Reports of using endoluminal fenestrated stent grafts in juxtahepatic caval injuries have been published.[100] These grafts have been placed both after damage control laparotomy and prior to laparotomy when the lesion is seen on CT.[101,102] Hommes et al[103] report the survival of a patient with intraoperative placement of an endovascular stent graft into the inferior vena cava for a juxtahepatic caval injury with perihepatic packing. Although these stenting techniques are not yet the norm, increased use may occur as technologies advance.

TAMPONADE WITH CONTAINMENT

At this time, it seems that the most successful method of managing injuries to the retrohepatic vena cava or hepatic veins is by using packs to tamponade the bleeding. Direct repair of damaged veins and use of the atriocaval shunt have had few survivors, and these have primarily been in the hands of experienced hepatobiliary surgeons in somewhat stable patients. In Memphis, the mortality of patients with juxtahepatic venous injuries treated with omental packing was

20.5%.[104] Cue et al[105] described four patients with injuries to the retrohepatic vena cava, hepatic veins, or both, who underwent initial packing. On planned reexploration and unpacking, the injuries were repaired, and three of the four patients survived.[105]

Drains After Hepatic Repair

In 1985, a review of 161 significant hepatic injuries demonstrated that the injury grade, blood loss, shock, and associated injuries were similar in patients who underwent postoperative closed-suction drainage and those who did not.[106] The study concluded that drainage should be done only in injuries with obvious bile leaks noted at the time of laparotomy. A more recent Cochrane review of elective (nontrauma) hepatic resections also concluded that there were no data to support routine postoperative drainage.[107] If a postoperative hematoma, biloma, or perihepatic abscess develops, almost all can be dealt with by percutaneous drain placement using radiographic guidance.

Complications of Operative Management

BLEEDING

Most reviews quote a 2% to 7% rate of postoperative bleeding.[67,93] Decreases in serial hematocrits, increasing abdominal distention, and episodes of hypotension or tachycardia signal continued bleeding. Hemodynamically unstable patients need a reoperation with reexploration of previously packed areas that have failed to stop bleeding. Kutcher et al[108] have recently examined the sensitivity and specificity of early postoperative CT scanning after laparotomy for hepatic trauma and concluded that it identifies clinically relevant ongoing bleeding and is sufficiently sensitive and specific to guide triage to angiography.

ABDOMINAL COMPARTMENT SYNDROME

As noted, an abdominal compartment syndrome may develop with perihepatic packing. Packs should be carefully placed around the liver, taking care to tamponade the bleeding, but not create excessive compression on the retrohepatic inferior vena cava. Crystalloid infusions should be minimized and bladder pressures serially measured in patients with ongoing resuscitation needs in the postoperative period.

HEMOBILIA (SEE PRIOR DISCUSSION AFTER NONOPERATIVE MANAGEMENT)

In a patient who develops significant upper gastrointestinal bleeding following repair of the injured liver, hemobilia should be considered as an etiology. As previously noted, the common signs and symptoms of hemobilia include jaundice, right upper quadrant pain, and a decrease in hematocrit. These findings are common in many patients after operation for severe hepatic trauma; therefore, making the diagnosis of hemobilia, with its reported 3% incidence,[109] can be difficult. The presentation may be days to weeks after operation. Classically, blood is seen emanating from the ampulla of Vater on upper gastrointestinal endoscopy, although bleeding may not always be present at the time the procedure is performed. Angiography will frequently identify the arterial bleeding and allow for embolization of the damaged vessel.[110,111] Operative debridement and drainage may be necessary if a large cavity has formed or sepsis is apparent, but is rarely necessary.

HYPERBILIRUBINEMIA

Biliovenous fistulae have been described but are quite rare.[112] This entity occurs as the bile in venous blood dissolves in the bloodstream and is carried directly to the right heart. This leads to a dramatic rise in bilirubin with relatively normal liver function tests. Series are small and management strategies have varied, but endoscopic retrograde cholangiopancreatography (ERCP) with stenting has been reported to be curative.[113]

BILE LEAKS

As with hepatic injuries managed nonoperatively, bile leaks are a common complication of operative management. In a study by Bala et al,[114] 40% of patients with high-grade hepatic injuries who required operative intervention developed a biliary complication. In a study by Asensio et al,[115] biliary fistulae (defined as >50 mL of biliary drainage per day for 14 days) were found in 22.5% of similar patients. Although the diagnosis can be confirmed by a HIDA scan, an ERCP affords the opportunity for diagnosis and treatment with sphincterotomy and stenting. A major injury to a left or right bile duct with a continued leak and/or a biliary stricture may require a late reoperation with a Roux-en-Y hepaticodochojejunostomy.

HEPATIC NECROSIS

Major hepatic necrosis can be a complication of the multimodality management of severe hepatic trauma. At the University of Maryland Shock Trauma Center, Dabbs et al[116] found that 29 of 30 patients developed major hepatic necrosis after initial operative intervention and 87% had undergone a damage control laparotomy. Many of the patients then had arterial embolization performed, making their risk of major hepatic necrosis around 70%. A large number of these patients then underwent resection of their necrotic hepatic parenchyma. Both serial debridement and formal lobectomy were performed, but lobectomy was associated with fewer procedures overall and a lower complication rate.[117]

OTHER FISTULAS

A pleurobiliary fistula is a rare complication. Early identification and management can prevent progression to a bronchobiliary fistula, with its potential for serious bile damage to the right lower lobe of the lung. After a penetrating thoracoabdominal injury, the patient may do well initially with resolution of a hemothorax and no evidence of jaundice,

with symptoms presenting later in the postoperative course. Definitive treatment has included pleural and/or abdominal drainage, ERC with sphincterotomy and stenting, or operative intervention.[118] Rothberg et al[119] recommended operative intervention in order to evaluate for significant diaphragmatic injury, hepatic necrosis, or lung necrosis with possible bronchial involvement.

A pleurocaval fistula may result from a penetrating thoracoabdominal wound as well. This fistula may be the source of a life-threatening air embolism.[120] An intraparenchymal arterioportal fistula is associated with initial hemorrhage and subsequent portal hypertension. In one case report in which the authors described a GSW that caused a left hepatic artery to portal vein fistula, the fistula was successfully managed by arterial embolization.[121] Portosystemic venous shunts have also been reported after severe blunt hepatic injuries.[122]

HEPATIC FAILURE

When hepatic failure occurs following severe trauma, options are limited. The Molecular Adsorbent Recirculating System (MARS; Baxter International, Deerfield, IL) is an extracorporeal liver replacement device that can be used to treat acute liver failure, although experience is limited in injured patients. In a study of 27 patients with acute liver failure, five of whom had hepatic trauma, survival was 60% in the trauma patients with recovery of both liver and renal function.[123]

INJURY TO EXTRAHEPATIC BILIARY DUCTS

Extrahepatic biliary and portal triad injuries make up only about 0.07% to 0.21% of all trauma admissions at Level I trauma centers, with roughly 30% to 40% caused by a blunt mechanism. At operation, technical problems include hemorrhage, adjacent organ injury, and small duct size. Injury to this area carries an overall 50% mortality, especially if a vascular injury is present. If injury to both the portal vein and hepatic artery are present, the mortality is 99%.[124,125]

Injury Types and Diagnosis

GALLBLADDER

Injury to the gallbladder accounts for up to 66% of injuries to the extrahepatic biliary tract.[126] Blunt injury often involves avulsion, contusion, or perforation. Patients with either blunt or penetrating rupture may also present with bile peritonitis and right upper quadrant pain. If an isolated injury to the gallbladder is seen on a CT scan, additional intra-abdominal injuries should be suspected (Fig. 33-18). The findings of an ill-defined contour of the wall, collapse of the lumen, or intraluminal hemorrhage highly suggest blunt injury to the gallbladder.[127] Blood in the gallbladder can cause stasis and blockage of the cystic duct, which may present later as acute cholecystitis.[128] With any magnitude of injury to the gallbladder, cholecystectomy is recommended.

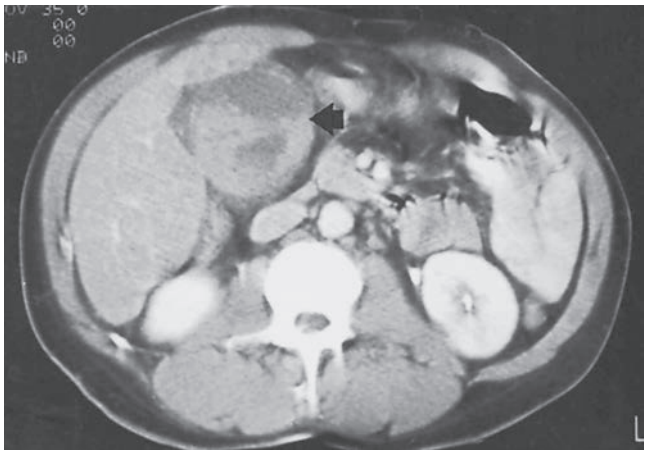

FIGURE 33-18 Computed tomography scan revealing a distended gallbladder filled with blood (dark arrow) in a patient with blunt abdominal trauma and virtually no peritoneal signs.

BILE DUCT

Most injuries to the bile duct are caused by penetrating trauma.[124] Blunt ductal injury occurs where the bile duct is fixed to its surroundings, such as near the pancreaticoduodenal junction.[129] In one multi-institutional trial, it was found that blunt injuries usually led to complete transections, whereas penetrating injuries led to partial transections the majority of the time.[124]

Injuries to the extrahepatic bile ducts are typically discovered at the first laparotomy. A much smaller group of patients have presented 24 hours and up to 6 weeks after trauma if the injury was not diagnosed during the original evaluation or operation. Patients with late presentation develop jaundice, abdominal distention and pain, intolerance to enteral feedings, a fever, or worsening base deficit due to bilious ascites or infection.[125]

Evaluation of the stable patient with a CT scan or ultrasound in the acute setting will not be able to differentiate abdominal blood from bile. There may be fullness of the head of the pancreas, duodenal thickening, or portal edema on the admission CT, but these are nonspecific findings. In the presence of bile staining noted at operation and no obvious injury, a cholangiogram through the gallbladder can be helpful.[130] A diagnostic peritoneal lavage would have lack of specificity for a ductal injury because injuries to the duodenum, small bowel, and liver may also produce bile.[130] Late presentation of a bile duct injury may not be recognized until symptoms are apparent. At that time, CT, ultrasound, or ERC can be used to visualize bile collections and localize the injury.[131]

Management of Injury to Extrahepatic Biliary Ducts

GENERAL CONSIDERATIONS

Extrahepatic biliary injuries remain a rare entity. A 12-year experience from the Royal Melbourne Hospital in Australia noted a 0.1% incidence of biliary tract injuries among all

trauma admissions. Blunt trauma caused 77% of the injuries, whereas 23% were from penetrating wounds. Concomitant injuries were present in 97% of patients, thus illustrating the importance of modern imaging and abdominal exploration as needed.[132]

General operative principles described for a major hepatic injury apply to a ductal injury as well. A hematoma or bleeding around, or within, the hepatoduodenal ligament or a severe hepatic parenchymal injury leading to the porta hepatis should raise suspicion of a portal triad injury. Bile staining should be fully investigated, as 12% of bile duct injuries may be missed at the initial operation.[129] The Pringle maneuver is helpful in decreasing the inflow to a vascular injury in the portal triad. In order to obtain adequate examination and exposure for repair, a wide right medial visceral rotation may need to be performed. This maneuver includes mobilizing the ascending colon and hepatic flexure, thus exposing the duodenum. Similarly, a full Kocher maneuver may be necessary to improve exposure of the entire common bile duct.

GALLBLADDER

As noted earlier, an isolated injury to the gallbladder is most often managed with open cholecystectomy; however, there have been reports of laparoscopic cholecystectomy in highly selected patients after penetrating trauma.[133] If chosen, laparoscopic cholecystectomy should include evaluation of adjacent structures, as most injuries to the gallbladder are associated with other intra-abdominal injuries. Although the laparoscope can give a good superficial exam of the peritoneal cavity, visualization of the duodenum, pancreas, and porta hepatis is difficult and requires some expertise. A minor contusion to the gallbladder could be managed nonoperatively,[134] but cholecystectomy is recommended to avoid delayed rupture.[135] Cholecystectomy should also be performed on all patients with injury to the cystic duct or right hepatic artery that would eliminate the blood supply to the gallbladder.

BILE DUCT

In the unstable patient, packing and placement of drains in the area of a presumed ductal injury are adequate until reexploration is performed. In the somewhat more stable patient who is becoming coagulopathic, a small T-tube placed in the injured duct will provide adequate drainage until a formal repair can be accomplished.[136] With a partial transection of a right or left hepatic duct, insertion of a small T-tube into the common hepatic duct with a long limb traversing the partially transected area, even without suturing, may provide enough support for full healing.

For the stable patient, definitive repair is preferred at the first operation. Four broad categories of injuries to the extrahepatic biliary ducts are as follows: (1) avulsion of cystic duct or small laceration; (2) transection without loss of tissue; (3) extensive defect in the wall; and (4) segmental loss of ductal tissue.[137]

Avulsions and small lacerations in the duct can have a small T-tube inserted into the defect or can be repaired primarily with 6-0 polyglycolic suture, making sure not to narrow the lumen. A T-tube with a limb under the repair can be used; however, this may be difficult to insert in a patient with a normal-sized duct. The techniques used to place a T-tube may also devascularize an already compromised duct. For avulsions in which primary repair may narrow the lumen, a piece of the cystic duct or proximal gallbladder wall can be rotated down for the repair as a cholecystectomy is performed.[138]

A rare stab wound that results in a clean transection of the bile duct without significant tissue loss can be repaired with an end-to-end anastomosis. Only minimal dissection around the duct or the lacerated ends is performed in order to avoid damage to the fragile ductal arteries at the 3 and 9 o'clock positions. Tension and/or ischemia of the anastomosis will certainly lead to stricture. End-to-end anastomoses are contraindicated after GSWs, especially since Ivatury et al[139] reported a 55% stricture rate after these repairs. Stewart and Way[140] had success in 67% of patients initially managed with Roux-en-Y reconstruction for complete duct laceration following laparoscopic cholecystectomy, with failure in all lacerations treated with an end-to-end anastomosis.

Extensive wall defects and segmental tissue loss require a biliary-enteric anastomosis as well (Fig. 33-19). In the past, many methods of "patching" were attempted. Saphenous vein grafts have had issues with shrinking and fibrosis, which then required stenting.[141] Prosthetic patches and jejunal mucosal patches have also been tried with anecdotal success only.[142]

Deciding which type of biliary-enteric anastomosis to perform depends on the injury location, access, and size of the duct. Roux-en-Y choledocho- or hepatodochojejunostomy with cholecystectomy is the most utilized approach to a complex injury. Healthy bleeding from the proximal end of the transected duct(s) is the main criterion for success (ie, avoidance of late stricture). A retrocolic Roux limb at least 40 cm long is created and brought up to the common bile or hepatic duct, or even to the hilar plate. An avulsion of the hepatic ducts at the bifurcation can be managed by suturing the ducts together medially before the end-to-side hepatodochojejunostomy.[143] If the distal common duct is not found due to its retraction behind the pancreas, drainage of the area is necessary.[130] Cholecystojejunostomy and ligation of the very distal common bile duct are a possibility if intraoperative cholangiography reveals a patent cystic duct. This is a viable option, especially in patients with small-caliber ducts or instability.

Placing a stent through a biliary-enteric anastomosis is a controversial topic. Surgeons in favor of stenting report that stenting allows for decompression and may allow for cholangiography if a T-tube is the stent. T-tubes must exit the duct outside of the repair area or a stricture will result. Some surgeons feel comfortable without stents, stating that a foreign body in an already small duct may promote stricture or obstruction.[144]

When an injury to the distal common bile duct is discovered, a pancreaticoduodenectomy may be appropriate if combined duodenal and pancreatic injuries are present as well. Primary repair or reimplantation of an avulsed ampulla should only be performed by an experienced hepatopancreatobiliary surgeon.

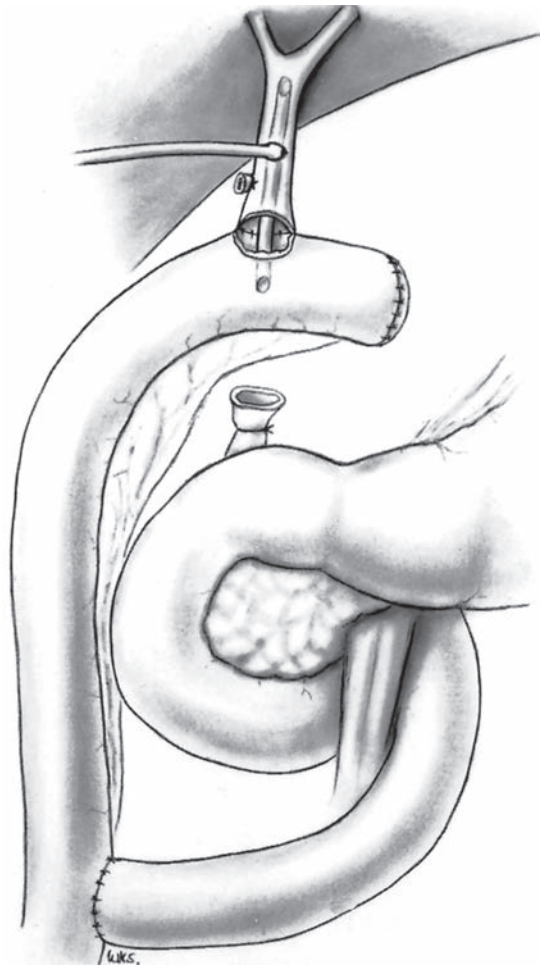

FIGURE 33-19 Roux-en-Y choledochojejunostomy. Anastomosis is performed in a one-layer fashion. The T-tube is brought out through a separate proximal stab wound. The gallbladder has been removed.

The major complications after repairs of injuries to extrahepatic biliary ducts are fistulas and strictures. A fistula may be managed nonoperatively with drainage alone, whereas a persistent fistula occasionally requires reoperation with a new reconstruction. A delayed stricture will present with recurrent episodes of cholangitis. A recent publication describes an aggressive technique of placing an increasing number of stents through a stricture until it resolves. Although the authors did have a complication rate of 9%, their mean duration of treatment was 12 months with a 48.8-month stricture-free interval after treatment.[145] Conversely, Johns Hopkins reported their experience with operative management of all postoperative bile duct strictures and had a 98% success rate.[146]

Spleen

Thomas H. Shoultz • Joseph P. Minei

KEY POINTS

- A high suspicion for splenic injury should exist when patients present with signs or symptoms of trauma to the left upper quadrant or thoracoabdominal region.
- In hemodynamically stable patients, dual-phase, multidetector computed tomography scan of the abdomen with intravenous contrast allows grading of splenic injuries and aids in clinical decision making.
- The revised Organ Injury Scale from the American Association for the Surgery of Trauma incorporates vascular injury and active bleeding as grade IV and grade V injuries.
- For patients with splenic vascular injury or active bleeding, angiography and embolization can significantly increase the success rate of nonoperative management over observation alone.
- If nonoperative management for splenic injury is undertaken, serial physical exams are imperative for avoiding missed injuries to the hollow viscera.
- For patients requiring surgical intervention, mobilization of the body and tail of the pancreas with the splenic hilum allows full mobilization of the spleen for examination and appropriate surgical treatment.
- The incidence of overwhelming postsplenectomy infection is exceptionally rare, but vaccination in the postoperative period remains the current standard of care.

Splenic injuries demonstrate themselves clinically more often than do hepatic injuries, making it the most commonly injured solid viscus requiring laparotomy. During the past 50 years, there has been increasing interest in the notion that not all splenic injuries require splenectomy. Nonoperative management with close observation is safe in appropriately identified patients. There is also increasing evidence supporting the safety of selective angioembolization; however, optimal patient selection is still critical. Although the paradigm has shifted toward frequent consideration of nonoperative management, it is important to always keep in mind that patients with splenic injury can succumb to hemorrhage.

HISTORICAL PERSPECTIVE

The spleen has been subject to injury for as long as man has suffered trauma. In ancient India, where malaria was endemic and large, fragile spleens were commonplace; intentional injury of the spleen was a method of assassination. Paid assassins called *thuggee* carried out their mission by delivering a blow to the left upper quadrant of the intended victim. They hoped to cause splenic rupture, and if this were severe enough, the targeted would bleed to death.

Ancient Greeks and Romans felt the spleen to play a significant role in human physiology. Aristotle thought that the spleen was on the left side of the body as a counterweight to the right-sided liver.[1] He believed that the spleen was important in drawing off "residual humors" from the stomach. The close relation of the stomach and spleen and the presence of the short gastric vessels so important in present-day splenic mobilization likely encouraged this belief. The spleen was also felt to "hinder a man's running," and Pliny reportedly claimed that "professed runners in the race that bee troubled with the splene, have a devise to burne and waste it with a hot yron."[2] The exceptional speed of giraffes was felt to be related to the erroneous belief that giraffes were asplenic. Early references to removal of the spleen to increase speed make it apparent that it has long been known that the spleen is not absolutely necessary to sustain life. Paracelsus believed that the spleen could be removed, and rejected the notion that it was important for the storage of "black bile."[3]

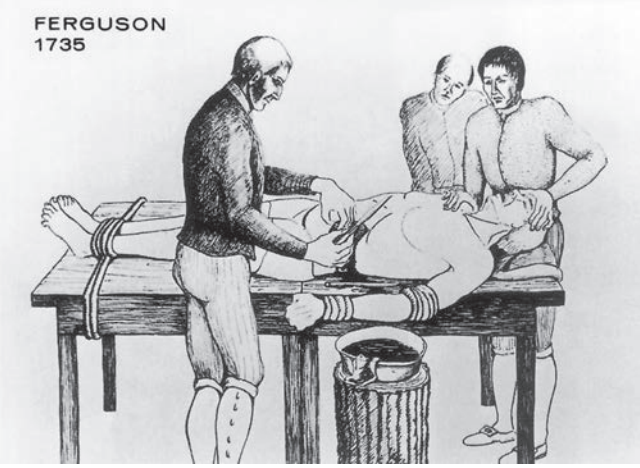

FIGURE 34-1 A depiction of the partial splenectomy done by John Ferguson of Scotland and reported in 1738. The operation actually had been done some years earlier. (Reproduced with permission from Hiatt JR, Phillips EH, Morgenstern L, eds. *Surgical Diseases of the Spleen*. Berlin Heidelberg, Germany: Springer-Verlag; 1997:6. Copyright © Springer-Verlag, Berlin Heidelberg 1997.)

In 1738, John Ferguson of Scotland removed a portion of the spleen through an open wound in the left side (Fig. 34-1). Once the era of abdominal surgery had begun, it was discovered that the spleen could be removed with what seemed like relative impunity. Mayo reported in 1910 that "the internal secretion of the spleen is not important, as splenectomy does not produce serious results."[4] Although some suggested that the spleen was important in some way for immune function and for the removal of senescent red blood cells, it was not felt that these functions were of great importance. Until several decades ago, this resulted in a philosophy in which any traumatic splenic injury, no matter how trivial, was treated with splenectomy.[3,4]

There were some early thoughts that the spleen played a role in combating infection, but it only has been in the last century that our understanding of the role of the spleen in immune function has developed.[5] The initial clinical impetus to more closely examine the immunologic role of the spleen was based on the observation that neonates and infants who required splenectomy for hematologic disease suffered otherwise inexplicably high rates of postoperative morbidity and mortality from overwhelming infection. Pneumonia and meningitis secondary to pneumococcus species and other encapsulated organisms were particularly common. The dramatic consequences of splenectomy in this very specific group of patients led to the investigation of the effects of splenectomy in pediatric trauma patients. Although the evidence for severe immunologic consequences of splenectomy in this group was less convincing than in pediatric patients with hematologic disease, there was a strong signal that splenectomy for trauma would lead to an increased rate of overwhelming sepsis, just as occurred after splenectomy for hematologic disease. Cases of overwhelming postsplenectomy sepsis in adults who had undergone splenectomy for trauma were also reported.[6,7]

The development of improved abdominal imaging and increasing questions about the safety of transfused blood paralleled our increased understanding of the importance of the spleen for immune function. The advent of computed tomography (CT) scanning of the abdomen and its continued improvement in speed and resolution markedly increased our ability to diagnose splenic injury nonoperatively, and it became apparent that clinically silent splenic injuries could occur. Concerns about the safety of stored blood transfusion with respect to hepatitis and human immunodeficiency virus, however, led to pressing questions about transfusions for patients with splenic injury.

Most splenic injuries are due to the same blunt and penetrating mechanisms that cause other traumatic injuries. Increased use of percutaneous procedures and abdominal ultrasound has revealed more obscure mechanisms such as colonoscopic manipulation and placement of a nephrostomy tube as potential causes of splenic injury.[8,9]

SPLENIC FUNCTION

Histologically, the spleen is divided into what has been termed *red pulp* and *white pulp*. The red pulp is a series of large passageways that filter old red blood cells and trap bacteria. Filtering is important in removing poorly functioning senescent red blood cells from the bloodstream and in keeping the hematocrit and blood viscosity within a normal range. The trapping of bacteria in the filters of the red pulp allows the antigens of the bacterial walls to be presented to the lymphocytes in the adjacent white pulp. The white pulp is filled largely with lymphocytes located such that they can be exposed to antigens either on microorganisms or freely circulating. Lymphocyte exposure to antigens results in the production of immunoglobulins. Other potentially important functions of the white pulp are the production of opsonins and activation of complement in response to appropriate stimuli.

All these functions of the spleen are, of course, lost after splenectomy. Collections of lymph tissue are also found in the liver, thymus, intestinal tract, and skin, and these areas may take over some of the functions of the spleen after splenectomy. In addition, some of the necessary functions of the spleen could conceivably be carried out by accessory spleens, but the removal of the spleen results in loss of most filtering and immune functions. How serious these losses are to normal function is a matter of debate. The loss of the filtering function of senescent red blood cells seems to be tolerated reasonably well. Although certain kinds of senescent red blood cells in the bloodstream are more pronounced after splenectomy, the homeostatic genesis and removal of red blood cells seems to remain intact. The loss of splenic function has been the subject of a great deal of investigation. There is evidence of an increased incidence of overwhelming sepsis after splenectomy for trauma; however, the precise incidence, especially in adults, is so low that it is difficult to quantify.

The possibility that small accessory spleens might provide residual splenic function raises the question of how much

splenic mass is necessary for the filtering and immune functions of the spleen. This is a question of more than academic importance, in that a variety of surgical techniques have been described for partial splenectomy or autotransplantation of the spleen after splenectomy.[10,11] The exact amount of spleen to reimplant after splenectomy or leave behind after partial splenectomy is dependent on the minimum amount of splenic tissue necessary for normal function. How much spleen is necessary for normal function is not precisely known but is thought to be between 30% and 50%.[12]

SPLENIC ANATOMY

The spleen develops initially as a bulge on the left side of the dorsal mesogastrium and begins a gradual leftward migration to the left upper quadrant. It changes in relative size during maturation. In children, it is relatively large because it is necessary for both reticuloendothelial function and production of erythrocytes. As the child's bone marrow matures, the spleen becomes less important and diminishes in size relative to the rest of the body. There are also differences between pediatric and adult spleens with respect to the splenic capsule and the consistency of the splenic parenchyma. The capsule in children is relatively thicker than it is in adults, and the parenchyma is firmer in consistency in children than it is in adults. These two differences have implications for the success of nonoperative management. A thicker capsule and tougher parenchymal consistency imply that pediatric spleens are more likely to survive an insult without major bleeding and the need for operative intervention. This is part of the explanation for why children are more often candidates for nonoperative management than are adults, and why nonoperative management tends to be somewhat more successful in children than it is in adults.

The normal adult spleen ranges in size from 100 to 250 g. A number of disease processes, however, can change both the size and consistency of the spleen. Malaria and its effects on the spleen with respect to enlargement and changes in consistency have been referred to earlier. Hematologic diseases such as lymphoma and leukemia can also change both the size and consistency of the spleen and make it more susceptible to damage. Other more common diseases such as mononucleosis make the spleen more vulnerable to injury. An equally important and prevalent pathology that can increase splenic vulnerability is portal venous hypertension. Usually such portal hypertension is secondary to cirrhosis of the liver, and when it is present, the spleen can become both enlarged and less firm in consistency.

It is perhaps not intuitive from the anteroposterior views depicted in anatomy textbooks, but the spleen is normally located quite posteriorly in the upper abdomen (Fig. 34-2). It is covered by the peritoneum except at the hilum. Posteriorly

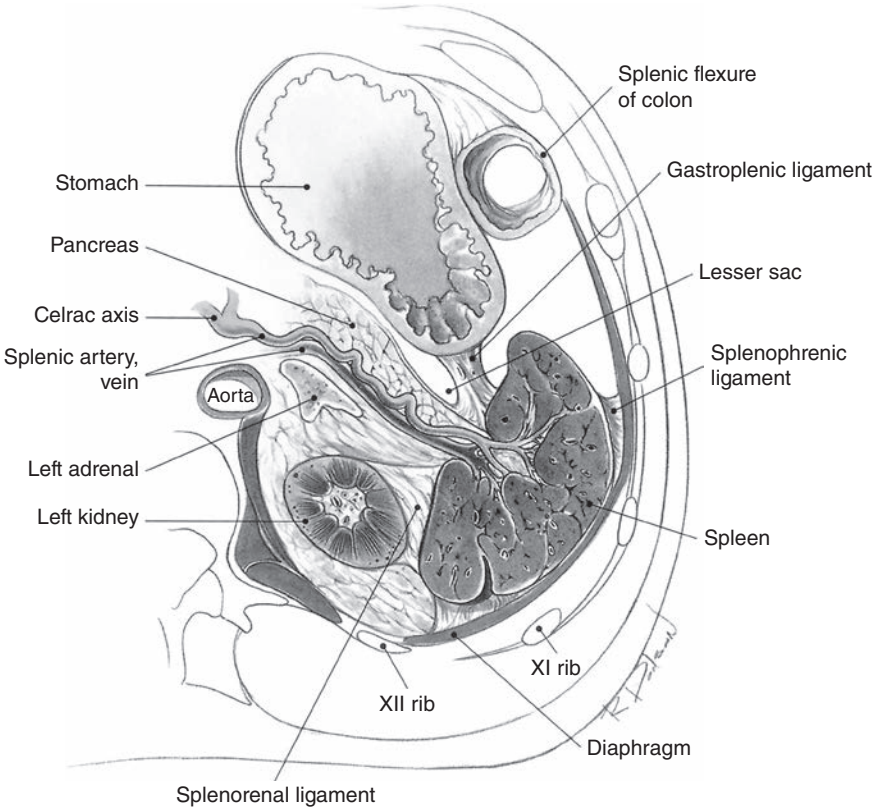

FIGURE 34-2 The spleen is located quite posteriorly in the left upper quadrant and is attached to surrounding structures by a variety of ligaments. (Reproduced with permission from Carrico CJ, Thal ER, Weigelt JA, eds. *Operative Trauma Management: An Atlas*. Norwalk, CT: Appleton & Lange; 1998. Copyright The McGraw-Hill Companies, Inc.)

and laterally the spleen is related to the left hemidiaphragm and the left lower ribs. The lateral aspect of the spleen is attached to the posterior and lateral abdominal wall and the left hemidiaphragm (splenophrenic ligament) with a variable number of attachments that require division during mobilization of the spleen. The extent of these attachments is quite variable. Minimal attachments will result in a fairly mobile spleen. Thick attachments, when present, will require sharp dissection. The lateral attachments tend to be smaller and less extensive in children than in adults. As the spleen lies adjacent to the posterior ribs on the left side, left posterior rib fractures should increase the index of suspicion for an underlying splenic injury. Because of the close relation of the spleen to the diaphragm, simultaneous injuries to the two structures are not uncommon. After penetrating trauma, a knife or bullet can injure both the left hemidiaphragm and the spleen. The diaphragm can also be injured in blunt trauma, and the spleen, either injured or uninjured, can herniate through a diaphragmatic defect into the left pleural space. The diaphragm should always be closely inspected during surgery for splenic injury.

Posteriorly, the spleen is related to the left iliopsoas muscle and the left adrenal gland. The left adrenal gland is usually fairly small and has a characteristic yellow-gold color. It tends to be related to the posterior aspect of the superior portion of the spleen and should be protected when seen during splenic mobilization.

Posteriorly and medially, the spleen is related to the body and tail of the pancreas. Therefore, mobilizing the tail and body of the pancreas along with the spleen increases the extent to which the spleen can be elevated out of the left upper quadrant.

Medially and to some extent anteriorly, the spleen is related to the greater curvature of the stomach. This relation is important in that the spleen can receive a variable amount of blood supply from short gastric branches of the left gastroepiploic artery. The short gastric vessels require division during full mobilization of the spleen.

Posteriorly and inferiorly, the spleen is related to the left kidney. There are attachments between the spleen and left kidney (splenorenal ligament) that require division during mobilization of the spleen. The left kidney should be left in place while mobilizing the spleen and tail of the pancreas from lateral to medial. There are exceptions to leaving the kidney in place, most notably if the kidney also has been injured or if mobilization of the spleen is being done to provide exposure to the aorta from the left side.

Finally, the spleen is related inferiorly to the distal transverse colon and splenic flexure. The lower pole of the spleen is attached to the colon (splenocolic ligament), and these attachments require division during splenic mobilization.

The splenic artery, one of the major branches of the celiac axis, takes a tortuous course along the superior aspect of the body and tail of the pancreas toward the splenic hilum. It divides at its terminus into a variable number of branches that provide a segmental blood supply to the spleen. Both the number of branches and the site at which the branching occurs are quite variable (Fig. 34-3). This variability is of surgical significance in that there is no absolute and dependable number of splenic artery branches that require division during splenectomy or segmental resection of the spleen. Most commonly, a number of separate splenic artery branches are ligated during splenectomy rather than a single ligation of the main splenic artery. It is possible to find the splenic artery along the superior margin of the body and tail of the pancreas if necessary, and sometimes it is helpful to ligate the artery at that location even after hilar branches have been ligated if there is evidence of continued bleeding.

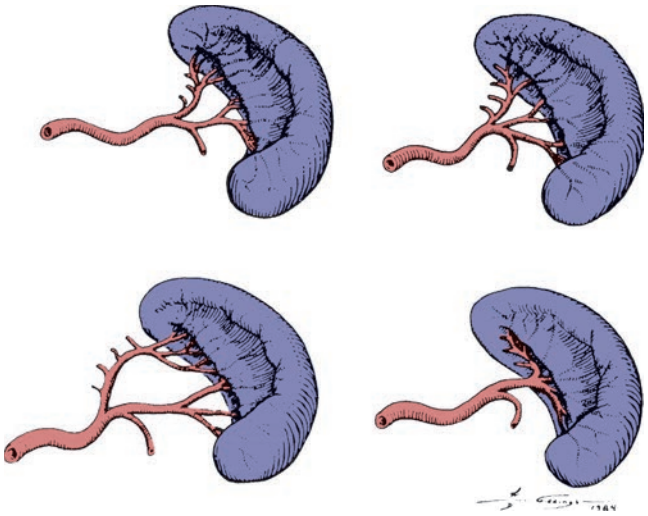

FIGURE 34-3 The arterial blood supply to the spleen can be quite variable. The most common configuration consists of two extraparenchymal divisions of the splenic artery (upper left figure).

The other sources of arterial blood supply for the spleen are the short gastric vessels that connect the left gastroepiploic artery and the splenic circulation along the greater curvature of the stomach. There is an average of four to six short gastric arteries. As implied by their name, these branches off the greater curvature are generally fairly short and are easily injured during mobilization of the spleen.

The venous drainage of the spleen, like the arterial inflow, is via two routes. The splenic vein drains the spleen via a number of tributaries that coalesce to form a single large vein that courses along the posterior aspect of the body and tail of the pancreas to its confluence with the superior mesenteric vein. Like venous anatomy elsewhere in the body, the location, size, and branches of the splenic vein can be quite variable. The other route of splenic venous drainage is via short gastric veins that course adjacent to the short gastric arteries. They drain into the left gastroepiploic vein during its course along the greater curvature of the stomach.

PATHOPHYSIOLOGY OF INJURY

Although nonoperative management is often appropriate after splenic injury, many patients with splenic injury still need emergency surgery to control the hemorrhage. In a large

multi-institutional survey, approximately 45% of patients with splenic injury required emergency surgery.[13] A study using rigid predefined criteria for nonoperative management revealed that 33% of isolated blunt splenic injuries require immediate operation and a further 23% treated with initial nonoperative management required operation, for an overall 56% operative rate.[14] Overall operative rates vary depending on setting, with higher operative rates for rural and nonteaching hospitals.[15] The higher operative rate in smaller hospitals may in part be due to different management strategies. The differential operative rates may be related to the fact that large referral hospitals see a higher percentage of transferred patients who have already withstood the test of time and have proven themselves good candidates for nonoperative management. The rate also varies when comparing large multi-institutional series with single-institutional series. Regardless of the setting, however, it is clear that rapid operative intervention is sometimes necessary. This is particularly true when patients have a coagulopathy either from preinjury anticoagulation or as a consequence of their injury.

Hemorrhage can also be a problem on a delayed basis. The concept of "delayed rupture" of the spleen is actually a misconception. The initial notion that the spleen could rupture on a delayed basis dates back to an era before abdominal CT scanning. In that era, it was observed that some patients who had suffered a traumatic injury did not manifest overt bleeding from their spleen for a number of days, or sometimes even weeks or months, after the traumatic event. With the advent of abdominal CT scanning, it became apparent that these were probably cases of "delayed bleeding" rather than delayed rupture. The distinction between these two entities is more than academic. If "delayed rupture" of the spleen can occur without much evidence of preexisting injury, CT scanning of the abdomen shortly after injury would be negative. In this case, there would be no good way to screen patients and make sure that they were not at risk for delayed splenic bleeding. In contrast, if what used to be called *delayed rupture* is actually just *delayed bleeding*, early diagnosis of the presence of the splenic injury should allow us to tailor our management such that the risk of the delayed bleeding is minimized.

Penetrating injuries to the spleen are most commonly managed operatively, often because of concerns about associated intraperitoneal injuries. Concerns about injury to the stomach, colon, or diaphragm from the knife or bullet are a common rationale for operative intervention in patients with penetrating injury to the spleen. However, some retrospective series have shown that selective nonoperative management of abdominal gunshot wounds in hemodynamically stable patients without peritonitis is as safe as immediate operation and may even be associated with lower rates of complication and hospital length of stay. From a practical standpoint, it is still unknown which patients on presentation are most likely to succeed with this nonoperative approach.[16,17] Operative intervention, of course, does not mandate splenectomy after penetrating injury any more than it does after blunt injury, although the risk of major arterial disruption after penetrating trauma is somewhat higher than after blunt trauma. Attempts at splenic salvage are reasonable after blunt or penetrating splenic injury, especially if the grade of injury is low and associated injuries are not particularly severe.

INITIAL EVALUATION AND MANAGEMENT

As with any other trauma patient, the initial management of the patient with splenic injury should follow the ABCs (airway, breathing, and circulation) of trauma evaluation and resuscitation. A particularly important general comment relative to initial resuscitation is that it is important to recognize refractory shock early and treat it with an appropriate operative response. There are some aspects of the initial evaluation, with respect to the spleen, that deserve special mention:

1. The possibility of an additional intra-abdominal injury in patients with splenic injury seen on CT scanning should be kept in mind. Injury to the gastrointestinal tract is of particular concern.
2. While operating on patients with splenic injury, it is important to look for associated injuries, particularly to the left hemidiaphragm and the pancreas.
3. When mobilizing the spleen, always mobilize the tail of the pancreas medially with the spleen to optimally expose the splenic hilum and minimize risk to the spleen and pancreas.
4. Despite the fact that nonoperative management of splenic injury is a commonly successful strategy, patients can still bleed to death from splenic injury. Therefore, a significant percentage of patients still require surgical intervention and splenectomy.

Elements of the history may be helpful in the diagnosis of splenic injury, and mechanism of injury is important. In patients injured in a motor vehicle crash, the position of the patient in the car can be of some importance in diagnosing splenic injury. Victims located on the left side of the car (drivers and left rear passengers) are perhaps slightly more susceptible to splenic injury because the left side of their torso abuts the left side of the car. This does not mean, however, that victims in other locations in a vehicle are not at risk. For patients who have suffered penetrating injury, the type and nature of the weapon may be important.

In the initial history taking, it is important to note any previous operations the patient has undergone. Of particular importance are any operations that may have resulted in splenectomy (ie, previous operations for hematologic disease or abdominal trauma). Any preexisting conditions that might predispose the spleen to enlargement or other abnormality should be asked about. The patient or significant others should be asked about the presence of hepatic disease, ongoing anticoagulation, or recent usage of aspirin or nonsteroidal anti-inflammatory drugs.

On physical examination, it is important to determine if the patient has left rib pain or tenderness. Left lower ribs are particularly important in that they overlie the spleen,

especially posteriorly. Even with tenderness over the left lower ribs as their only indication of possible abdominal injury, 3% of patients will have a splenic injury.[18] In children, the plasticity of the chest wall allows for severe underlying injury to the spleen without the presence of overlying rib fractures. Such a phenomenon is also possible in adults but is less common than it is in children.

The absence of tenderness over the left lower ribs does not preclude the presence of an underlying splenic injury and, in some cases, may be related to an altered level of consciousness from an associated traumatic brain injury (TBI) or intoxication. In elderly patients, rib fractures may not manifest in a fashion similar to that seen in younger patients. Patients over the age of 55 may not describe lower rib pain and may not have particularly noteworthy findings on physical examination despite severe trauma to the chest wall and an underlying splenic injury.

Another finding on physical examination that is occasionally helpful in the presence of a splenic injury is the presence of Kehr's sign. Kehr's sign is the symptom of pain near the tip of the left shoulder secondary to pathology below the left hemidiaphragm. There is minimal shoulder tenderness, and the patient typically does not have pain on range of motion of the left arm and shoulder unless there is an associated musculoskeletal injury. Kehr's sign after splenic injury is the result of irritation of the diaphragm by subphrenic blood. The sensory innervation of the left hemidiaphragm comes from cervical roots 3, 4, and 5, which are redundant for the ipsilateral shoulder, and referred pain from the diaphragmatic irritation causes the left shoulder pain. Although it is relatively uncommon, the presence of Kehr's sign shortly after trauma should increase the index of suspicion for splenic injury.

The physical examination of the abdomen sometimes demonstrates localized tenderness in the left upper quadrant or generalized abdominal tenderness, but not all patients with splenic injury will reliably manifest peritoneal or other findings on physical examination. Ecchymoses or abrasions in the left upper quadrant or left lower chest may also be present. The unreliability of the physical examination of the abdomen is obvious in patients with an altered mental status and may be absent in patients with normal mentation as well. As a consequence, imaging of the abdomen in hemodynamically stable patients has become an important element of diagnosis and management.

There are no laboratory studies specific to patients with splenic injury, although a hematocrit and type and crossmatching of blood are useful initial laboratory tests. Coagulation studies may be warranted if there is reason to believe that the patient is coagulopathic. As with all other early posttraumatic bleeding, splenic bleeding will not always cause a drop in initial hematocrit. An extremely low hematocrit on arrival of the patient in the resuscitation room, however, especially if the transport has been short and prehospital fluid resuscitation has been minimal, should alert the surgeon to the possibility of severe ongoing hemorrhage.

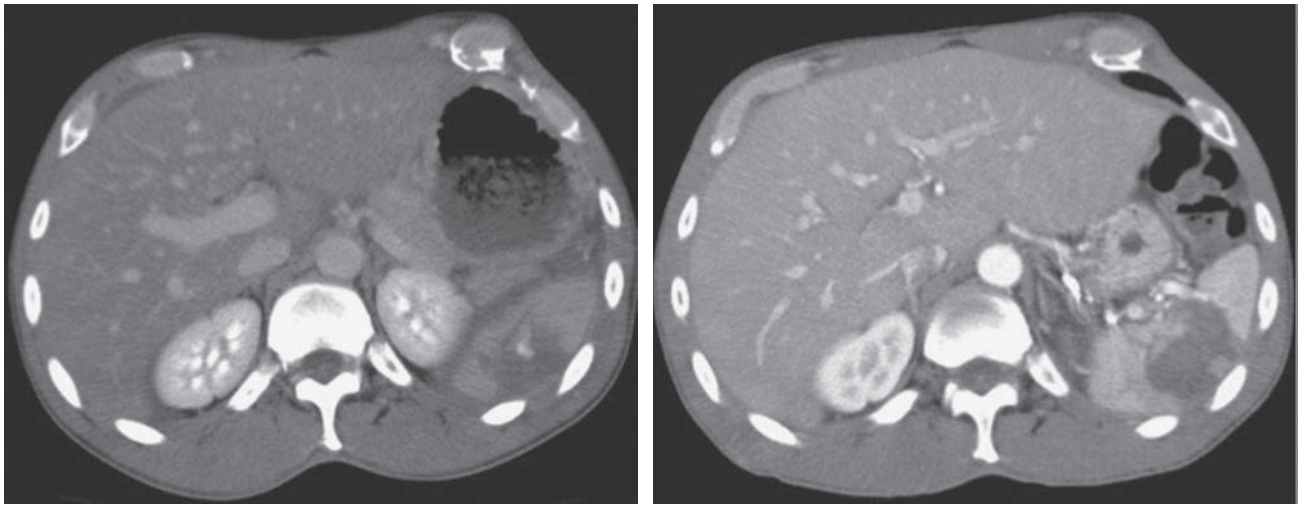
Plain x-rays generally are not helpful in the diagnosis of splenic injury. Rupture of the left hemidiaphragm is sometimes apparent on an initial chest x-ray, however, and can suggest an associated splenic injury. A severe pelvic fracture on an anteroposterior pelvic film can sometimes be of importance in subsequent decision making about how to manage a splenic injury, as the presence of simultaneous splenic and severe pelvic injuries may dictate the removal of the spleen. When penetrating trauma is the mechanism of injury, an initial chest x-ray is important in assessing for associated thoracic injury and, in the case of gunshot wounds, helping to determine the path of a bullet and the location of a retained bullet or bullet fragments.

IMAGING AND DIAGNOSTIC PERITONEAL LAVAGE

Diagnostic peritoneal lavage (DPL) is used much less frequently now. Its role as an initial diagnostic maneuver to dictate subsequent testing or operative intervention has been supplanted in many institutions by both ultrasonography and CT scanning of the abdomen. Peritoneal lavage maintains some utility when ultrasonography is not available in that it is a quick way of determining if a hemodynamically unstable patient has intraperitoneal bleeding. Although DPL is not specific for splenic injury, ongoing intraperitoneal hemorrhage results in a positive peritoneal lavage that should prompt timely operative intervention. DPL may not yield positive results when there is an associated diaphragmatic injury because the instilled fluid may be decompressed and retained in the pleural space. If the DPL yields little or no return of fluid, a diaphragmatic injury should be considered and extraperitoneal sources of hemorrhage assessed.

Ultrasound of the abdomen for free fluid, the so-called focused assessment with sonography in trauma (FAST) exam, is now an essential imaging modality in diagnosing hemoperitoneum in patients with blunt trauma, and in many institutions it has become an additional adjunct to the primary survey. Like DPL, it is most useful for guiding management in unstable patients, but it may also determine the need for further imaging in stable patients. As with peritoneal lavage, the ability of ultrasound to localize bleeding to specific organs in the peritoneal cavity is limited. Small injuries and subcapsular hematomas of the spleen can also be missed by ultrasonography if they do not result in a significant hemoperitoneum. There have been attempts to use ultrasound not only to diagnose intraperitoneal fluid, but also to diagnose specific injuries such as splenic injuries. Such attempts have met with limited success, and the most common reason to perform FAST exams is for detection of intraperitoneal fluid as a determinant of the need for either further imaging of the abdomen or emergency surgery.

CT scanning of the abdomen is the most common imaging study that may allow for nonoperative management of a splenic injury. When performed, it should be done with intravenous contrast and using dual-phase imaging. Oral contrast is much less helpful and does not increase the sensitivity of CT for detecting a splenic injury. The importance of



A B

FIGURE 34-4 Computed tomography (CT) images of the abdomen from a 43-year-old male who was assaulted with a bat. (**A**) Representative delayed-phase CT image obtained the day of injury demonstrates a grade IV injury with active extravasation. (**B**) CT image after angioembolization shows partial splenic infarct and no extravasation.

dual-phase imaging was demonstrated by Bosack et al[19] in a retrospective review of 120 blunt abdominal trauma patients. Dual-phase CT has better overall diagnostic performance than single-phase CT for detection of splenic trauma. The arterial phase was important for the diagnosis of splenic pseudoaneurysms, while the portal venous phase was better for the detection of active bleeding and parenchymal injuries.

Radiation exposure from CT, especially in children, has been raised as a potential concern, and some selection should be used with respect to which patients with abdominal trauma should undergo scanning.[20] Undue concern about radiation, however, should not put a patient at risk for a missed splenic injury and occult bleeding.

The findings of splenic injury on CT scan are variable. Hematomas and parenchymal disruption generally show up as hypodense areas. Free fluid can be seen either around the spleen or throughout the peritoneal and pelvic spaces. Locations where fluid frequently accumulates after splenic injury are Morrison's pouch, the paracolic gutters, and the pelvis. When a large amount of fluid is present in the peritoneal cavity, it can sometimes be seen between loops of small bowel as well as in the subphrenic spaces.

When looking at CT scans of patients with splenic injury, it is important to also look at the adjacent left kidney and the distal pancreas. Injury to the spleen implies a blow to the left upper quadrant that can injure adjacent organs. The diagnosis of a pancreatic injury is particularly important in that this can significantly affect the patient's subsequent course and prognosis. Also, it is important to remember that the presence of free fluid is not solely related to bleeding from a visible splenic injury in all cases. One of the pitfalls of CT diagnosis is that free fluid in the peritoneal cavity or in the pelvis may be attributed to a splenic injury when in fact the fluid is secondary to both a splenic injury and an associated injury to the mesentery or bowel.

Other than an obvious injury, the most important CT finding in the spleen is the presence in the disrupted splenic parenchyma of a "blush," which represents active bleeding from a vascular injury and appears as a hyperdense area of contrast that becomes brighter in subsequent phases (Fig. 34-4). Other vascular injuries are pseudoaneurysms and arteriovenous fistulae, which are radiographically indistinguishable from each other and appear as areas of contrast that fade with subsequent phases. There is evidence that the presence of a vascular injury correlates with an increased likelihood that continued or delayed bleeding will occur, resulting in failure of nonoperative management. These arterial injuries need further assessment with either angiography or repeat CT scanning.[21,22]

It is important to remember that, historically, the CT grade of splenic injury and a patient's subsequent clinical course have only been only roughly correlated. Bleeding and nonbleeding vascular injuries are associated with higher-grade parenchymal injuries on CT scan, but CT scan does not capture all vascular injuries. Therefore, high-grade splenic injuries may warrant empiric splenic angiography.[23]

Magnetic resonance imaging (MRI) has been used sporadically in the diagnosis of splenic injury. The images obtained are sometimes quite impressive but, given that CT scanning has both a very high sensitivity and specificity for the presence of splenic injury (especially when newer generation multidetector scanners are used), MRI so far has not proven to hold an obvious advantage. Furthermore, MRI is usually less available than is CT scanning, especially after hours. The logistical difficulties inherent in trying to obtain MRIs in a badly injured patient who requires close monitoring and, possibly, even mechanical ventilation make MRI even less helpful as a diagnostic modality. Continued improvements in MRI and our increasing ability to use it even for critically ill patients could conceivably increase the role of MRI in the characterization of splenic injury in the future.

Radioisotope scintigraphy and conventional angiography were each used for diagnosis of splenic injury in the past but are largely of historical interest at this point, as they have been replaced by CT, as described earlier. Angiography with embolization for bleeding does, however, have an important therapeutic role in the management of splenic injury.

GRADING SYSTEMS FOR SPLENIC INJURY

Based primarily on the CT imaging characteristics of the spleen, a number of different grading systems have been devised to quantify the degree of injury in patients with injured spleens.[24-26] Widespread use of an Organ Injury Scale (OIS) allows for objective standardization of terminology and ensures that individual injuries are described in precise terms understandable to others. Standardized organ injury scaling is useful in clinical research, in describing populations of splenic injury patients, and in risk stratifying patients for treatment algorithms (Fig. 34-5).

Based on available published literature and a consensus of experts in the field, in 2018, the American Association for the Surgery of Trauma (AAST) developed a revised OIS for splenic injuries (Table 34-1).[27] The Solid Organ Injury Scale includes three sets of criteria to assign grade: imaging, operative, and pathologic.

The updated spleen OIS is structured, as with the prior scale, by grades I through V. The most significant change is the incorporation of CT-diagnosed vascular injury, defined as pseudoaneurysm, arteriovenous fistula, or active bleeding. Presence of vascular injury regardless of parenchymal destruction results in a grade IV or V, with the latter defined by active bleeding beyond the splenic capsule. The consideration of these high-risk imaging features in the revised scale acknowledges the increased risk of failure of nonoperative management in their presence and thus provides a potential branch point for the decision to pursue angiography or other splenic intervention.[28]

NONOPERATIVE MANAGEMENT

Nonoperative management of splenic injury has become more common over time. Although approximately 40% of patients with splenic injury will require immediate operative intervention, nonoperative management is reasonable for hemodynamically stable patients.[29]

Patient Selection

Appropriate patient selection is the most important element of nonoperative management. Determining which patients require emergency surgery and which can be initially managed nonoperatively is a multifactorial decision, although hemodynamic status, age, grade of splenic injury, quantity of hemoperitoneum, and associated injuries have been shown to roughly correlate with the success or failure of nonoperative management. The decision for nonoperative management must also consider the institutional resources available.

Of paramount importance in the determination of the appropriateness of nonoperative management is the hemodynamic stability of the patient. Hemodynamic stability can be a somewhat illusory concept and one for which there is no consensus definition. Stability in itself is a beguiling term when describing an acute trauma patient, because patients in shock may maintain stable vital signs until they abruptly decompensate, requiring rapid treatment and further diagnostic maneuvers. Hypotension is generally considered to be worthy of concern. Historically, a prehospital systolic blood pressure (SBP) less than 90 mm Hg has mandated triage to a trauma center. In fact, that criterion is too low, because a prehospital SBP of less than 110 mm Hg has been shown to be associated with poor outcomes.[30,31] Hypotension in the prehospital period or emergency department is worrisome, and a high index of suspicion for ongoing hemorrhage should be maintained when either is present. Patients who have been hemodynamically unstable in the prehospital phase and remain hemodynamically unstable during their initial emergency department stay are, in most instances, inappropriate candidates for abdominal CT scanning. They require either a direct trip to the operating room (OR) or at least a FAST exam to help guide the initial decision-making process.

Assuming hemodynamic stability, the other important prerequisite for consideration of nonoperative management is the patient's abdominal examination. In patients who are awake and alert and can cooperate with a physical examination and provide feedback, it is important that they not have diffuse peritonitis. Although patients with splenic injury will often have localized pain and tenderness in the left upper quadrant and abdominal findings secondary to intraperitoneal blood, obvious diffuse peritonitis can be a sign of intestinal injury and mandates an abdominal exploration. If a patient with a splenic injury is sent for CT scanning and subsequent nonoperative management, it is important to perform repeat physical examinations. If the examination worsens, the possibility of a blunt intestinal injury should be considered. The most common CT finding in patients with blunt intestinal injury is free fluid in the peritoneal cavity. As previously noted, the free fluid can be mistakenly attributed solely to the splenic injury, and the presence of an associated injury to the bowel can be missed.

The success rates of nonoperative management of splenic injuries are very high in many of the published series. Reported success rates for nonoperative management are 95% or higher for pediatric patients and 80% to 94% in adults.[32-34] These high success rates can be misleading, however, in that they apply only to the group of patients in whom nonoperative management was chosen rather than all patients with splenic injury. When patients undergoing immediate splenectomy are included, the overall splenic salvage rates tend to be 50% to 60% in adult patients. It is important to remember that these series generally do not include patients in whom the initial plan was for nonoperative management, but an emergency operation was necessary when the patient became

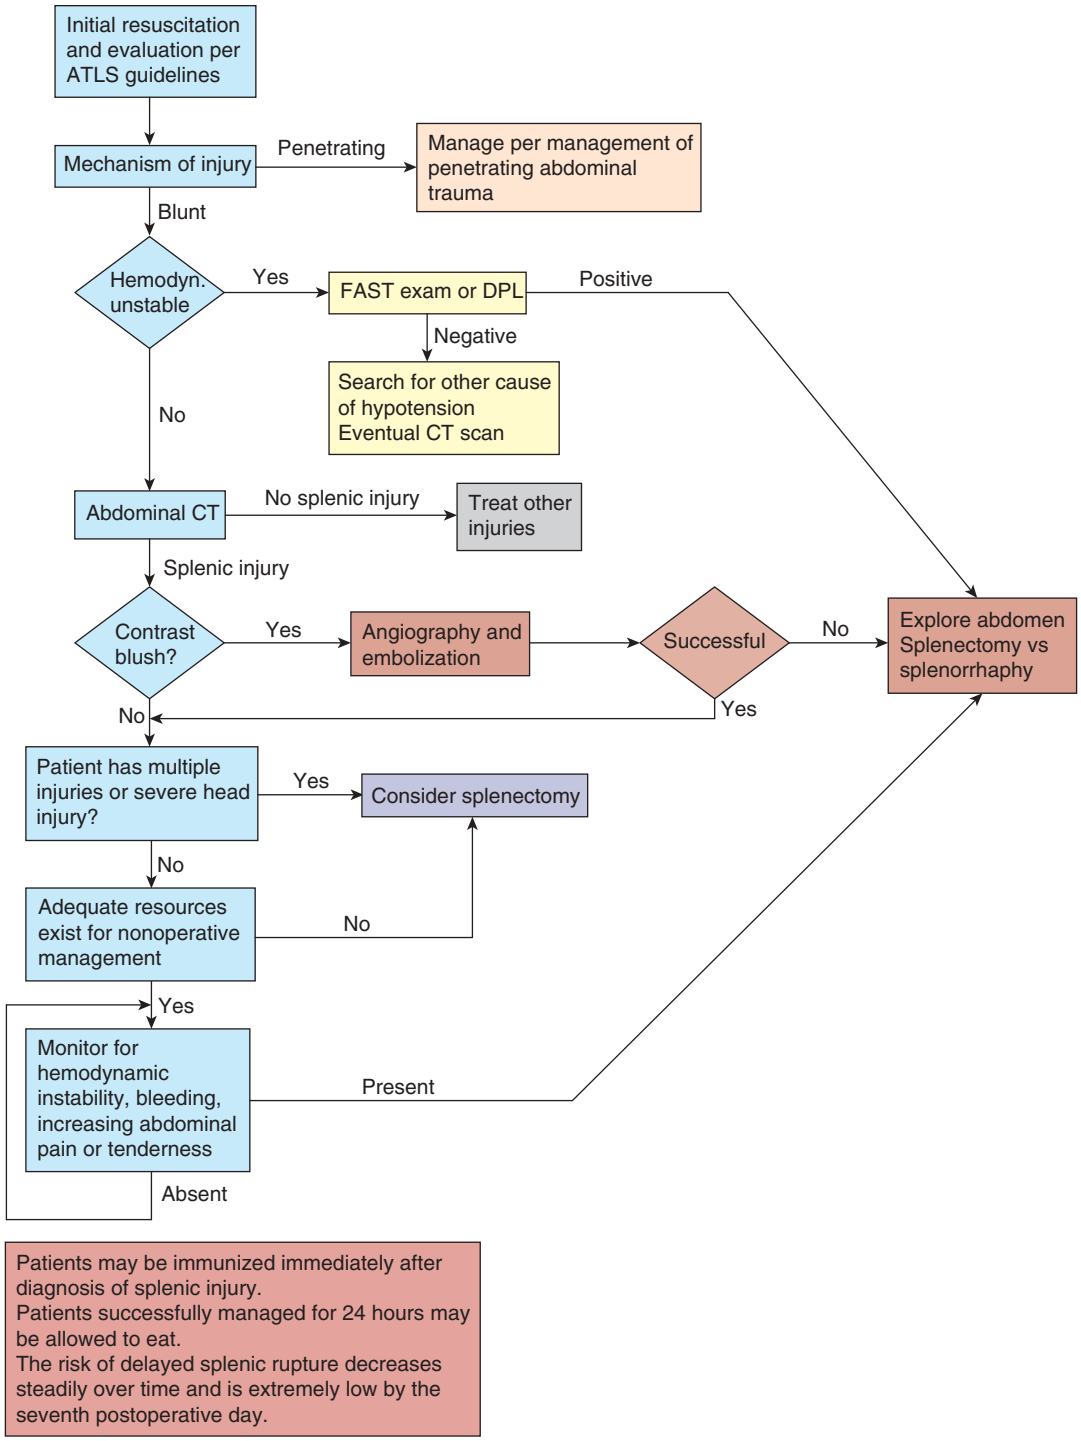


FIGURE 34-5 Algorithm for the diagnosis and management of splenic injury. ATLS, Advanced Trauma Life Support; CT, computed tomography; DPL, diagnostic peritoneal lavage; FAST, focused assessment with sonography in trauma; Hemodyn., hemodynamically.

hypotensive or developed peritonitis in the emergency department or in the CT scanner. The published series of nonoperatively managed spleens generally include only the selected patients who were stable enough to undergo CT scanning of the abdomen and in whom the CT scan showed an injured spleen. Patients who became unstable either before or during the scan and were taken emergently to surgery are usually not counted as patients who underwent "nonoperative" management. When these patients are reported at all, they are placed into the "operative" group rather than into the "failed nonoperative" group. Published series of splenic injuries, particularly in pediatric patients, are more likely to describe patients

TABLE 34-1: The Splenic Organ Injury Scaling System of The American Association for The Surgery of Trauma, 2018 Revision

AAST grade[a]	AIS severity	Imaging criteria	Operative criteria	Pathologic criteria
I	2	• Subcapsular hematoma <10% surface area • Parenchymal laceration <1 cm depth • Capsular tear	• Subcapsular hematoma <10% surface area • Parenchymal laceration <1 cm depth • Capsular tear	• Subcapsular hematoma <10% surface area • Parenchymal laceration <1 cm depth • Capsular tear
II	2	• Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <5 cm • Parenchymal laceration 1–3 cm	• Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <5 cm • Parenchymal laceration 1–3 cm	• Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <5 cm • Parenchymal laceration 1–3 cm
III	3	• Subcapsular hematoma >50% surface area; ruptured subcapsular or intraparenchymal hematoma ≥5 cm • Parenchymal laceration >3 cm depth	• Subcapsular hematoma >50% surface area or expanding; ruptured subcapsular or intraparenchymal hematoma ≥5 cm • Parenchymal laceration >3 cm depth	• Subcapsular hematoma >50% surface area; ruptured subcapsular or intraparenchymal hematoma ≥5 cm • Parenchymal laceration >3 cm depth
IV	4	• Any injury in the presence of a splenic vascular injury[b] or active bleeding confined within splenic capsule • Parenchymal laceration involving segmental or hilar vessels producing >25% devascularization	• Parenchymal laceration involving segmental or hilar vessels producing >25% devascularization	• Parenchymal laceration involving segmental or hilar vessels producing >25% devascularization
V	5	• Any injury in the presence of splenic vascular injury with active bleeding extending beyond the spleen into the peritoneum • Shattered spleen	• Hilar vascular injury that devascularizes the spleen • Shattered spleen	• Hilar vascular injury that devascularizes the spleen • Shattered spleen

[a]Grade based on highest grade assessment made on imaging, at operation, or on pathologic specimen. More than one grade of splenic injury may be present and should be classified by the higher grade of injury. Advance one grade for multiple injuries up to a grade III.
[b]Vascular injury is defined as a pseudoaneurysm or arteriovenous fistula and appears as a focal collection of vascular contrast that decreases in attenuation with delayed imaging. Active bleeding from a vascular injury presents as vascular contrast, focal or diffuse, that increases in size or attenuation in delayed phase. Vascular thrombosis can lead to organ infarction.

treated at referral centers where there are large numbers of transfer patients who have already been triaged for stability prior to their arrival at the referral center. Finally, the literature on the success of nonoperative management of splenic injury should be interpreted with the awareness that publication bias tends to favor series in which success rates are high.

Other important considerations beyond hemodynamic stability and abdominal findings in the determination of the appropriateness of nonoperative management have to do with the medical environment and some specific characteristics of the patient. Nonoperative management should generally be undertaken only if it will be possible to closely follow the patient. If close inpatient follow-up is simply not possible, abdominal exploration may be appropriate. Similarly, if rapid mobilization of the OR and quick operative intervention in the case of ongoing or delayed bleeding is not possible, early rather than emergent operative intervention may be appropriate. Finally, the patient's circumstances after discharge occasionally may be important in the decision-making process. Risk of delayed bleeding after 24 hours of successful nonoperative management for grade I splenic injuries is rare. Nonetheless, for patients who are to be discharged to a location remote from medical care, the consequences of delayed bleeding are greater in that they may not be close enough to a hospital that can perform an emergency operative procedure. In such circumstances, an otherwise reasonable candidate for nonoperative management may be considered for operative intervention.

For patients who are stable enough to undergo CT scanning and in whom an injured spleen is identified, nonoperative management is reasonable if they continue to remain

stable. In addition to vital signs, one of the other commonly followed parameters in such patients is the hematocrit. A common practice is to determine a cutoff value below which the hematocrit will no longer be simply monitored. If the hematocrit drops to that level or below, operative intervention is undertaken. Such an approach works best if there are no associated injuries; when associated injuries are present, it can be quite difficult to know if the spleen is continuing to bleed or if the fall in hematocrit is secondary to bleeding from other injuries.

In general, there is consensus that hemodynamically stable patients without peritonitis who can be followed closely are candidates for nonoperative management. Historically, there has been a debate about certain subgroups of patients and their appropriateness for nonoperative management.[35]

Pediatric patients are excellent candidates for nonoperative management because they have a low incidence of delayed bleeding after splenic injury.[36,37] As nonoperative management has become the standard of care in this population, there has been an increase in angioembolization with great success.[38,39] Because of the trauma mechanisms suffered by pediatric patients as opposed to adult patients, children are more likely to have isolated splenic injuries. As previously noted, the relative thickness of the splenic capsule is greater in children, which likely confers more structural integrity to the spleen. The spleen in children is also more likely to fracture parallel to the splenic arterial blood supply rather than transverse to it (Fig. 34-6).[40] This orientation of splenic injury tends to decrease the amount of blood loss from the splenic parenchyma. Children are more likely to have excellent physiologic reserve and minimal preexisting disease. Finally, the risks of splenectomy with respect to immunologic consequences are greater in young children than they are in adults.

Historically, older patients were thought to have a worse prognosis with respect to nonoperative management than younger patients. Other series examining the question of the threshold at 55 years of age and nonoperative management suggest the success of nonoperative management is no different in this group than it is in younger patients. In fact, there is an increasing body of evidence that being elderly is not a contraindication for nonoperative management, although the evidence in this area is still somewhat conflicting.[41,42]

The presence of severe associated injuries, particularly a TBI, has been suggested as another relative contraindication to nonoperative management of a splenic injury. As previously mentioned, following the hematocrit in a patient with severe associated injuries can be difficult to interpret because the underlying hemorrhage may not be attributable to the spleen alone. Furthermore, the effects of ongoing or delayed splenic bleeding are felt to negatively impact the prognosis of a severe TBI if secondary injury from hypotension is incurred.

Although these factors do not mandate operative intervention in all patients who fall into these groups, they should lower the threshold for operative intervention on an individual basis.

There is little uniformity about what constitutes a "failed" attempt at nonoperative management. Different surgeons and different institutions have set different criteria for operative intervention, and much of the decision making is subjective. As has already been pointed out, there is no perfect relationship between the severity of injury seen on CT scanning and a patient's subsequent success or failure of nonoperative management. However, higher grade injuries are less likely to succeed with observation alone, and the revised AAST grading criteria take this into account. Some of this discrepancy is probably related to the imperfect nature of the scoring systems and a lack of sensitivity of CT scanning. Also, it is likely that some of the differences are in the approach and thresholds for operative intervention. In some instances, concern about a "bad-looking" spleen on a CT scan might prompt more aggressive and quicker surgical intervention and make failed nonoperative management of severe splenic injuries a self-fulfilling prophecy.

As previously noted, an objective finding on CT scan that has proven useful as a prognostic sign with respect to nonoperative management is that of a vascular injury (eg, pseudoaneurysm, arteriovenous fistula, or active bleeding) in the injured spleen (Fig. 34-4). In general, a vascular injury seen on initial CT scan should be evaluated with angiography and treated with embolization if ongoing bleeding is present and the patient is normotensive (Fig. 34-7). Active bleeding on CT scan is also associated with a higher need for operative intervention. This approach seems reasonable because angiography with splenic embolization has improved success rates in patients managed nonoperatively. The most dramatic improvement is seen in patients with higher-grade splenic injuries. A 2011 meta-analysis revealed a decrease in nonoperative failure rates from 44% to 17% in grade IV injuries and from 83% to 25% in grade V injuries.[43] To optimize therapeutic potential and resource utilization, only patients

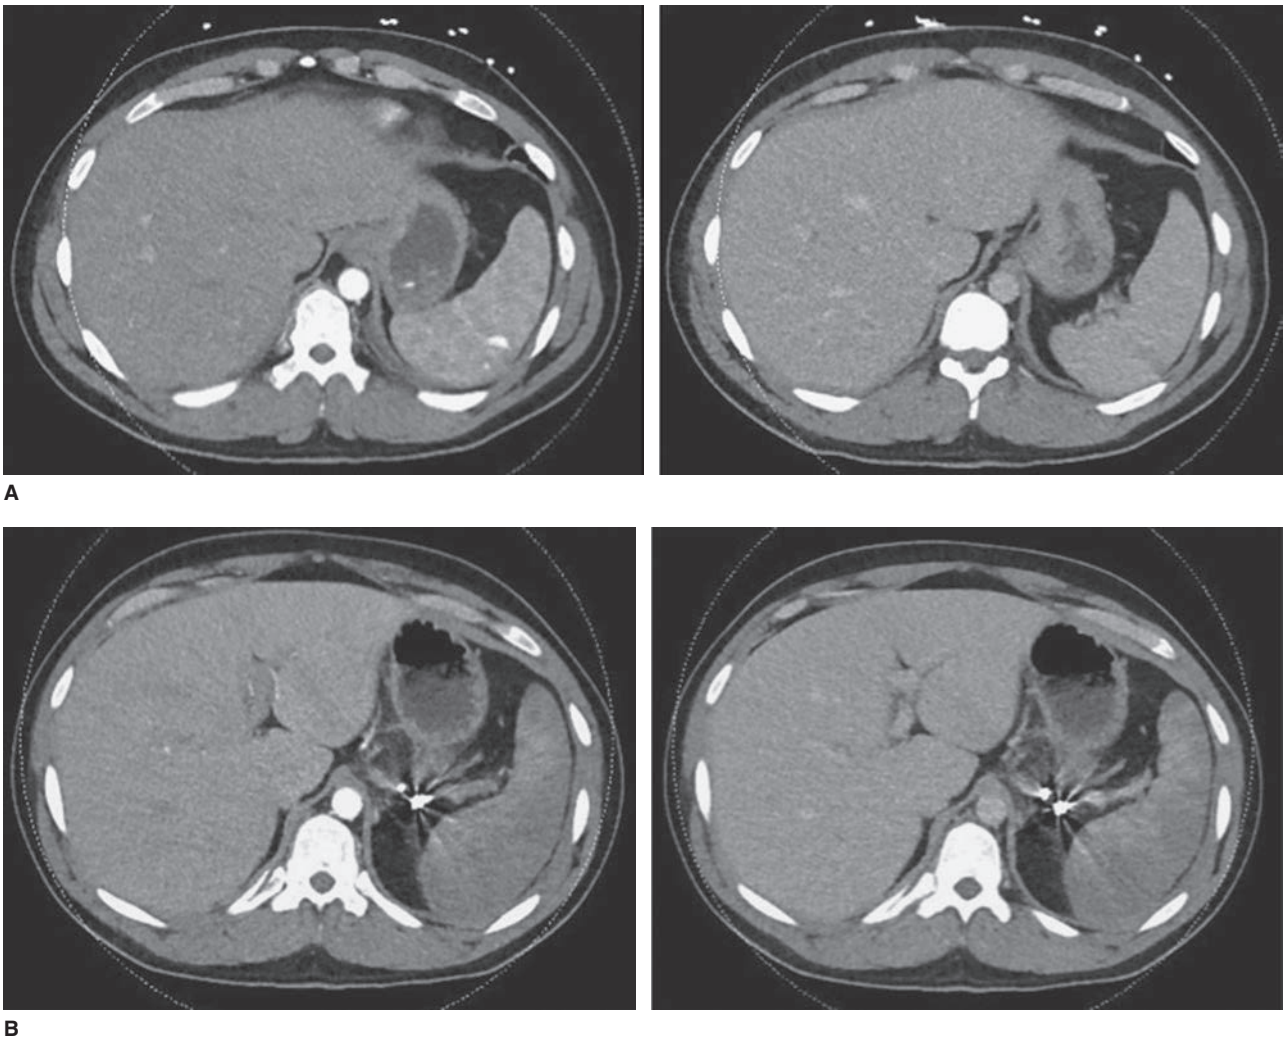

FIGURE 34-7 Computed tomography (CT) images of the abdomen from a 28-year-old male involved in a motor vehicle collision. Representative images with the arterial phase on the left and portal venous phase on the right. (**A**) CT scan reveals a pseudoaneurysm seen in the arterial phase. (**B**) CT images after angioembolization show no evidence of pseudoaneurysm.

with high-grade splenic injuries should undergo angiographic embolization. Prospective evaluation of a protocol to perform angiography and embolization on grade III to V splenic injuries revealed significantly decreased failure rates in the protocol group.[44]

Patient Management

After nonoperative management has been selected, the initial resuscitation should be continued and other diagnostic and therapeutic procedures carried out as necessary. There is little scientific evidence to dictate the specifics of how nonoperative management of splenic injury should be done. The most rigorous attempts to systematize recommendations for nonoperative management have been in children; however, those guidelines may overestimate the minimum amount of time needed for inpatient observation (Table 34-2).[45-47] Strong consideration should be given to admitting to a monitored unit for the patient's initial nonoperative management. This may include patients with at least grade III splenic injuries and patients with multiple associated injuries that make following serial hematocrit levels and physical examinations difficult, and in some centers, even lower-grade injuries. Most centers monitor such patients for 24 to 72 hours. Although there are some theoretical reasons why bed rest might be a good idea, there is little empirical evidence that it makes a difference and it is no longer commonly practiced. The patient's vital signs and urine output should be monitored closely, serial physical examinations performed, and serial hematocrits measured.

Vaccines against encapsulated organisms, *Streptococcus*, meningococcus (*Neisseria meningitidis*), and *Haemophilus influenzae* infections may be considered as part of nonoperative management in high-risk patients. There are some

TABLE 34-2: Proposed Guidelines for Resource Utilization in Children with Isolated Spleen or Liver Injury

	CT grade			
	I	II	III	IV
ICU stay (days)	None	None	None	1
Hospital stay (days)	2	3	4	5
Predischarge imaging	None	None	None	None
Postdischarge imaging	None	None	None	None
Activity restriction (weeks)[a]	3	4	5	6

[a]Return to full-contact, competitive sports (ie, football, wrestling, hockey, lacrosse, mountain climbing) should be at the discretion of the individual pediatric trauma surgeon. The proposed guidelines for return to unrestricted activity include "normal" age-appropriate activities.

theoretical reasons to believe that the vaccinations are more effective if given while the spleen is still in situ. The evidence to support such a practice, however, is contradictory, and it is very difficult to study the effectiveness of vaccination timing even in splenectomized patients because the incidence of overwhelming postsplenectomy infection is extremely low.

How long a patient should be kept in the hospital is poorly defined. There is no strong evidence supporting any particular approach, but a large multi-institutional study showed that most failures of nonoperative management occur within the first 6 to 8 days after injury.[48] Some institutions will keep patients in the hospital for an arbitrary length of time, which may range from several days to up to 1 week. Longer periods of observation have obvious financial and insurance implications but will pick up most of the delayed bleeds while the patient is still an inpatient. Our institutional approach is to consider the grade of injury, associated injuries, and social situation of the patient to determine the length of hospital stay. In many circumstances, associated injuries dictate the length of hospitalization more than does the splenic injury. Also, it is important to pay attention to where the patient lives and how close he or she will be to medical attention when deciding about timing of discharge. Patients without the ability to obtain immediate medical attention may need to be kept in the hospital longer.

Prophylaxis against deep venous thrombosis (DVT) is a continuing problem in patients undergoing nonoperative management for a splenic injury. Sequential compression devices on the lower extremities should be used routinely. Early mobilization or range-of-motion exercises are also important in minimizing thromboembolic complications. Pharmacologic prophylaxis is more problematic because of concerns about exacerbating bleeding from the injured spleen. After 24 to 48 hours of successful nonoperative management, it is reasonable to begin pharmacologic prophylaxis against DVT. If associated injuries require it, warfarin prophylaxis is also reasonable beginning approximately 1 week after injury. These recommendations are based primarily on physician gestalt rather than large series data; however, there are an increasing number of studies supporting the safe use of early DVT chemoprophylaxis in the nonoperative management of patients with blunt splenic injuries.[49,50] Both the rate of clinically significant thromboembolic events in patients with splenic injury and the rate of failure of nonoperative management in anticoagulated patients are quite low, making prospective study of the risks and benefits of anticoagulation prophylaxis in this patient population difficult.

The issue of follow-up CT scans in patients undergoing nonoperative management of splenic injuries is controversial.[51,52] Most series indicate that they are not necessary or that the frequency with which they alter management is extremely low. A variety of different suggestions have been made in the literature about follow-up CT scans, ranging from no follow-ups at all to routine follow-ups at frequent intervals. The rationale is that some patients have developed pseudoaneurysms of the spleen on follow-up imaging, even if the initial CT scan did not demonstrate a vascular injury. The author's institutional policy is to study only patients who have persistent abdominal signs and symptoms after a week or more of observation.

When patients are discharged, they should be counseled not to engage in contact sports or other activities during which they might suffer a blow to the torso. The best length of time to maintain this admonition is unknown, but typical recommendations range from 2 to 6 months. There is experimental evidence that most injured spleens have not recovered their normal integrity and strength until at least 6 to 8 weeks after injury, so the recommendation to avoid contact sports for 2 to 6 months seems reasonable. Other than with respect to contact sports, there are no major restrictions for patients who have undergone successful nonoperative management.

OPERATIVE MANAGEMENT (SEE ATLAS FIGURES 56, 57, AND 58)

In general, preoperative antibiotics should be given but do not need to be continued in the postoperative period unless dictated by associated injuries. A nasogastric tube is inserted

during the procedure to decrease the volume of the stomach and allow for easier visualization and mobilization of the spleen.

A midline incision is the best incision for splenic surgery as well as most trauma operations on the abdomen. It is versatile, can be extended easily both superiorly and inferiorly, and is the quickest incision if speed of intervention is important. For operations on an injured spleen, it may be necessary to extend the incision superiorly and to the left of the xiphoid process. This maneuver improves exposure of the left upper quadrant, particularly in obese patients and those with a narrow costal angle.

Transverse incisions in the left upper quadrant have occasionally been suggested for patients with a presumed isolated splenic injury. A midline incision is preferable because it is quicker and allows the surgeon to deal with a variety of different intra-abdominal findings. One situation in which a left subcostal approach may be the incision of choice is when the patient is morbidly obese and preoperative CT scanning has suggested that an isolated splenic injury is present or the patient has had a prior midline laparotomy concerning for a hostile abdomen.

As with all trauma laparotomies, it is important to rapidly examine all four quadrants of the abdomen in patients who are hemodynamically unstable. This initial investigation of the abdomen should not be definitive. It should only be used for rapid exploration and packing, especially of the upper quadrants. Definitive management of any injuries found should not be attempted until the entire abdomen has been inspected. While the quadrants are being inspected, it is helpful to look for clot. Clotting tends to localize to the site of injury, whereas defibrinated blood will spread diffusely in the abdomen. Clotted blood will often indicate the site of an injury and is helpful in determining where to direct definitive management after the abdomen has been packed.

In patients who are thought to have an isolated splenic injury based on initial imaging or failed nonoperative management, direct attention can be turned sooner to the left upper quadrant. If viscera other than the spleen seem to be more badly injured and are bleeding more profusely than the spleen, the spleen should necessarily take second priority and be left packed until it is appropriate to attend to it. In comparison, a quick splenectomy is often a wise early move in a patient with multiple serious injuries in that it rapidly eliminates the splenic hemorrhage as a source of ongoing shock.

Once attention has been directed to the left upper quadrant, all the structures in that quadrant should be inspected (Fig. 34-2). There should be an initial look at the greater curvature of the stomach and the left hemidiaphragm. If the spleen is mobilized, the left hemidiaphragm should be reinspected. If the left hemidiaphragm is injured in a patient with blunt trauma and the spleen is in the left side of the chest, it should be pulled down into the abdomen through the defect. The left lobe of the liver and left kidney should also be inspected, as should the tail of the pancreas. If the spleen is to be mobilized, inspection of the tail of the pancreas is easier after mobilization has been accomplished.

The anterior and anterolateral surfaces of the spleen can sometimes be seen fairly easily through the midline incision prior to any splenic mobilization, particularly if the patient is thin and there is a wide costal margin. If the patient is heavy and/or the costal margin is narrow, adequate inspection without some splenic mobilization may be very difficult. If the left upper quadrant is adequately inspected and there is no evidence of any bleeding or a splenic injury, the spleen does not require mobilization. If it is known that there is a small splenic injury, but it is not the primary reason for abdominal exploration or the spleen does not seem to be bleeding at the time of exploration, splenic mobilization is also not always necessary. If the surgeon is in doubt about the need for mobilization, the best thing to do is to mobilize the spleen so that the full extent of injury is elucidated and the spleen can be repaired or removed as necessary. It is important to be as gentle as possible during mobilization of the spleen so that the splenic injury is not worsened.

Splenic mobilization should be done in a stepwise fashion to provide adequate mobilization while minimizing the chance of furthering injury. Proper mobilization allows for better visualization of the left kidney, the left hemidiaphragm, and the posterior aspects of the body and tail of the pancreas. The sequence of splenic mobilization is important in that it allows for splenic salvage and splenorrhaphy up until the final step of hilar ligation.

In mobilizing the spleen, it is important to remember how posteriorly it is situated (Fig. 34-2). Also, it is important to remember that there is a great deal of variability in the length of the different ligaments around the spleen and in how mobile the spleen is before any dissection is done. If mobilization is done correctly, even spleens with fairly short surrounding ligaments and spleens in obese patients can be mobilized to a level at or above the anterior abdominal wall.

The first step in mobilization of the spleen is to cut the splenophrenic and splenorenal ligaments laterally (Fig. 34-8). This step should be started with sharp dissection and can then be continued with a combination of blunt dissection and further sharp dissection. The dissection should be taken up to near the level of the esophageal hiatus so that all the lateral and superior attachments are cut. Cutting the lateral attachments is sometimes facilitated by putting a finger or clamp underneath them and then sharply dividing the overlying plane. In obese patients and in those with a spleen that is very posterior, it may be necessary to do some of the dissection by feel.

After the lateral attachments have been divided, the next step is to mobilize the spleen and tail of the pancreas as a unit from lateral to medial. One of the easier ways to do this is to cup the nondominant hand over and around spleen while sliding the back of the fingertips against the underlying left kidney, thus elevating the spleen and pancreas from the retroperitoneal bed. The kidney can be palpated easily because it is quite firm and provides an excellent landmark for the proper plane of dissection. A common error is to try to mobilize the spleen alone without the adjacent pancreas. Not mobilizing the pancreas with the spleen is easy to do if the surgeon is not posterior enough and is not in the plane between the

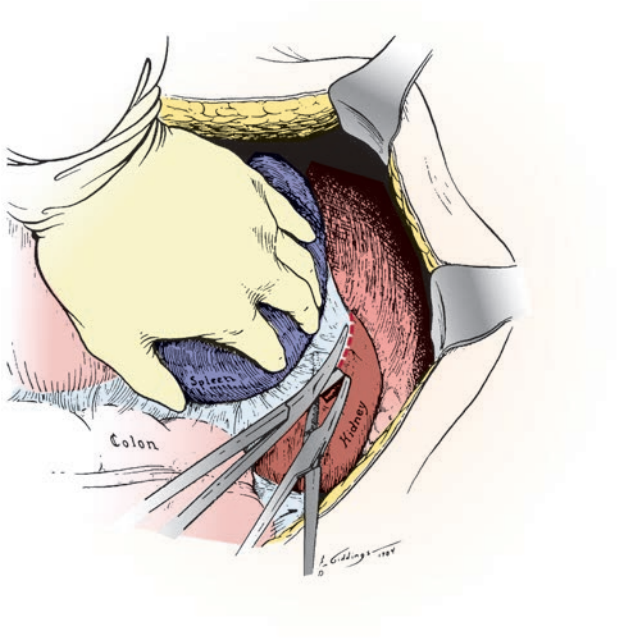

FIGURE 34-8 Mobilization of the spleen is begun by early division of its lateral attachments.

tail of pancreas and kidney. If the tail of the pancreas is not mobilized with the spleen, the degree of splenic mobilization possible is much more limited and it is more difficult to avoid injury to the spleen.

Injuries can occur during mobilization of the spleen. The splenic hilum can be damaged from behind as the surgeon's fingers attempt mobilization from lateral to medial. The pancreas is more difficult to see if it is not mobilized with the spleen and can be damaged during hilar clamping if the spleen is to be removed. The pancreas is quite variable in length and requires varying degrees of mobilization. If the pancreas is fairly long, a great deal of its body and tail will require mobilization in order to bring the spleen anteriorly and to the midline.

After the spleen and pancreas have been mobilized as a unit, it is generally apparent that the next constraining attachments of the spleen are the short gastric vessels. Because of the dual blood supply of the spleen through its hilum and through the short gastric vessels, it is possible to divide the short gastric vessels without compromising splenic viability. The best way to divide the short gastric vessels is to have an assistant elevate the spleen and tail of the pancreas into the operative field and then to securely clamp the vessels starting proximally on the greater curvature of the stomach. The short gastric vessels should always be clamped and tied. They can be small and difficult to see, and it is tempting to simply divide the loose tissue between the spleen and stomach with the scissors or electrocautery. This should not be done because the short gastric vessels can then bleed either immediately or on a delayed basis. It is not uncommon for a clamp to encroach on the gastric portion of a short gastric vessel, including a small portion of stomach. In such cases, the tie on the stomach can necrose the wall, leading to a delayed gastric leak. Care should be taken to avoid this situation, but this concern can be addressed by oversewing the short gastric tie on the stomach side with a series of Lembert sutures in the seromuscular layer of the stomach.

The final step necessary for full mobilization of the spleen is division of the splenocolic ligament between the lower pole of the spleen and the distal transverse colon and splenic flexure. Obvious vessels in this ligament should be divided between clamps. During division of both the short gastric vessels and the splenocolic ligament, bleeding from the spleen can be controlled using digital compression of the hilum. If the patient is exsanguinating and the bleeding is massive, occasionally a clamp can be placed on the hilum during the later steps of mobilization. Mass clamping should only be done in extreme circumstances because it increases the chances of injury to the tail of the pancreas.

After the spleen has been fully mobilized, it is possible to inspect it in its entirety and to examine the posterior aspect of the body and tail of the pancreas as well. It is helpful after mobilization to pack the splenic fossa to tamponade any minor bleeding and to help keep the spleen and distal pancreas elevated into the field. During this packing maneuver, the left adrenal gland can be inspected and the left hemidiaphragm reexamined.

Factors that figure into the decision about what to do with the injured spleen after mobilization include the degree of splenic injury, the overall condition of the patient, and the presence of any other intra-abdominal injuries. Obviously, if the spleen is not injured at all, it should be left in place. Similarly, if there is a trivial injury to the spleen and it is not bleeding, the spleen can be simply returned to the left upper quadrant and no further therapy is necessary. If there is a grade I injury of the spleen that is bleeding minimally or not bleeding at all, hemostatic agents can be used to stop the bleeding or prevent future bleeding. A variety of hemostatic agents are available, including microfibrillar collagen, gelatin sponge, and fibrin glue. Whichever agent is chosen, the bleeding from the spleen should have ceased by the time the patient is closed.

If the injury is more severe (grades II and III) and the patient's overall condition is not too serious, splenorrhaphy can be done.[53] Splenorrhaphy has become much less common with the increasing use of nonoperative management. Because we are no longer operating as much on the spleen, especially for lower grades of splenic injury, the number of splenic injuries found at surgical intervention that are amenable to splenorrhaphy has decreased along with experience with the techniques. The simplest version of splenorrhaphy has already been described earlier and is the placement of topical agents. Electrocautery of the spleen is only rarely helpful and has met with limited success, whereas argon beam coagulators may be helpful for hemostasis, especially of parenchyma that has been denuded of splenic capsule.[54,55] The spleen can also be sutured, especially when there is an intact capsule, but it does not hold sutures particularly well. Therefore, it is often necessary to use pledget materials to bolster

the repair. Several different methods for suturing the spleen have been described, and use of monofilament or chromic suture has some advantages in that either is less likely to cause injury while being placed through the splenic parenchyma. The splenic parenchyma is fairly soft even in the presence of an intact capsule, and it is easy to cinch sutures so tightly that the parenchyma is further disrupted.

Partial splenectomy also has been described and is possible because of the segmental nature of the splenic blood supply. A pole or even half of the spleen can be removed, and the remaining spleen will survive provided that its hilar blood supply is left intact. One method of performing partial splenectomy is to ligate the blood supply to the damaged portion of the spleen and then observe the spleen for its demarcation into viable and nonviable portions. The damaged nonviable portion is removed, and the resultant cut splenic parenchyma is made hemostatic with the use of either mattress sutures or mesh wrapping.

Wrapping of either all or part of an injured spleen with absorbable mesh has been used on occasion as well. This technique is moderately time consuming, but reported success rates are high because of careful patient selection. Such an approach should be reserved for highly selected cases of isolated splenic injury in stable patients.

Splenectomy should be performed in patients who are unstable, have serious associated injuries, or have the higher grades of injury (grade IV or V). Bleeding from the splenic parenchyma can be temporarily controlled with digital pressure on the hilum while the spleen is being mobilized. As previously noted, mass clamping of the hilum should be reserved for profoundly hypotensive patients because it increases the risk of damage to the adjacent tail of the pancreas. If the decision has been made to remove the spleen, this is best done with serial dissection and division of the hilar structures after mobilization. Suture ligation should be used for large vessels. As mentioned in the section "Splenic Anatomy," a number of different splenic arterial and venous branches must be divided before removal of the spleen (Fig. 34-3). During the course of this dissection, it is common to encounter accessory spleens in the hilum. If an accessory spleen is encountered, it should be left in place if possible.

A special circumstance is the patient who has failed nonoperative management. The majority of these patients undergo splenectomy rather than splenorrhaphy. One reason is that the spleen is somewhat softer after a period of nonoperative management than it was before injury, and both mobilization of the spleen and splenorrhaphy are more difficult. Also, it is likely that splenic injuries that have failed nonoperative management are worse than injuries that do not fail nonoperative management. Another important factor is that the surgeon operating on a spleen that has failed nonoperative management has already decided that the spleen is a problem and is psychologically prepared for splenectomy at the time of operation. The worst-case scenario for such a surgeon is to perform splenorrhaphy after nonoperative management and have it fail, in which case the patient would require yet another trip to the OR.

As has been mentioned earlier, it is helpful to pack the splenic bed during the latter stages of splenic mobilization and during splenectomy. After the spleen has been removed, the packs in the left upper quadrant should be removed and the splenic fossa reexamined. Inspection of the splenic fossa is facilitated by using a rolled-up laparotomy pad. The laparotomy pad is placed deep in the splenic fossa and then rolled by the surgeon's fingers up toward the cut vessels at the splenic hilum. During the course of this inspection, it is important to carefully visualize the splenic bed, stumps of the splenic vessels, and stumps of the short gastric vessels along the greater curvature of the stomach. This is because postoperative hemorrhage after splenectomy is most commonly related to bleeding from the cut ends of the short gastric vessels.

Splenic tissue has a remarkable ability to survive in ectopic locations even without a clearly identifiable blood supply. Greater or lesser degrees of spontaneous splenosis after splenectomy for trauma are quite common, and patients with splenosis demonstrate some degree of splenic function after splenectomy.[56,57] The observation that accidentally seeded pieces of splenic tissue could survive and function led to the logical suggestion that portions of the spleen could be intentionally autotransplanted to ectopic sites after splenectomy. Studies of autotransplantation in both animals and humans have demonstrated that some of the splenic tissue survives and has some level of function.[58,59] Whether or not enough of it survives without attachment to the splenic artery in an adequately functioning form to provide adequate protection against postsplenectomy sepsis is an open question.[60,61] Reports of overwhelming infection after autotransplantation suggest that autotransplantation is not universally successful in restoring normal immune function.[62] These observations, combined with the relatively time-intensive technique of autoimplantation and the exceedingly low rate of overwhelming postsplenectomy infection, have rendered this practice largely of historical interest.

Drains should not be routinely placed after either splenectomy or splenorrhaphy unless there is concern for an associated pancreatic injury or an associated renal injury if there is concern about a postoperative urine leak.

COMPLICATIONS

Nonoperative Management

The most common complication of nonoperative management of the spleen is continued bleeding. Many cases of the bleeding are probably just persistent bleeding that never stopped after the original injury. In these circumstances, there is hemodynamic instability or a progressive drop in hematocrit. Although about 60% to 70% of the failures of nonoperative management occur early after admission, some occur on a delayed basis, and approximately 10% occur more than 1 week after injury.[46] A recent prospective observational study by Zarzaur et al[63] of 383 patients reported a 0.27% incidence of outpatient bleeding and subsequent splenectomy.

Early failures of nonoperative management can be determined by closely following the patient's hemodynamic status,

hematocrit, and physical examination. In many patients, drop in hematocrit will be gradual and steady, but will ultimately dictate the need for surgical intervention. In other patients, especially those in whom the bleeding is delayed, bleeding can occur rather suddenly and be fairly dramatic. If an emergency operation is not performed in such cases, the patient is at risk for exsanguination. The pathophysiology of persistent bleeding after splenic injury and early failure of nonoperative management is fairly straightforward. The pathophysiology of the more delayed bleeds is less obvious, and there are several hypotheses on why it occurs. One hypothesis is that as the blood in a subcapsular hematoma breaks down, increased osmotic forces pull water into the hematoma and expand the capsule. A similar pathophysiology has been described as an explanation for the increase in size of subdural hematomas. Another hypothesis for delayed bleeding from a splenic injury is the concept of "remodeling" of the clot in the splenic parenchyma. This hypothesis is based on the observation that the clot undergoes revision and degradation over time. It is possible that as this remodeling process occurs, the initial hemostasis of the splenic injury is lost. The observation that splenic injury can result in intraparenchymal pseudoaneurysms raises the possibility that delayed bleeding could be the result of rupture of a pseudoaneurysm. Finally, it is simply possible that the damaged spleen, highly vulnerable to further injury, suffers what would otherwise be a minor second blow and starts to bleed again. The failure rate for nonoperative management varies due in part to the lack of a standardized definition of failure. Some surgeons and institutions have a low threshold for operative intervention after an attempt at nonoperative management, and some have a very high threshold. When nonoperative management has failed and the patient requires operative intervention, splenectomy is most often the appropriate operation unless there is minimal concern about subsequent bleeding.

Another potential complication of nonoperative management of splenic injuries is that an associated intra-abdominal injury that requires operative intervention will be missed.[64-66] This is most commonly a problem for missed injuries of the bowel and pancreas. Injury to the small bowel is particularly troublesome, as often free fluid is the only finding of blunt intestinal injury seen on CT of the abdomen. When splenic injury is present, it is easy to attribute the free fluid to bleeding from the spleen. If patients are good candidates for nonoperative management of their splenic injury, it is possible to miss the bowel injury and delay needed abdominal exploration. Pancreatic injuries are occasionally missed on initial CT scanning done shortly after injury and can result in serious morbidity or even mortality if not treated in an expeditious fashion. The proximity of the tail of the pancreas to the spleen makes the combination of injuries to the two organs a possibility. Repeated physical examinations, measurement of pancreatic enzymes, and repeat abdominal CT scanning are all helpful in minimizing the number of missed injuries to the small bowel and pancreas when signs or symptoms justify.

Failure of nonoperative management is not without negative consequences. In a multicenter study, 10 (13%) of 78 patients who failed nonoperative management died, with most of the deaths related to delayed treatment of intra-abdominal injuries. A significant number of the cases of failed nonoperative management could be traced to an inappropriate initial decision to proceed with nonoperative management in hemodynamically unstable patients and/or when there was misinterpretation of the diagnostic imaging studies.[47]

There are no other abdominal complications specific to nonoperative management of the spleen, but intrathoracic complications can occur. Associated pleural sympathetic effusions may result from blood and clot beneath the left hemidiaphragm, whereas a hemothorax may be caused by bleeding from associated fractured ribs.

DVT in the lower extremity is another potential complication after nonoperative management of a splenic injury because prophylaxis is sometimes delayed, as previously described. There is no firm evidence that the rate of thromboembolic complications is higher in patients with nonoperative management of a splenic injury. When a patient with a splenic injury develops a DVT or pulmonary embolism, it can be difficult to decide when and how to proceed with treatment. Anticoagulation of the patient puts the injured spleen at risk, while placement of a caval filter is invasive and expensive. Such patients should be managed on a case-by-case basis, particularly regarding whether the thromboembolic complication has clinical manifestations or was discovered incidentally. Fortunately, these cases are rare in that most clinically apparent thromboembolic problems will not manifest themselves until after the major risk of bleeding from the injured spleen has passed.

Although angioembolization has been used to diagnose and control splenic bleeds since the 1960s, the earliest report of angioembolization to control bleeding specifically for traumatic injury was in in 1981.[67] The increased use of selective angioembolization has led to recognition of a number of complications unique to this modality. Major complications include continued splenic hemorrhage requiring splenectomy and contrast-induced nephropathy. Minor complications include splenic infarction or abscess, groin hematoma or infection, coil migration, and reactive left pleural effusions. When comparing angioembolization proximal or distal to the main splenic trunk, distal embolizations have a higher incidence of minor complications. Although it appears that the overall rate is low, there is still much to be learned about complications from angioembolization.[68,69]

Patients who are managed nonoperatively often receive blood products secondary to the splenic injury or because of associated injuries. There are well-known risks associated with transfusion. These include the risk of blood incompatibility, transmission of bloodborne diseases such as hepatitis, and the significant immunologic effects of transfusion, especially in critically ill and injured patients.[70,71]

Operative Management

There is a risk of bleeding after splenectomy from the short gastric vessels or splenic bed and after splenorrhaphy from the splenic parenchyma. As after any operative procedure, it

is important to closely follow the patient and to reexplore if postoperative bleeding is suspected. Patients with multiple associated injuries and a coagulopathy generally should have undergone splenectomy rather than splenorrhaphy. In these patients, the coagulopathy will be treated, but the possibility of surgical bleeding in the postoperative period should always be entertained when the patient has hemodynamic instability. In patients who have undergone splenorrhaphy, the risk of continued bleeding from the repaired spleen is low.

Gastric distention is a risk, because theoretically when the short gastric vessels have been cut and ligated, gastric distention can result in loss of a tie on the gastric end of a vessel with resultant hemorrhage. Even though this danger may be more theoretical than real, a short period of gastric decompression is practiced by some surgeons.

As previously noted, necrosis of a portion of the greater curvature of the stomach has been described, most commonly related to inclusion of a portion of the gastric wall in the ties placed on the gastric side of the cut short gastric vessels. The resultant gastric leak contaminates the abdomen, in particular the left upper quadrant, and can lead to the formation of a subphrenic abscess or generalized peritonitis.

Pancreatic injuries can be related either to the original trauma or to an iatrogenic injury during mobilization or removal of the spleen. A pancreatic injury will cause an increase in pancreatic enzymes, an ileus, and a generalized inflammatory state. The diagnosis is made from a combination of clinical and CT findings.

The rare complication of an arteriovenous fistula in the ligated vessels in the hilum of the spleen has also been described as a risk of splenectomy. The best way to avoid such a complication is to avoid mass ligation of the hilar structures.

There is some evidence that the long-term risk of thrombotic events is increased after splenectomy for trauma.[72,73] Clinically significant thrombocytosis, however, is still less common after a splenectomy for trauma than it is after a splenectomy for other diseases. As previously noted, appropriately timed prophylaxis should be a standard measure in all injured patients and should cover the risks associated with the transient postsplenectomy thrombocytosis.

There is some evidence that early postoperative complications are more common after splenectomy than they are in patients who do not have their spleens removed.[74,75] Evidence is conflicting, however, and a difficulty in reviewing the literature on the subject is that it is hard to standardize the severity of injury in patients who have undergone splenectomy as compared to patients who have not undergone splenectomy. Some of the series that have suggested an increased risk of complications after splenectomy have noted that such patients were more severely injured than those who did not undergo a splenectomy.

OVERWHELMING POSTSPLENECTOMY INFECTION

The first experimental evidence supporting the possibility that the spleen is of immunologic importance dates to 1919; however, splenectomy remained the treatment of choice for both iatrogenic and traumatic splenic injuries until just several decades ago.[76] In the early 1950s, it was noticed that neonates and young children (up to 6 months of age) with hematologic diseases who required a splenectomy had a high subsequent risk of serious infection. It became clear that an asplenic state in neonates and young children with hematologic diseases was a risk factor for overwhelming infection. From this observation, it was a logical next step to investigate the risk of overwhelming infection in both children and adults who had undergone splenectomy for trauma.[77-79] Several studies suggested that the rate of overwhelming infection after splenectomy is increased when compared with a control population of patients who have not had their spleens removed. The actual rate at which overwhelming infection in asplenic patients occurs is unknown. One estimate is a 0.026 lifetime risk for adults and a 0.052 lifetime risk for children, but all the estimates of risk tend to be very low. Not all studies have documented an increased risk of overwhelming life-threatening infection after splenectomy. One single-institution study reviewed 18 years of splenectomy patients and identified no incidents of overwhelming postsplenectomy infection.[80] Therefore, the clinically significant risk is very low and probably does not merit much consideration when considering the most appropriate treatment of an adult patient with a splenic injury.

When infection does occur in the asplenic state, encapsulated organisms such as pneumococcus and meningococcus are the most common pathogens and pneumonia and meningitis are the most common infections. Because of the inference that overwhelming infection is more common after splenectomy, vaccines to prevent infection by pneumococcus, meningococcus, or *Haemophilus* organisms are recommended for splenectomized patients. There is empirical evidence in both animals and humans that the use of vaccines results in an antibody response; however, because the incidence of overwhelming infection after splenectomy is very low, it is difficult to prove that the vaccines actually have an impact on postsplenectomy infection and mortality. Nonetheless, they have become the standard of care in patients who have had a splenectomy. In patients who have undergone splenectomy, the exact timing of vaccination is somewhat controversial, but evidence from a randomized trial suggests that postsplenectomy trauma patients vaccinated in a delayed fashion (14 days postoperatively) have improved functional antibody responses compared to those vaccinated at 1 day or 7 days after splenectomy.[81-83] As with the question of the overall effectiveness of vaccines in preventing postsplenectomy infection, study of the optimal timing of vaccination is hampered by its low incidence. The most important principle of vaccination after splenectomy is to remember to perform it before discharge from the hospital in patients who are unlikely to return for postoperative follow-up. Whether or not patients should be revaccinated and when such revaccinations should be done remain open questions. One recommendation based on longitudinal antibody studies in a general group of patients (not just trauma postsplenectomy patients) is for revaccination every 6 years.

Another measure that has been suggested for postsplenectomy patients is the continuous administration of antibiotics or the provision of a supply of antibiotics to be taken at the first sign of infection. When such measures have been tried, studies of patients' compliance with the antibiotic regimen have been discouraging.[84] The exact role of antibiotics in postsplenectomy patients is difficult to ascertain for the same reason that the effectiveness of the vaccines is difficult to prove and is not routinely recommended in adults.

Stomach and Small Bowel

Ronald M. Stewart • David H. Livingston

KEY POINTS

- The normal stomach is relatively free of bacteria and other microorganisms because of the low intraluminal pH.
- The thick-walled stomach is relatively resistant to blunt rupture except when it is full and the crash has high kinetic energy or there has been inappropriate placement of a lap seat belt.
- The presence of an anterior penetrating gastric wound requires a thorough exploration of the lesser sac to identify the posterior wound.
- A suspected "missing" gastric perforation from a gunshot wound mandates a provocative test by insufflating and distending the stomach with either air or saline down the nasogastric tube.
- Because the stomach has an excellent blood supply, two-layer suture closures are performed to close perforations and injuries.
- Hollow viscus injuries present in 1% to 3% of all blunt trauma patients, with small bowel injuries accounting for 90% of these injuries.
- A transverse seat belt contusion ("seat belt sign") across the abdominal wall carries an increased risk of injury to the small bowel and mesentery.
- Modern computed tomography (CT) scans have improved the ability to diagnose injuries to the small bowel but can still be normal in 4% of patients with documented blunt rupture.
- Free fluid on CT scanning without solid organ injury does not mandate laparotomy but does mandate close observation and serial examination.
- Blunt ruptures of the small bowel, most often related to lap seat belts, most commonly occur near the ligament of Treitz or ileocecal valve or at the site of adhesions.
- Delays in operation in patients with ruptures of the small bowel and stomach are associated with increased complications and death.
- In patients with multiple small bowel injuries, the overarching concept is to leave as much bowel as possible with the smallest number of repairs and anastomoses.
- The complication rate is similar for stapled and handsewn small bowel anastomosis.
- Closure of an enterocutaneous fistula from prior repair of the small bowel is best accomplished with resection and anastomosis.

INTRODUCTION

Injuries to the stomach and small bowel are common following penetrating abdominal trauma. The incidence of gastrointestinal injury following gunshot wounds and stab wounds that penetrate the peritoneal cavity is in excess of 80% and 30%, respectively. Blunt injuries to the stomach and small bowel are much less common than penetrating injuries, but collectively compose the third most common type of blunt abdominal hollow viscus injuries (HVIs). Given these data, the trauma surgeon must be able to diagnose and treat these potentially life-threatening injuries.

The operative repair of injuries to the stomach and small bowel is relatively straightforward. The key to the successful management of stomach and small bowel injuries is prompt recognition and treatment, thus decreasing the likelihood of abdominal septic complications, including anastomotic leaks, fistulas, and intra-abdominal abscesses.

HISTORICAL PERSPECTIVE

Intestinal injuries were reported early in the medical literature, and small bowel perforation from blunt trauma was first reported by Aristotle.[1] Hippocrates was the first to report

intestinal perforation from penetrating abdominal trauma. In 1275, Guillaume de Salicet described the successful suture repair of a tangential intestinal wound. Reports of attempted surgical repair of gastric and intestinal wounds appeared in the literature during the American Civil War, the Spanish-American War, the Russo-Japanese War, and other military conflicts. The dismal results of surgical intervention led to abandonment of laparotomy even with obvious intestinal injury during these military campaigns.[2]

By the late 19th century, improved anesthesia and surgical techniques led to renewed interest in laparotomy and repair of penetrating abdominal injuries. Theodore Kocher was the first surgeon to report successful repair of a gunshot wound of the stomach. Dr. George Goodfellow is credited with the first laparotomy to treat a gunshot wound.[3] Dr. Goodfellow was a follower of Lister and sterilized his instruments and his hands. The patient's intestines were covered with a large amount of "purulent stinking lymph" as the victim had six holes in his intestines.

A laparotomy for intestinal perforation at the start of World War I carried a mortality rate of 75% to 80%, almost equal to the mortality rate of nonoperative management. In the latter part of World War I, operative management was recognized as the preferred management for penetrating abdominal trauma.

In World War II, prompt evacuation, improvements in anesthesia, and better understanding and treatment of shock led to mortality rates of 13.9% for jejunal or ileal injuries and 36.3% if multiple injuries were present.[4] Further improvements in mortality were noted during the Korean and Vietnam Wars. Earlier evacuation and improvements in resuscitation combined with prompt recognition and repair of injuries are responsible for the current low morbidity and mortality following injuries to the stomach and small bowel.

ANATOMY

The nondistended stomach, especially in a supine individual, is located largely in the intrathoracic abdomen, where it is offered some protection by the lower chest wall. The position of the stomach can be quite variable and, in the erect individual, may extend into the lower abdomen, particularly when distended with food or liquid. The stomach is fixed along the lesser curvature by the gastrohepatic ligament, cephalad by the gastrophrenic ligament, and distally by the retroperitoneal duodenum. The greater curvature of the stomach is loosely bound to the transverse colon via the greater omentum and to the spleen by the gastrosplenic ligament. The stomach enjoys a rich blood supply from the left and right gastric arteries, the left and right gastroepiploic arteries, and the short gastric arteries (Fig. 35-1).

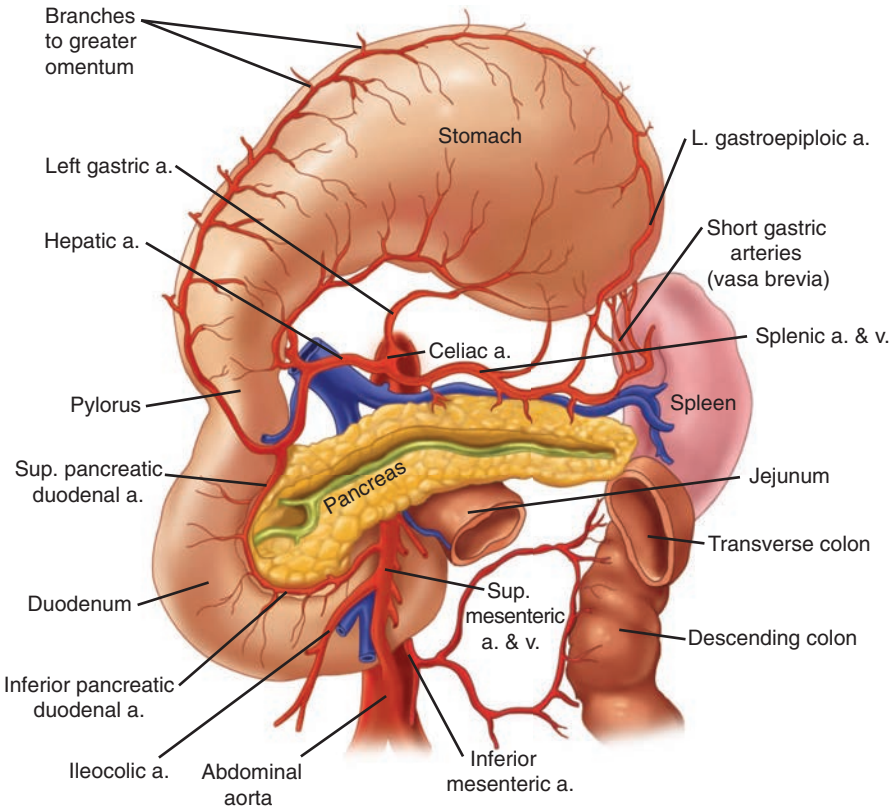

FIGURE 35-1 Blood supply to the stomach. An anomalous left hepatic artery can arise as a branch of the left gastric artery. This should be looked for when doing gastric resections. a., artery; v., vein. (Reproduced with permission from Mercer DW, Liu TH, Castaneda A. Anatomy and physiology of the stomach. In: Zuidema GD, Yeo CJ, eds. *Shackleford's Surgery of the Alimentary Tract*. 5th ed., Vol II. Philadelphia, PA: Saunders; 2002:3. Copyright © Elsevier.)

Venous drainage follows the arterial supply to the stomach for the most part.

The normal stomach is relatively free of bacteria and other microorganisms because of the low intraluminal pH; however, up to 10^3 organisms/mL, including lactobacilli, aerobic streptococci, and even *Candida*, may be isolated. Increasing gastric pH, due to chronic use of antacids, H_2-receptor blockade, or proton pump inhibitors, will lead to increased bacterial concentrations in the stomach and proximal gastrointestinal tract.[5] This increases the risk of peritoneal contamination with gastric perforation. Because trauma patients often have full stomachs, spillage of retained food will also increase the risk of infection following gastric injury.

The small bowel distal to the ligament of Treitz is approximately 5 to 6 m in length in the adult. Protected anteriorly only by the abdominal wall musculature and occupying most of the true abdominal cavity, the small intestine is anatomically vulnerable to injury. The small intestine is suspended from the retroperitoneum by its mesentery, the base of which extends from the duodenal-jejunal flexure, superior to inferior and left to right, to the level of the right sacroiliac joint. The arterial supply to the small bowel is provided by the superior mesenteric artery (SMA), which emerges from under the pancreas and then courses anterior to enter the root of the mesentery. The blood supply to the majority of the small bowel comes from the left side of the SMA via intestinal arteries (Fig. 35-2). The jejunal and ileal branches vary in number and lead to numerous intestinal arcades, which ensure excellent collateral blood supply. The ileocolic artery is the termination of the SMA. Venous return from the small

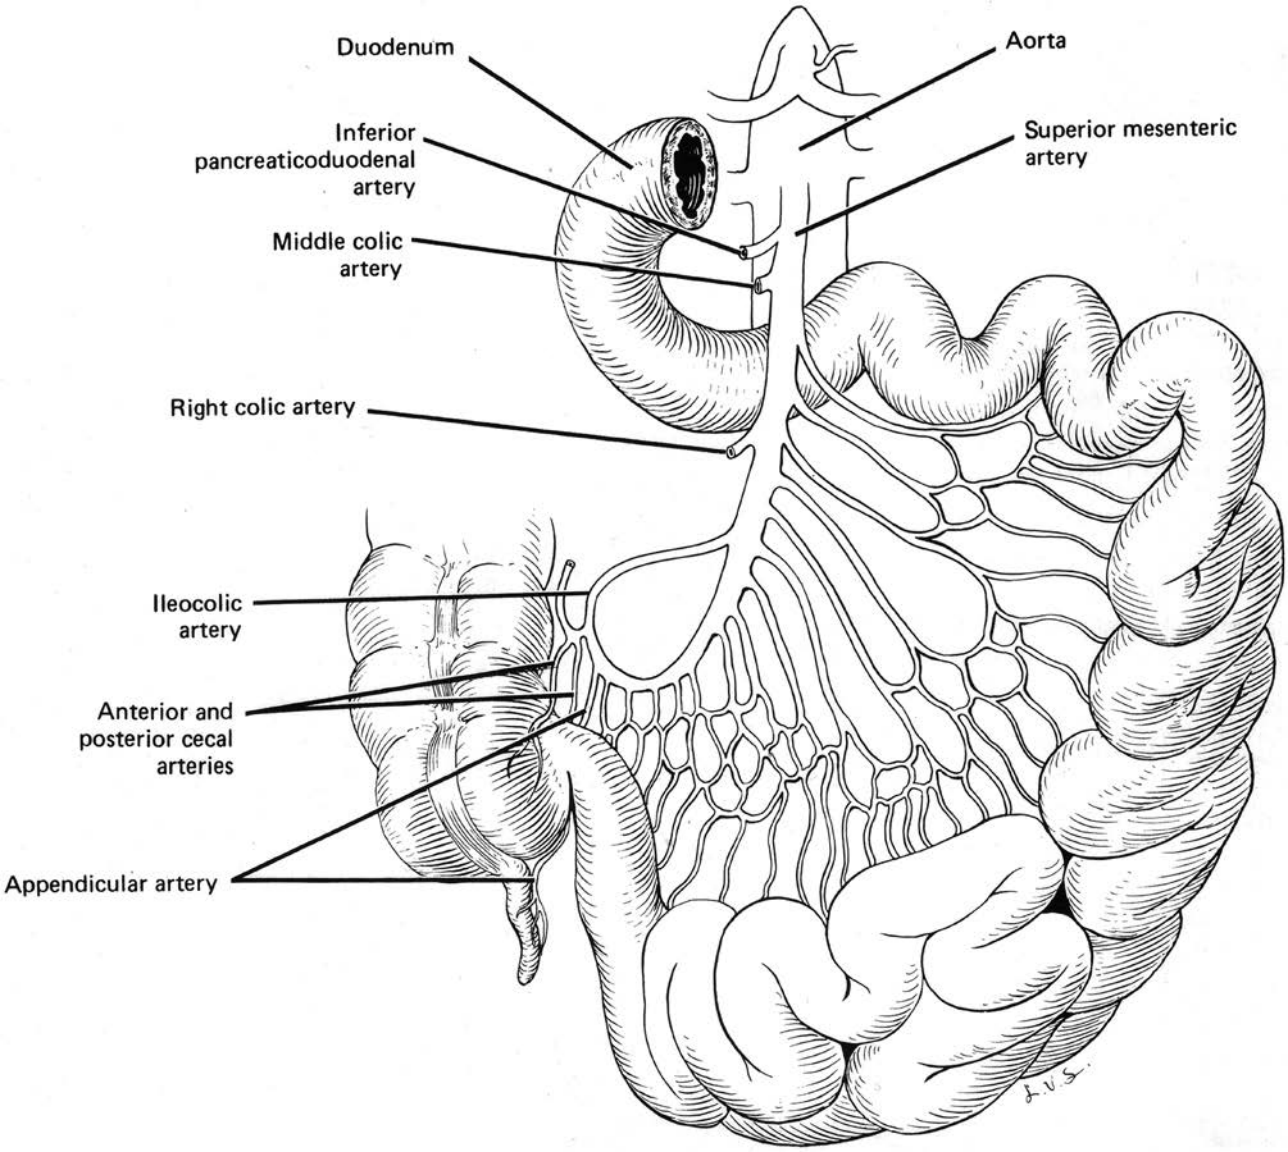

FIGURE 35-2 Blood supply to the small bowel. Multiple branches to the jejunum and ileum originate directly from the superior mesenteric artery. The distal ileum is supplied via the ileocolic artery. FIGURE 35-3 The jejunum and ileum can be distinguished from one another by differences in luminal diameter, number of arterial arcades, and the presence or absence of fat encroaching on the gut wall. (Modified with permission from Tavakkoli A, Ashley SW, Zinner MJ. Small intestine. In: Brunicardi FC, Andersen DK, Billiar TR, et al, eds. *Schwartz's Principles of Surgery,* 11th ed. New York, NY: McGraw Hill; 2019.)

intestine follows the arterial supply. The inferior mesenteric vein runs lateral to the ligament of Treitz to drain into the splenic vein, which combines with the superior mesenteric vein to form the portal vein.

FUNCTION

Although no clear distinction exists, the first 40% or so of the bowel is jejunum and the remainder is the ileum (Fig. 35-3). The jejunum has a larger diameter, more circular folds, and larger villi, but less lymphoid tissue than the ileum. The mesentery of the jejunum contains only a single arcade, whereas more than two or three sets of vascular arcades are present in the ileum. Mesenteric fat is also more prominent in the ileum than in the jejunum. The proximal jejunum is the primary site of absorption of carbohydrate, protein, and water-soluble vitamin absorption. Fat absorption occurs over a larger length of small bowel. The ileum is the primary site of carrier-mediated bile salt and vitamin B_{12} absorption. Distinctions between jejunum and ileum are of clinical importance only if a significant length of bowel is resected. The ileocecal valve is thought to act as a "brake" to the delivery of small bowel content into the cecum. It may also be a barrier for reflux of colonic content into the small bowel. Ileal peristalsis probably is the main factor in those functions.

The luminal content of the proximal small bowel is of neutral pH and is relatively sterile, containing few bacteria. Most studies of the small bowel microflora have demonstrated increasing bacterial counts with distance away from the pylorus.[6] The proximal small bowel flora resembles the gastric flora, and alterations in the bacterial load of the stomach will influence the bacteriology of the small bowel. The jejunum and proximal ileum contain gram-positive and gram-negative organisms at 10^4 to 10^5 colony-forming units (CFU)/mL. The bacterial concentration in the distal ileum rises to 10^5 to 10^8. There is also a higher number of anaerobic species in the ileum. This increase in bacterial load in the ileum is thought to contribute to an increased risk of infection with full-thickness injury in the distal small bowel versus the proximal small bowel. Again, because trauma patients have not been fasting, the risk of an increased volume of luminal contents resulting in a greater degree of intestinal spillage containing bacteria likely plays an important role.

DIAGNOSIS

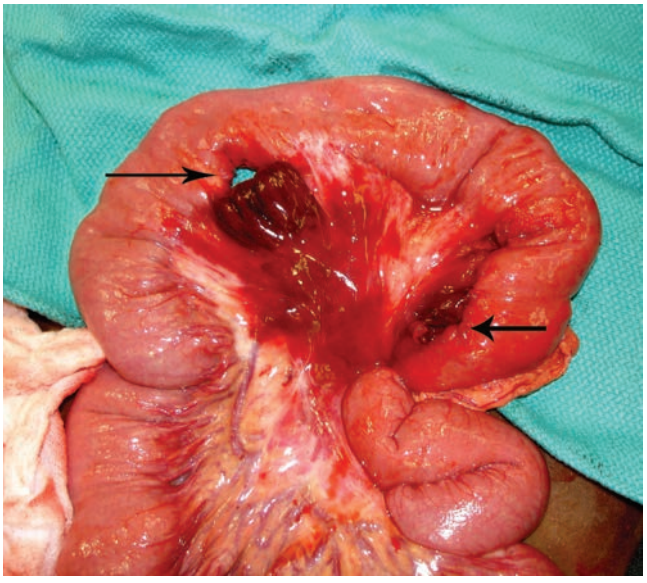
Following penetrating trauma, the diagnosis of injuries to the stomach and small bowel is almost always made during an exploratory laparotomy. The small bowel is at risk of perforation following virtually any penetrating injury that violates the peritoneum. Patients who present with hemodynamic instability or evisceration of abdominal contents after penetrating abdominal trauma obviously need an emergent laparotomy. Bloody nasogastric aspirate may be indicative of gastric injury, and free air demonstrated on an upright chest x-ray should be presumed to be from some HVI after blunt trauma.

Blunt HVIs are infrequently encountered. In the multi-institutional study from the Eastern Association for the Surgery of Trauma (EAST), HVIs were found in 1.2% to 3.1% (depending on the cohort denominator used) of admissions during the 2-year study period, and 90% of these were in the small bowel.[7]

Blunt gastric injuries are extremely rare and usually related to excessive force such as a pedestrian struck by a motor vehicle or a high-speed motor vehicle crash. The stomach has a thick wall and is relatively resistant to a blunt injury; however, contributing factors include a full stomach, trauma to the left side of the body, and the inappropriate use of a seat belt. Blunt gastric ruptures most frequently involve the anterior gastric wall.[8,9] Peritoneal signs and a bloody nasogastric tube aspirate are usually present and are diagnostic. Associated injuries to the liver, spleen, and pancreas, as well as injuries to the chest and head, are common due to the degree of force necessary to produce a gastric blowout.[10]

A small bowel perforation secondary to blunt abdominal trauma is uncommon, although 90% of all HVIs occur in the small bowel, as previously noted. Motor vehicle crashes are

A



B

FIGURE 35-4 Direct blows to the abdominal wall following a bicycle crash are a classic mechanism of blunt small bowel injury in children. (**A**) Abdominal wall imprint of the handlebars. (**B**) Two full-thickness injuries (arrows) and the associated mesenteric hematoma. These injuries were treated by a single resection.

the most important mechanism for blunt intestinal trauma, followed by falls, bicycle accidents (Fig. 35-4), or a localized blow. Mechanisms postulated for injury to the small intestine to occur include the following: (1) crushing of bowel against the spine; (2) shearing of the bowel from its mesentery of a fixed point by sudden deceleration; and (3) bursting of a "pseudo-closed" loop of bowel due to a sudden increase in intraluminal pressure. Garret and Braunstein first referred to the seat belt mark as ecchymoses across the abdominal wall that corresponds to the lap belt (Fig. 35-5).[11] With the advent of the three-point restraint system, restraint injuries may also involve the neck and chest. Depending on the severity of the blunt force trauma, "seat belt syndrome" may include HVI, abdominal wall disruption, associated lumbar fractures, and a major abdominal vascular injury (see Chapter 38).[12]

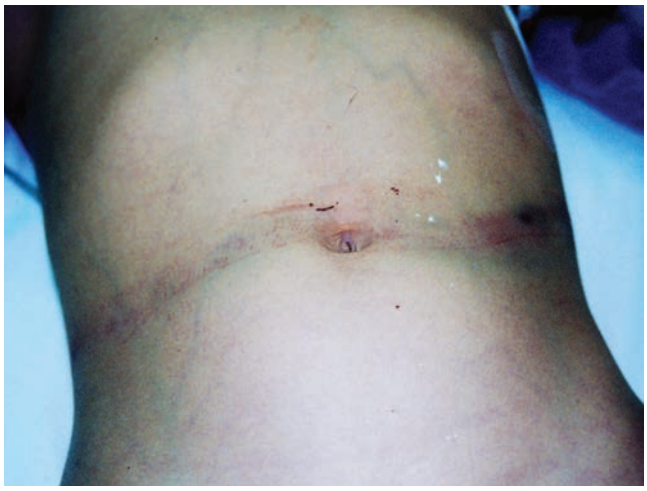
Anderson et al[13] reported a 4.38-fold increase in risk of small bowel injuries with use of a lap/shoulder restraint and a more than 10-fold increase in risk with lap belts alone, compared with no restraint use. In an EAST multi-institutional study, the seat belt sign (SBS) was associated with a 4.7-fold increase in relative risk of small bowel perforation in patients following motor vehicle crashes.[14] Because the degree of force transmitted against the torso is unknown in the vast majority of blunt trauma patients, the presence of an SBS or handlebar bruise is simply a clear indication that there has been a significant impact to the abdominal wall. Thus, it should be no surprise that the presence of an HVI is significantly higher in this subpopulation than in the population at large.

Children with an SBS also have a higher rate of gastrointestinal injury, especially given the poor fit of seat belts in children. Sokolove et al[15] demonstrated that children with an SBS had a significantly greater risk of intra-abdominal injury, including gastrointestinal and pancreatic injuries. The increased risk of injury was only apparent in patients with abdominal pain or tenderness. In a study by Chidester et al,[16] the SBS only had a sensitivity of 25% and a specificity of 85% for abdominal injury. Similar to the study by Sokolove et al, the presence of SBS with abdominal tenderness was more predictive of abdominal injury.

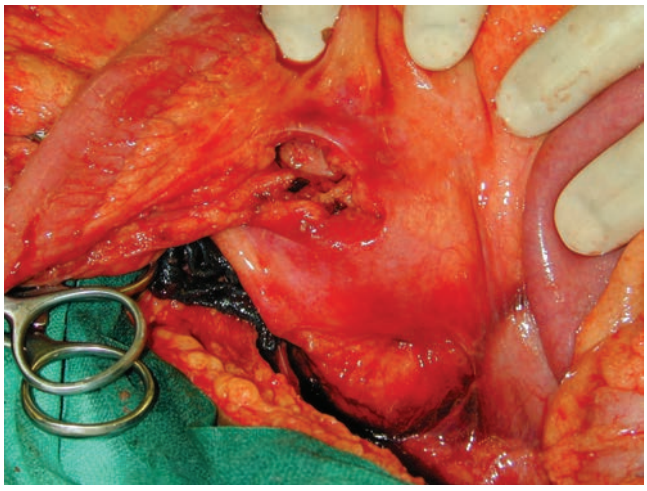
The contemporary view of the seat belt syndrome is a constellation of injuries, some of which may be subtle in presentation and appearance.[17] As noted earlier, the seat belt syndrome is more common in children and associated with the use of a lap belt only, most often because the child is not properly restrained in a booster seat. The full manifestations of the seat belt syndrome from anterior to posterior involve injury to the skin, subcutaneous tissue, abdominal wall musculature, small bowel, small bowel mesentery, sigmoid colon and mesentery, cecum, aorta, proximal iliac arteries, and spine (Fig. 35-5). When there is a seat belt contusion, particularly above the level of the iliac crests, an intentional and careful search for injuries to the sigmoid colon, aorta, and iliac vessels and spine should be undertaken.

The association of a Chance-type fracture of the lumbar spine as an independent predictor of HVI is variably reported in the literature (Fig. 35-5). In the EAST multi-institutional trial with small bowel perforations, there was no difference in the incidence of Chance-type fracture in patients with perforations of the small bowel compared with those without perforations.[14] The incidence of bowel perforations ranged from 2% to 3% of patients. Similar to SBS, the presence of severe fractures of the thoracolumbar spine is evidence that the torso has sustained a significant degree of blunt force trauma. Because almost all spine fractures are now diagnosed by computed tomography (CT) scanning, the identification of associated intra-abdominal and intrathoracic injuries should no longer be a question.

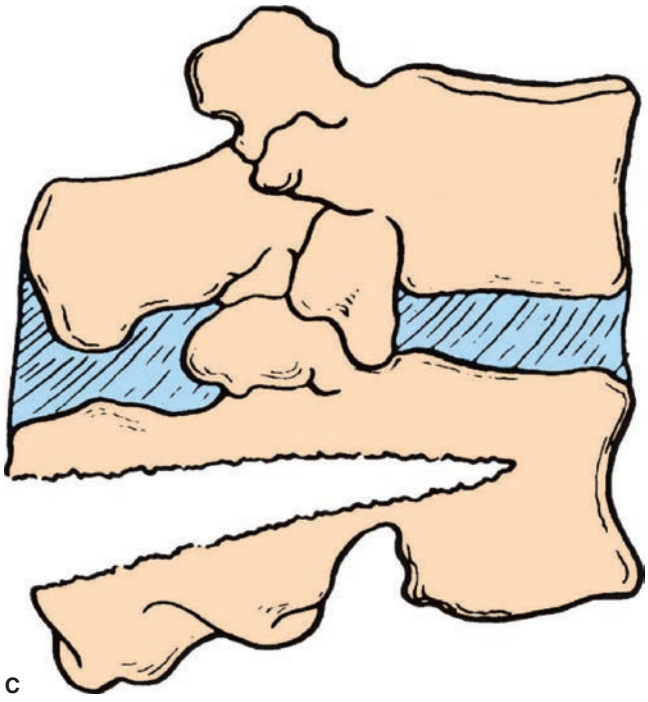
CT scanning is the primary diagnostic modality in hemodynamically stable patients following blunt trauma. Although a focused assessment with sonography in trauma (exam) may



A



B

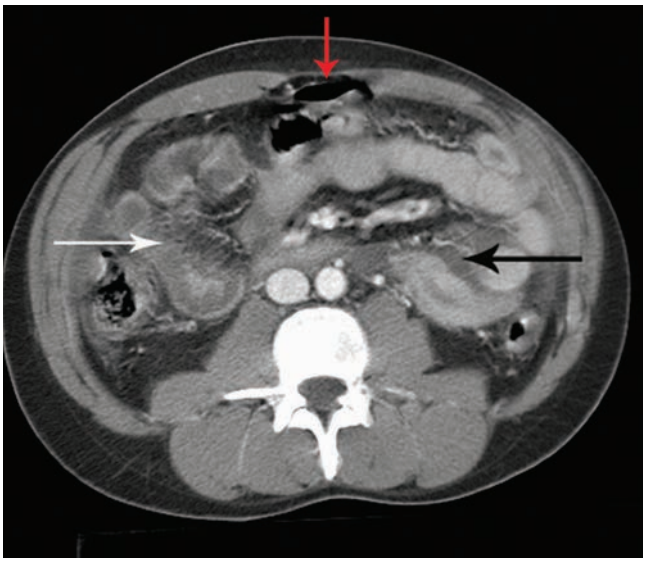


C

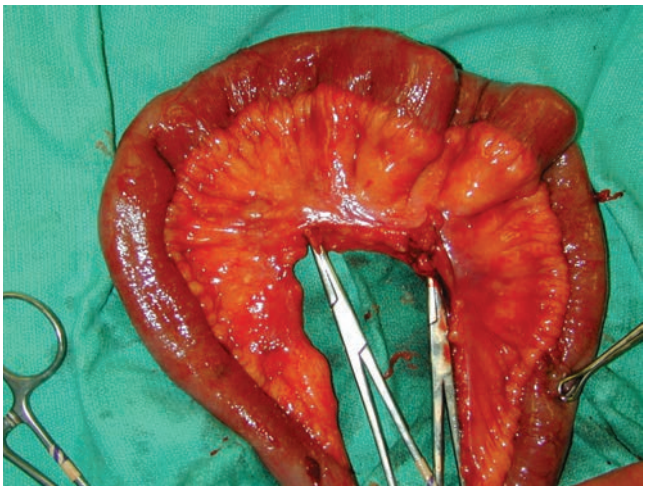
D

FIGURE 35-5 The "seat belt syndrome" is secondary to a direct blow to the mid abdomen from the lap portion of the seatbelt. It presents with ecchymosis of the abdominal wall (**A**) and is associated with mesenteric and small bowel injuries (**B**). (**C**) Increasing force can result in a transversely oriented fracture through bone, known as a Chance fracture. (**D**) Aortic or iliac vascular injuries require a high degree of suspicion and are often associated with seat belt signs and Chance fractures.

demonstrate free fluid, patients who are hemodynamically stable will still undergo CT scanning. Thus, the primary diagnostic modality for blunt HVI is CT. Initially, following introduction of CT scanning for trauma in the 1980s, the reliability to diagnose blunt HVI was poor. The advent of helical CT scanning in the early 1990s and many advances since have made CT extremely accurate. Although it may not identify overt HVI itself, it provides the astute trauma surgeon with findings that indicate a high likelihood of injury. Findings on CT associated with HVI include the following: fat stranding; hematoma of the mesentery; extraluminal air; thickened (>4–5 mm) wall; abnormal bowel contour; and free fluid without injury to a solid organ (Fig. 35-6). It is apparent that when a blunt small bowel perforation is



A



B

FIGURE 35-6 Computed tomography (CT) findings suggesting of blunt small bowel injury (**A**) include thickened loops of bowel (white arrow), free fluid within loops of bowel (black arrow), and free air (red arrow). (**B**) The associated small bowel injury from the findings on the CT included extensive mesenteric rent with two frank perforations (one identified by the Babcock clamp).

present, abdominal CT is usually abnormal.[18-21] CT findings specific for the rupture of the small bowel include extraluminal oral contrast and discontinuity of the wall of a hollow viscus, although oral contrast is rarely used for trauma CT scanning. Even when it is employed, extravasation is noted in less than 10% of documented cases of small bowel rupture. Active extravasation of contrast can be a specific sign of a mesenteric laceration, as is a mesenteric hematoma or fluid collection in the mesenteric folds.

Malhotra et al[21] reviewed the Presley Regional Trauma Center experience with screening helical CT evaluation of blunt injuries to the bowel and mesentery. In a group of 8112 scans, 100 were suspicious for injuries to the bowel or mesentery. There were 53 patients with bowel/mesentery injuries (true positive) and 47 without (false positive). The most common finding in both true-positive and false-positive groups was unexplained intraperitoneal fluid, which was present in 74% and 79% of scans, respectively. A pneumoperitoneum and bowel wall thickening were much more common in the true-positive scans. Multiple findings suspicious for bowel/mesenteric injury were seen in 57% of the true-positive scans but in only 17% of false-positive scans. The overall sensitivity and specificity of CT for bowel/mesenteric injury were 88.3% and 99.4%, respectively, whereas the positive and negative predictive values were 53.0% and 99.9%, respectively.

In an EAST multicenter study of HVI in 2019, sensitivity of CT scanning improved, but a significant number of patients with proven small bowel ruptures still had a negative CT scan. There was also a decrease in case mortality from 6% to 1.3%, associated with a shortened time to operation related to improved detection of findings indicative of HVI.[22]

The importance of free fluid on CT scan without overt solid organ injury has been vigorously debated. As outlined earlier, free fluid is common in patients without HVI. In a multicenter EAST study, free fluid without solid organ injury had a 38% incidence of a ruptured small bowel, but this means that 62% of patients did not.[21] In a multicenter prospective series of 2299 patients by Livingston et al,[23] 90 patients with free fluid and no solid organ injury were identified. In that group, only seven patients (9%) sustained an HVI.[15,23] Even with the use of multidetector CT scans, free intraperitoneal fluid is the most common finding of a blunt injury to the intestine or mesentery.[19,23] The amount and locations of the free fluid have been used to identify patients with HVI from those without HVI. Although patients with fluid in multiple areas are clearly at a higher risk from HVI than those with trace fluid in one location, the data are not sufficient to mandate laparotomy on that basis alone.[24] These patients do not have a "negative" CT scan, do require observation and serial abdominal examinations, and should never be discharged from the trauma receiving area.

Laboratory studies including hematocrit, white blood cell (WBC) count, and serum amylase are not useful in the initial evaluation of patients with blunt rupture of the stomach and small bowel.[15] In patients with a solid organ injury who are being managed nonoperatively or in patients with penetrating injuries undergoing serial clinical exams, unexplained tachycardia, hypotension, leukocytosis, an increase in serum amylase, or the development of a metabolic acidosis should arouse suspicion of a missed HVI. This is especially true in patients with an altered mental status, such as those with a concomitant traumatic brain injury or those who require intubation for other reasons. In this population, peritoneal lavage has been suggested as an adjunct with examination of the fluid for succus or WBCs. Although the presence of succus is a clear indication for laparotomy, an elevated WBC count is less predictive. Confounding issues include the presence of blood and the time between the injury and the lavage.[25]

Jacobs et al[26] found that a lavage WBC count of more than 500/mm^3 as the sole positive lavage criterion was a nonspecific indicator of intestinal perforation. In the presence of hemoperitoneum, Otomo et al[27] suggested using an adjusted WBC criterion (calculated as WBC ≥ red blood cells/150) as positive. These criterion had a sensitivity of 96.6% and a specificity of 99.4% for intestinal injury when performed more than 3 hours after injury. What is true is that a patient who is having unexplained signs of sepsis in the face of free fluid in the abdomen, especially one who cannot be easily examined, should be considered to have an HVI and undergo urgent operative exploration.

The diagnosis of a blunt intestinal injury is especially problematic in pediatric patients, in whom the findings on physical examination and x-rays may be less sensitive than in adults and may contribute to delays in operative treatment. Canty et al[28] suggested a delay of up to 24 hours after blunt intestinal trauma did not increase mortality or morbidity; however, a delay in definitive repair over 24 hours was directly associated with increased morbidity but not mortality. Additionally, a multi-institutional retrospective study of 214 patients failed to demonstrate a correlation between time to surgery, complication rate, and hospital length of stay.[29]

In contrast to that pediatric experience, Fakhry et al[30] published a multicenter experience in 198 patients with blunt injuries to the small bowel. There were 21 deaths (10.6% of total), with nine of these deaths attributable to a delay in operation. In patients in whom rupture of the small bowel injury was the major injury, the incidence of mortality increased with time to operative intervention. Mortality rates were 2% if the patient was operated on within 8 hours, 9.1% if operated on between 8 and 16 hours, 16.7% if operated on between 16 and 24 hours, and 30.8% if operated on more than 24 hours after injury (P = .009). The incidence of postoperative bowel-related complications, especially an intra-abdominal abscess, also increased significantly with time to operative intervention. In a retrospective review, Malinoski et al[31] noted that patients with delays of 5 or more hours had a 3.2 odds ratio of increased mortality. Clearly, these data would suggest that patients at high risk for HVI be carefully observed and monitored with early and aggressive intervention if their clinical condition deteriorates.[32]

LAPAROSCOPIC EVALUATION AND TREATMENT

The role of diagnostic laparoscopy for possible abdominal trauma has been controversial since its introduction to modern surgical practice. It has been considered by some to be helpful in avoiding laparotomy in hemodynamically stable patients with possible penetrating thoracoabdominal trauma and a suspected diaphragmatic injury.[33] With improved techniques and capabilities, many diaphragmatic tears and even gastric perforations may be repaired using laparoscopic techniques. Indications for diagnostic laparoscopy are less certain for patients with suspected blunt intestinal trauma. Early reports demonstrate an excessively high rate of missed injuries.[33] Because laparoscopic training and skills have markedly improved over time, it is possible that laparoscopic evaluation of a very select subset of patients, such as those with free fluid and worsening abdominal pain, but not frank peritonitis, may be an option.

OPERATIVE MANAGEMENT

Stomach

The surgeon should ensure that the incision is carried superiorly in the paraxiphoid area to facilitate exposure of proximal stomach and distal esophagus. The use of any one of the table-mounted self-retaining retractor systems can greatly facilitate this exposure. In the hemodynamically stable patient, the reverse Trendelenburg position can aid in exposure of this area by decreasing the pooling of blood to allow better visualization.

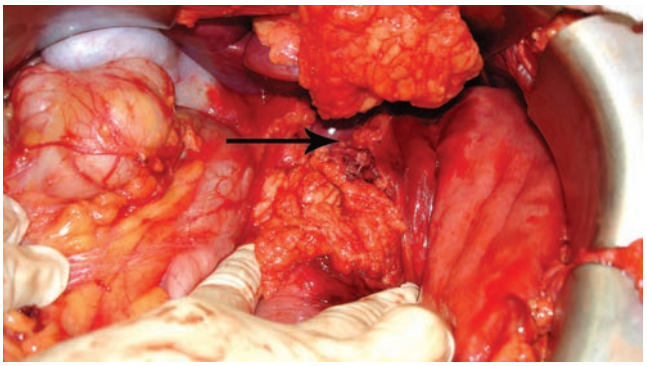
Mobilization of the stomach is essential for detection of gastric injuries. Exposure is generally easier if the stomach is decompressed first by a properly placed nasogastric tube. Unfortunately, most trauma patients appear to have eaten just prior to sustaining their injury, resulting in a stomach full of solid food. Almost all injuries can be managed despite a full stomach, albeit with some difficulty. Rarely, an injury may need to be extended into a gastrotomy to evacuate the stomach sufficiently to repair the injuries. A bloody nasogastric return should arouse suspicion for a gastric injury, as previously noted. Certain areas of the stomach, including the gastroesophageal junction, the proximal gastric fundus, the lesser curvature, and the proximal posterior area of the body and fundus, are difficult to assess (see Atlas Figure 62). Division of the left triangular ligament and mobilization of the lateral segment of the left lobe of the liver are helpful in exposing the anterior gastroesophageal junction. Encircling the esophagus at the gastroesophageal junction with a Penrose drain to maintain downward traction on the stomach can be useful to repair injuries in the proximal stomach.

If the gastrohepatic ligament is divided, care must be taken to avoid injury to the vagus nerve or its branches or the occasional anomalous left hepatic artery. To visualize the superior portion of the gastric fundus, the short gastric vessels should be divided and ligated. Overzealous traction in this area may cause tearing of these vessels or the splenic capsule, leading to troublesome bleeding. In patients with a concomitant splenic injury or those with extensive injuries to the body and fundus, mobilization of the spleen will facilitate exposure of the injuries to both organs.

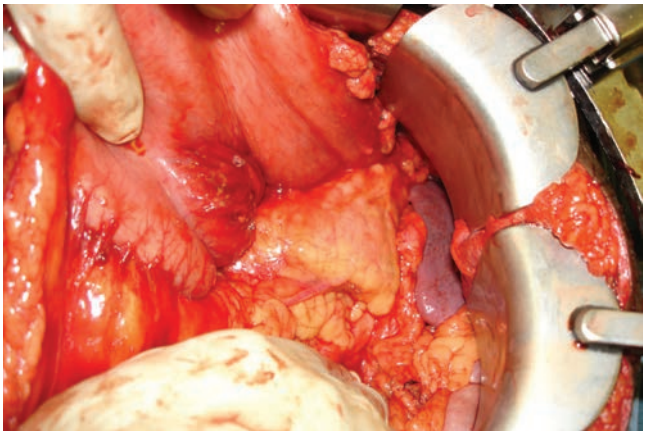
The posterior wall of the stomach may be inspected several ways. The easiest and most expeditious is to enter the lesser sac through an avascular portion of the gastrocolic omentum along the body and/or antrum, leaving the gastroepiploic vessel intact. In obese patients with a thickened omentum and foreshortened mesentery, it is often better to enter this space in the upper or mid portion of the greater curvature of the stomach to avoid making a rent in the transverse mesocolon and possibly causing injury to the middle colic artery. For injuries that are close to the greater curve, it is better to expose

the surrounding area by ligating the branches of the epiploic vessel to the stomach. This dissection may be extended as necessary including up to the short gastric vessels to visualize an injury high in the fundus. Once the lesser sac is entered, the avascular gastropancreatic adhesions must be incised all the way up the lesser curve to ensure complete visualization of the posterior wall of the stomach. When there is an injury to the transverse colon or splenic flexure, mobilization of the left colon and splenic flexure will allow the lesser sac to be entered laterally through the space created by taking down the attachments from the spleen.

When an anterior hole in the stomach is found, a diligent search for a second hole *must* be undertaken. This is usually relatively straightforward, but there are several areas that can hide injuries and should be carefully inspected. These include the greater and lesser curvatures of the stomach, proximal posterior gastric wall, fundus, and cardia. Any hematoma, especially those on the greater and lesser curves where fat can easily obscure an injury, must be opened and explored (Fig. 35-7).



A



B

FIGURE 35-7 (**A**) Blunt injury to the stomach resulting in a full-thickness laceration to the lesser curve. The surgeon's hand is depressing the antrum of the stomach, and the extensive hematoma can be observed. The extent of laceration (black arrow) that is identified is also obscured by the fat on the lesser curve of the stomach, requiring full exploration for successful repair. (**B**) The posterior aspect of the stomach following full mobilization of the lesser sac demonstrating how benign the hematoma of the lesser curve can appear before exploration.

TABLE 35-1: Stomach Injury

Grade[a]	Description of injury	AIS-90
I	Contusion or hematoma	2
	Partial-thickness laceration	2
II	Laceration in GE junction or pylorus <2 cm	3
	In proximal one-third of stomach <5 cm	3
	In distal two-thirds of stomach <10 cm	3
III	Laceration >2 cm in GE junction or pylorus	3
	In proximal one-third of stomach ≥5 cm	3
	In distal two-thirds of stomach ≥10 cm	3
IV	Tissue loss or devascularization less than two-thirds of stomach	4
V	Tissue loss or devascularization greater than two-thirds of stomach	4

AIS, Abbreviated Injury Scale; GE, gastroesophageal.

If a suspicion still exists after the search for a second hole is unsuccessful, a useful diagnostic adjunct is to have the anesthesiologist insufflate the stomach with air through a nasogastric tube. With the stomach submerged in saline, a telltale leakage of bubbles localizes any missed injury. Another option is to put 200 mL of saline containing an ampule of methylene blue down the nasogastric tube. An area of occult injury will be demarcated by blue staining. Very rarely, a tangential wound to the stomach and bowel can occur, but this is a diagnosis of exclusion. In the management of gastric injuries, it should be assumed that there should always be an even number of holes created.

Gastric injuries should be graded (Table 35-1), and the severity of the injures will often dictate treatment. Following blunt trauma, almost all grade I intramural hematomas require no treatment. Occasionally a hematoma that is expanding requires unroofing and control of hemorrhage. The entire area can then be imbricated with absorbable or nonabsorbable sutures. Following penetrating trauma, any hematoma must be explored because it may be hiding a full-thickness laceration. Gastric lacerations can be closed primarily in one or two layers using absorbable or nonabsorbable sutures. Many surgeons believe that there are several advantages to a two-layer repair. The first is that it quickly closes the hole and decreases any continued contamination. The second is that due to the vascularity of the stomach, ongoing bleeding is common and the first layer can help ensure hemostasis. The stomach is extremely difficult to narrow because it is capacious and will further expand over time; thus, the rule of thumb is to take large secure bites of the gastric wall with the sutures. Anterior and posterior wounds near the greater or lesser curve are often best treated by connecting the injuries into one discrete laceration. This allows the surgeons to ensure that the edges of the injury are well visualized circumferentially and will ensure complete closure. Staplers may also be used to close some gastric injuries. Because the stomach is thick, care must be taken to ensure that the proper sized staples are used.

For injuries near the gastroesophageal junction and the pylorus, care must be taken to avoid stenosis. The use of a bougie can help during closure of an injury near the gastroesophageal junction. Occasionally, a pyloric wound may be converted to a pyloroplasty to avoid possible stenosis in this area. Extensive wounds (grade IV) may be so destructive that either a proximal or a distal gastrectomy is required. Reconstruction with a gastroduodenostomy, gastrojejunostomy, or Roux-en-Y gastrojejunostomy is dictated by the anatomy and the presence or absence of associated duodenal and/or pancreatic injuries. Often these patients are in hemorrhagic shock due to other injuries and should be treated with damage control–type resections followed by later reconstructions. In rare cases, a total gastrectomy and a Roux-en-Y esophagojejunostomy are necessary for severe injuries (grade V).

Small Bowel

Examination of the small intestine for injury should be done systematically from the ligament of Treitz to the ileocecal valve. The small bowel should be completely eviscerated to the right. Any prior adhesions should be lysed to facilitate this maneuver. This also allows for the identification and control of mesenteric bleeding. The ligament of Treitz should be identified, and the small bowel examined loop by loop. Following blunt trauma, small bowel injuries are generally obvious and are often associated with extensive mesenteric bleeding and hematomas. Conversely, in penetrating trauma, especially stab wounds, small bowel injuries may be small and subtle. This is the reason that all hematomas on or adjacent to the bowel wall must be explored. Injuries should be marked with a suture or Babcock clamp to decrease spillage, but no attempt should be made to definitively repair any injury until the entire bowel is inspected. At that point, a plan of treatment can be devised as to how many bowel resections and repairs are needed. The overarching concept is to leave as much bowel as possible with the smallest number of repairs and resections. Thus, one might elect to resect an otherwise reparable injury if it is adjacent to an injury that requires resection. Small nonexpanding mesenteric hematomas away from the wall of the bowel should be reassessed at intervals throughout the operative procedure to assure their stability.

If significant bleeding from the mesentery is encountered, it should be controlled directly by either placement of clamps on the ends of the bleeding vessels followed by suture ligature or the accurate placement of sutures in a figure eight fashion. Mesenteric vessels often retract several millimeters from an injury, and the peritoneum over the mesentery may need to be opened to accurately identify the area of injury. Mesenteric defects are closed later to prevent internal hernias.

Bleeding at the root of the mesentery requires extra caution in obtaining hemostasis because of the concern for inadvertent damage to or ligation of the SMA or superior mesenteric vein. Clinical judgment about bowel viability has only a 65% predictive value under the best circumstances. Adjunctive techniques to access bowel viability such as intravenous fluorescein and bowel inspection using a Wood's lamp, Doppler flow studies, intraoperative laser angiography with indocyanine green, and bowel surface oximetry may be useful. If planned resection of small bowel will be so extensive that it may result in a short gut syndrome, an option is to terminate the procedure and provide temporary abdominal closure. Then a second-look procedure can be performed after the patient is rewarmed and perfusion deficits corrected before deciding to perform an extensive bowel resection. Performing resection at this later time may allow preservation of bowel that was of questionable viability at first operation. With massive bowel resections, it is important to note the location and length of the segment of the resected bowel. The most critical measurement is the length of the remaining small bowel. Preserving as much of the ileum as possible and the ileocecal value, if feasible, may obviate the complications related to extensive resections of the small bowel.

Exposure and repair of distal duodenal/proximal jejunal injuries are facilitated by taking down the ligament of Treitz. The entire small bowel in this area can be easily dissected back to the superior mesenteric vessels. There are often small vessels at the medial aspect that should be taken carefully using a right-angle clamp and fine ties. Following adequate mobilization, the injuries should be able to be clearly identified and either repaired or resected.

Treatment of an injury to the small bowel depends on its grade (Table 35-2). Serosal tears can be either closed with seromuscular sutures or left alone depending on size and if one is certain as to the depth of the wound. Similarly, intramural hematomas can either be left alone or be safely inverted with 3-0 or 4-0 seromuscular sutures. In general, the type of sutures used depends on surgeon preference.

Full-thickness perforations or ruptures of the small bowel usually less than 50% of the circumference (grade II) and not

TABLE 35-2: Small Bowel Injury Scale

Grade[a]	Type of injury	Description of injury	AIS-90
I	Hematoma	Contusion or hematoma without devascularization	2
	Laceration	Partial thickness, no perforation	2
II	Laceration	Laceration <50% of circumference	3
III	Laceration	Laceration ≥50% of circumference without transection	3
IV	Laceration	Transection of the small bowel	4
V	Laceration	Transection of the small bowel with segmental tissue loss	4
	Vascular	Devascularized segment	4

[a]Advance one grade for multiple injuries up to grade III.

AIS, Abbreviated Injury Scale.

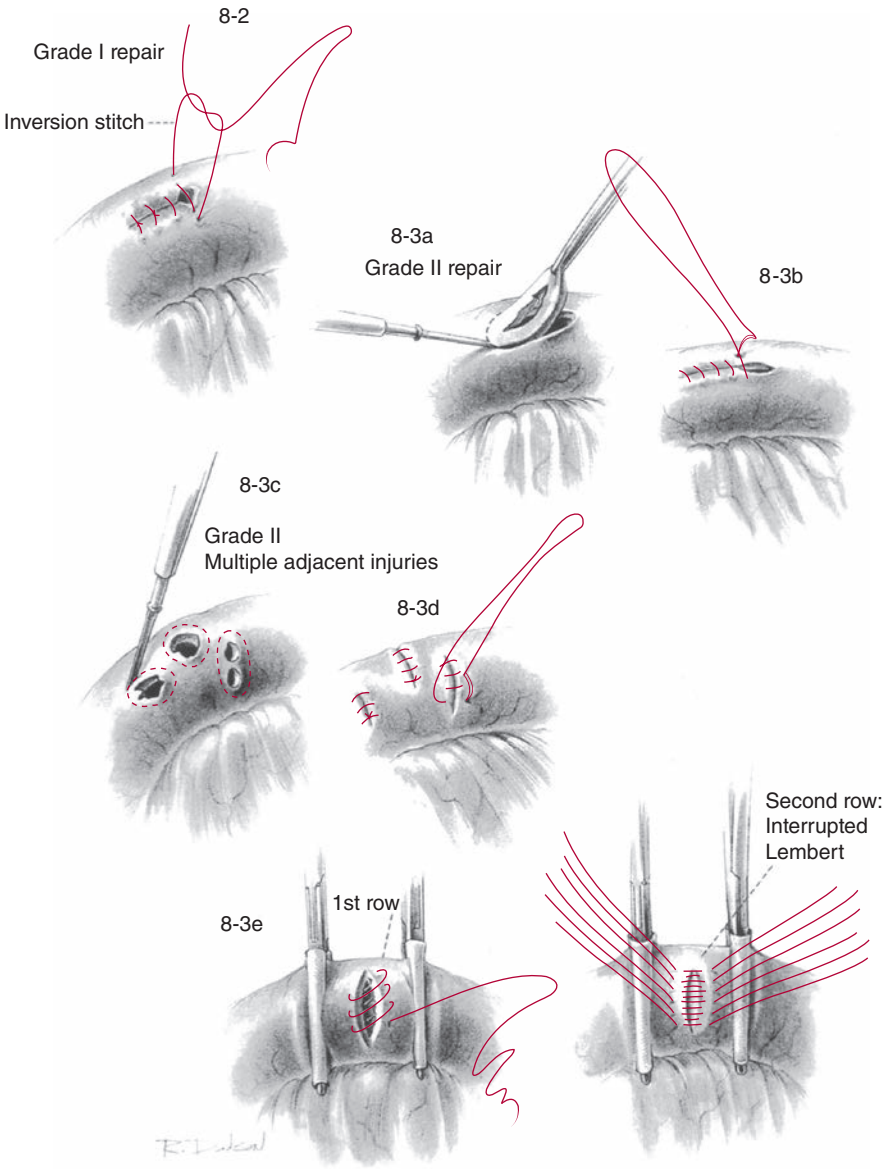

FIGURE 35-8 Treatment of grade I and II small bowel injuries. Grade I injuries are treated by inversion with seromuscular sutures. Grade II injuries are treated by careful debridement and primary closure. Either a one- or two-layer closure may be used. Adjacent through-and-through perforations are treated as a single defect by dividing the bridge of tissue separating them with electrocautery. (Reproduced with permission from Carrico CJ, Thal ER, Weigelt JA, eds. *Operative Trauma Management: An Atlas*. Norwalk, CT: Appleton & Lange; 1998. Copyright The McGraw-Hill Companies, Inc.)

involving the mesenteric border are most often amenable to suture repair (Fig. 35-8). The wound should be closed transversely by a single- or two-layer technique as it ensures the widest lumen. With lacerations or injuries along the antimesenteric border of bowel, the wound can be reoriented in a transverse fashion. If this is not possible, resection is often the best treatment. Adjacent through-and-through wounds of the bowel should be joined transversely using electrocautery and closed as a single defect. Multiple grade II injuries can usually be closed individually. Small bowel resection for multiple perforations may be favored if resection and anastomosis would take less time than closing the perforations individually and the amount of bowel sacrificed is minimal. An additional concern is the tendency to compromise the bowel lumen with closure of multiple perforations in a short segment.

Grade III and higher injuries usually require resection and anastomosis (Fig. 35-9). Occasionally, grade III wounds that are oriented transversely or in the relative large proximal to mid jejunum may be primarily repaired provided that an adequate lumen (at least 30% of the circumference) is maintained.

STAPLES VERSUS SUTURES

There continues to be controversy as to the risks of stapled versus handsewn anastomoses for traumatic bowel injuries.[34-41] Most of the available data are from retrospective studies,

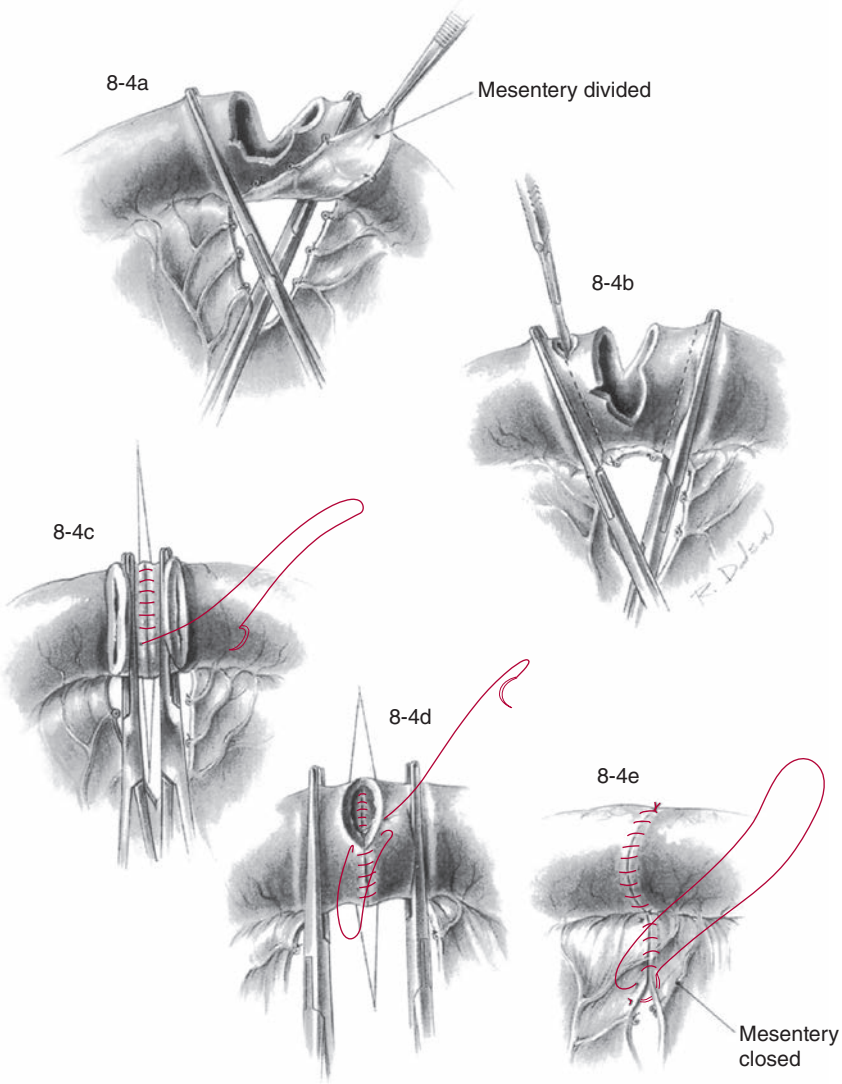

FIGURE 35-9 Grade III small bowel injuries are usually treated by resection and anastomoses. Proximal small bowel injuries or transversely oriented wounds may on occasion be primarily repaired. (Reproduced with permission from Carrico CJ, Thal ER, Weigelt JA, eds. *Operative Trauma Management: An Atlas*. Norwalk, CT: Appleton & Lange; 1998. Copyright The McGraw-Hill Companies, Inc.)

and there has only been one prospective study (Table 35-3). There are no controlled clinical trials comparing techniques for intestinal anastomosis following trauma. It is clear from over four decades of experience in thousands of patients undergoing elective resection that the complication rate is similar for stapled and handsewn anastomoses. Extrapolating this to trauma, where most patients are not in shock and not receiving aggressive fluid resuscitation, the lack of difference between handsewn and stapled anastomoses in the available series should not be surprising.

In contrast, patients who have significantly thickened bowel due to edema from massive resuscitation, damage control laparotomy, or sepsis must be considered separately. In a small retrospective series of emergency general surgery patients, Farrah et al[39] found that there was a higher rate of anastomotic failure with staples versus sutures (15% vs 6%; P <.003). Recently, in an American Association for the Surgery of Trauma multicenter trial, Bruns et al[40] prospectively studied 595 emergency general surgery patients undergoing 649 anastomoses (253 handsewn and 396 stapled) and documented a similar rate of anastomotic failure (12.5%). Of note, the handsewn group was more likely to be on vasopressors, have a higher lactate level, and have a lower albumin level. Thus, there remains a perception and treatment bias for the use of sutures in this group of patients.

In summary, the use of either staples or sutures to create an intestinal anastomosis is likely equivalent in almost all patients, and the trauma surgeon should use the technique that he or she is most comfortable using. In the severely injured patient, with a thick bowel wall and alterations in blood supply, it is also likely that the usual fixed staple height, which is perfectly acceptable for normal bowel, may not be optimal. In these cases, sutures may be advantageous. The other instance where sutures may be preferred is when the architecture of the anastomosis is unfavorable for stapling. This occurs at the ligament of Treitz or in the distal ileum near the ileocecal valve.

TABLE 35-3: Type of Small Bowel Anastomoses

Author	No. of patients	Site of injury	Handsewn	Stapled	Results and comments
Brundage et al[38]	84	Small bowel (101) and colon (17)	60	58	Retrospective single-institution study. Stapled anastomoses had significant increase in anastomotic leak requiring reoperation.
Witzke et al[34]	257	Small bowel only, but included primary repair (131) and resection/ anastomoses (144)	34	110	Retrospective single-institution study showed no difference in rate of intra-abdominal abscess, fistula, an anastomotic leak, or postoperative bowel obstruction.
Brundage et al[35]	199	Both small bowel (224) and colonic anastomoses (61)	84	140	Retrospective study from five Level I trauma centers. Higher leak rate and overall complication rate for stapled anastomoses.
Kirkpatrick et al[36]	227	Small bowel only; both primary repair (104) and resection with anastomoses (123)	24	52	Retrospective study from two institutions. No differences in anastomotic complication as related to technique used. Increased anastomotic complications associated with pancreaticoduodenal injury, or if done as part of a damage control procedure; 47 anastomoses were done using sutures/staples in a combined technique.
Farrah et al[39]	231	Small bowel to small bowel (125) Small bowel to colon (89) Colon to colon (15)	100	133	Retrospective series from single institution with large EGS population. Stapled anastomosis had over twice the leak rate of handsewn.
Bruns et al[40]	595	Small bowel to small bowel (466) Small bowel to colon (139) Colon to colon (44)	253	396	15-center AAST prospective observation trial of EGS patients undergoing emergency surgery. Overall leak rate was identical at 12.5%. The use of handsewn anastomosis in sicker patients reveals some treatment bias.

AAST, American Association for the Surgery of Trauma; EGS, emergency general surgery.

RESTORING INTESTINAL CONTINUITY FOLLOWING DAMAGE CONTROL

Trauma patients with intestinal injuries who require damage control laparotomy are often left with multiple disconnected segments of small and large bowel. At the time of reoperation, the surgeon needs to examine the remaining bowel and determine viability and how best to restore intestinal continuity. The concept is similar to that in patients with multiple bowel injuries who did not require damage control. Leave as much bowel as possible with the smallest number of anastomoses.

At the reoperation, segments resulting from injuries that initially did not appear in close proximity to each other on the index operation have contracted, resulting in insufficient length to adequately perform both a proximal and distal anastomosis. Shorter segments may be more likely to be engorged due to edema and intraluminal contents, which may compromise intestinal viability. In our experience, segments less than 15 cm are usually better resected. One specific difference in a bowel resection for damage control compared to that in a hemodynamically stable patient is that little thought is given to architecture of the initial resection as long as the remaining segment is viable. As the bowel fans out on its mesentery during the reoperation, the surgeon must be keenly aware that the transected ends of bowel may be ahead of their mesenteric blood supply. Although this blood supply may be sufficient to keep the segment viable, it may not be sufficient to support an anastomosis. If there is any question, one should not hesitate to re-resect the ends of the bowel more proximally. Although proximal bowel needs to be anastomosed, the risks and benefits of creating an ileostomy versus an anastomosis to the right colon must be carefully weighed. There is an old surgical adage that "the anastomosis never made, never leaks." Conversely, an ileostomy will require subsequent surgery.

The open abdomen does not appear to place the enteric anastomosis at risk of breakdown in the patient if the abdominal cavity can be closed "early."[41,42] In a Western Trauma Association multi-institutional trial that enrolled 244 patients with enteric injuries and an open abdomen, the leak rate for small bowel anastomoses was 3%.[43] In a recent series of emergency general surgery patients who underwent bowel resection, the need to treat with an open abdomen (odds ratio, 2.529; 95% confidence interval, 1.492–4.286) was independently associated with anastomotic failure.[40] In all patients who undergo a bowel anastomosis or repair, attempts should be made to protect the suture lines by using omentum, hiding the anastomosis laterally beneath the

abdominal wall or with other loops of bowel. In any reoperation to achieve abdominal wall closure, unless there is a specific indication, no attempt to dissect out and inspect the anastomosis or repair should be attempted. Achieving early fascial closure is the optimal modality to decrease anastomotic leaks.[44,45]

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

The postoperative care of patients after repair of injuries to the stomach and small bowel is usually relatively straightforward and is no different than that of elective surgical patients. Antibiotics such as cefoxitin or ampicillin-sulbactam are limited to no more than a 24-hour course, although appropriate dosing may be problematic in patients undergoing massive transfusion.[46] The use of routine nasogastric decompression, although still practiced by some, has been debunked by multiple prospective randomized controlled trials and a meta-analysis.[47] The potential impact of other clinically important variables, including the presence of multiple associated injuries, hemorrhagic shock, and postresuscitation bowel edema, as well as an impaired sensorium from a traumatic brain injury or drugs and alcohol, may make short-term nasogastric decompression the more prudent choice in select patients. Patients with extensive gastric repairs or resections may also benefit from a short course of nasogastric decompression, although this practice is also not generally supported by data. Nutritional support should be started as soon as feasible after the patient is resuscitated (see Chapter 62). Often, overall injury burden and shock rather than the gastric or small bowel injuries per se will dictate how well patients will tolerate gastric or enteral nutrition.

Complications that follow repair of injuries to the stomach and small bowel include intra-abdominal septic complications and anastomotic disruption. As previously noted, the most important etiologic factor in the development of an intra-abdominal abscess is delayed recognition and surgical treatment.[11,12] Anastomotic failures may present as peritonitis, as an abscess, or with the development of an external fistula.

Bleeding complications after repair of injuries to the stomach and small bowel trauma are rare but may present as bleeding into the peritoneal cavity or into the bowel lumen. Bleeding from an unrecognized short gastric vessel or from a torn splenic capsule is a common iatrogenic source of bleeding in patients with gastric injuries. Bleeding from the mesentery or lesser curvature of the stomach may not be apparent intraoperatively in the hypotensive patient and may only become clinically apparent when the patient's blood pressure normalizes. Continued bleeding postoperatively then manifests as hypotension and a falling hematocrit.[48] Bleeding from a gastric suture line presents as bloody nasogastric secretions, and endoscopic hemostatic techniques can be carefully employed in this setting. Finally, unexplained gastrointestinal bleeding from the small bowel may be the harbinger of an anastomotic disruption.

An anastomotic leak following repair of a gastric or small bowel injury can lead to significant morbidity and mortality. The definition of anastomotic leak is variable in both emergency and elective gastrointestinal reviews on the topic.[49] As noted earlier, anastomotic failures may present as a contained leak, diffuse peritonitis, or a gastrocutaneous or enterocutaneous fistula (ECF). Risk factors for breakdown of intestinal suture lines include resection and anastomosis rather than repair, massive transfusion and fluid administration, associated pancreatic injuries, and the development of the abdominal compartment syndrome. In patients with enteric injuries managed with an open abdomen, failure to obtain fascial closure after postinjury day 5 has been found to result in an increased leak rate.[41,43] Additional factors include evidence for ongoing hypoperfusion and the use of vasopressors during the initial resuscitation and early postoperative management in the intensive care unit.[50]

CT scanning obtained after day 4 to 5 is the best diagnostic imaging study to identify intra-abdominal pathology such as abscesses or anastomotic leaks that are not clinically obvious. Therapeutic options depend on the location of the initial injuries and pathology identified on CT. Percutaneous drainage is the primary intervention for fluid collections and intra-abdominal abscesses. A small area of radiographic inflammation in a stable patient may be treated as clinically insignificant leak with antibiotics. Anastomotic leaks diagnosed in the immediate postoperative period should be treated by reoperation with resection of the anastomosis back to healthy noninflamed bowel and, if appropriate, restoration of intestinal continuity. After 10 or 14 days, the inflammatory process may make the dissection and reoperation extremely difficult. In these cases, the goal is to control the effluent and provide adequate external drainage to create a controlled fistula. The use of latex or rubber drains and tubes will increase the inflammatory reaction and, provided there is no distal obstruction, will allow the fistula to close.

Enterocutaneous Fistula

An ECF is a dreaded complication following trauma laparotomy and may be the result of an anastomotic leak, missed injury, delayed perforation, or complications from an open abdomen following a damage control laparotomy. An ECF developing with an open abdomen is often referred to as an enteroatmospheric fistula (EAF). An EAF is actually a stoma without the benefit of the abdominal wall. As such, control of effluent from these fistulas can be exceedingly problematic. Factors associated with the development of an EAF include deserosalization and iatrogenic injury to the bowel in an open abdomen or adhesion of bowel loops to the fascial rim or adjacent bowel loops.[51] Excessive force on the bowel from coughing or even movement by the patient in this setting can lead to shearing of the bowel and bowel disruption. The goal in a patient with an open abdomen is to protect the bowel. Measures include keeping as much omentum as possible over the bowel or the use of nonadherent dressing materials. If negative-pressure therapy is to be used over the exposed small bowel, the white hydrophilic sponges should be used. Excessive use of negative-pressure therapy of abdominal wounds to promote granulation tissue may also contribute to the development of an EAF.[51] Dressing changes need to be performed

gently by experienced caregivers. Aggressive attempts should be made to obtain abdominal fascial or "skin only" closure as early as possible. It is our practice to aggressively attempt to close patients in the first week following damage control. Inability to make progress by that time results in immediate split-thickness skin grafting with planned late reconstruction of the abdominal wall. This can be done right over the intestines without waiting for any granulation tissue. A single-institution review of the development of an ECF in the era of open abdomen management was published by Fischer et al.[52] The overall incidence of ECF following trauma laparotomy was 1.9%. Patients with open abdomen had a higher ECF incidence (8% vs 0.5%) and a lower rate of spontaneous closure (37% vs 43%). The development of an ECF initiates the requirement for a prolonged stay in the intensive care unit and hospital as well as the need for a team of dedicated and experienced nurses, wound care therapists, and surgeons.

The three important concepts in the management of an ECF are as follows: (1) control of effluent and any associated infection; (2) nutritional support with fluid and electrolyte management; and (3) wound care with protection of the skin. In a posttraumatic ECF, there is no concern for radiation or neoplasia. Therefore, closure of the fistula will depend on location, size, nutritional status of the patient, and the absence of distal obstruction (ie, if the fistula tract has a higher pressure gradient than that of the normal alimentary tract, drainage will decline and the fistula will close). For example, a fistula emptying into an abscess cavity will never close because there is no pressure differential from the bowel until that abscess cavity is drained and collapsed. Fistulas that eventually form stomas to the skin or those in an open abdomen will never close based on lack of pressure differential and epithelization. These fistulas will eventually all require surgical intervention. Fistulas have been classified as high output (>500 mL/d), moderate output (200–500 mL/d), or low output (<200 mL/d). Yet, this distinction does not take into account the reason why a fistula actually stays open. The only reason to measure output is to help guide fluid management and nutritional support. In most patients, normal saline with 10 to 20 mEq of potassium per liter is a suitable fluid to use for the initial intravenous fluid replacement. Patients with an ECF may also develop significant calcium, magnesium, and phosphate deficits that should be measured and corrected. Careful attention should also be made to acid-base balance. Occasionally, measurement of the electrolyte composition of the fistula effluent is helpful for guiding fluid replacement (Table 35-4).

The delivery of adequate nutritional support is critical to help support the patient and hopefully eventually close an ECF (see Chapter 62). Enteral nutritional support is the preferred way of providing nutrition; however, with a high-output proximal small bowel fistula, this route may fail to provide adequate nutrition, aggravate fluid and electrolyte imbalances, and make wound care more difficult. In this situation, total parenteral nutrition (TPN) may be necessary. Adjuncts to control fistula drainage include a nasogastric tube and suppression with H_2-receptor antagonists or proton pump inhibitors. Somatostatin analog will decrease the volume of output but has not been shown to be beneficial to ECF closure.

Protecting the integrity of the skin surrounding the fistula is important and will improve patient comfort. Consultation with wound care nurses can be exceedingly helpful in devising systems to protect the skin and control effluent. In many cases, the surgeon must be resourceful to devise a system that works. It should also be realized that as the patient's wound heals, the architecture of the ECF and the abdominal wall will change, requiring the surgeon to alter the collection system sometimes daily. Negative-pressure therapy may be useful, but often ECF fluid is viscous and not amenable to a standard dressing. Creation of a negative-pressure system with opening for stomas has been devised; however, excessive negative pressure may prevent the ECF from closing.

Spontaneous closure of an ECF may occur in patients without epithelization (stomas) and distal obstruction who are free of sepsis and provided adequate nutritional support. Surgery will be required for patients whose ECF forms a stoma and those with longstanding fistulas. Definitive surgery is ideally delayed 3 to 6 months following the initial operation. Failure to obtain spontaneous closure should not be a primary factor in the timing of operative intervention but rather nutritional and wound status. Ideally, the patient should be in optimal shape, nutritionally replete, and free of ongoing inflammation before embarking on an often long and difficult surgical procedure. There are, however, patients whose tenuous nutritional balance mandates operative closure at an earlier time than ideal because these patients will never get better otherwise. Resection of a fistula requires complete lysis of adhesions to identify all small bowel limbs involved and eliminate the possibility of distal obstruction as a contributing factor for the failure of spontaneous closure (Fig. 35-10). Resection of the involved bowel segments back to healthy small intestine is the optimal management. In a

TABLE 35-4: Composition and Volume of Gastrointestinal Secretions

Type	Volume (mL/y)	Na (mEq/L)	K (mEq/L)	Cl (mEq/L)	HCO_3 (mEq/L)
Salivary	1500	10	26	15	50
Stomach	1500	60–100	10	100	0

FIGURE 35-10 Morbidly obese (body mass index, 50 kg/m^2) patient who sustained a gunshot wound to the abdomen with an injury to the iliac artery. (**A**) Postoperative dehiscence resulted in an ECF (arrow) secondary to traction on a loop of bowel. The fistula was in the proximal jejunum and a feeding tube could never be passed distally for unclear reasons. Patient remained on total parenteral nutrition for 3 months until able to be explored. (**B**) The fistula complex is isolated with extension of the incision cephalad and extensive lysis of the adhesions to identify the anatomy. (**C**) Complete dissection disclosed three separate fistulas (clamps) with obstruction distal to the first fistula, which explains the inability to intubate the bowel.

study by Lynch et al,[53] simple oversewing or wedge resection of the ECF was associated with a 36% recurrence rate compared to 16% with resection and reanastomosis. After resection of the fistula and reestablishment of gastrointestinal continuity, attention is then directed to coverage of the bowels and closure of the abdominal wound. It is perfectly acceptable, and may be preferable, to leave the patient with a planned hernia following surgery to close an ECF. If the patient was closed with split-thickness skin grafting, operating through the skin graft is both possible and preferred.[54] Embarking on a complex abdominal wall reconstruction requiring unilateral or bilateral component separation after a long and complicated operation to close an ECF is not optimal. In these patients, the fistulas can be resected or closed and the overlying skin

FIGURE 35-11 (**A**) Patient sustained severe duodenal injury requiring damage control, skin grafting of the abdomen, and placement of a decompressive gastrostomy tube (*A*) and an end feeding jejunostomy (*B*). Intestinal continuity was restored with a Roux-en-Y gastrojejunostomy through the skin graft, taking care not to devascularize it from the underlying viscera. (**B**) The abdomen was then closed using simple interrupted sutures from the skin graft to the native abdominal wall. The patient underwent abdominal wall reconstruction using mesh 8 months later.

simply reclosed (Fig. 35-11). The use of prosthetic materials, including cross-linked biological materials, is ill-advised due to concerns for the breakdown of intestinal anastomotic repair, the development of a de novo intestinal fistula, and serious wound complications and infection, as well as overall expense.[55,56]

Later reconstruction once intestinal continuity has been established and the patient has recovered from the ECF operation is a very reasonable and safe approach, and patients tolerate a hernia much better than they tolerate a fistula.

Small Bowel Obstruction

Small bowel obstruction (SBO) is a well-known complication following any abdominal operation. Patients with nontherapeutic laparotomies for trauma had a 2.4% incidence of SBO in a report by Renz and Feliciano.[57] The rate is higher if operative repair is required and may be up to 7.4% in patients with penetrating abdominal trauma and 10.8% in patients with injuries to the small or large bowel.[58] Trauma laparotomy does not appear to have added risk versus that reported following elective colorectal and general abdominal surgery on the development of an early SBO and need for operative management. The management of SBO following trauma laparotomy is similar to that following elective surgery.

Short Gut

Multiple intestinal injuries requiring extensive resection of significant amounts of small bowel may lead to problems with nutrition due to malabsorption. Removal of significant portions of the jejunum may lead to lactose intolerance; however, this is usually self-limited. Resection of the distal ileum often leads to vitamin B_{12} deficiency as well as bile salt deficiencies and subsequent fat malabsorption. Ileal resection including the ileocecal valve also removes the "ileal braking mechanism" that may cause decreased transit time throughout the gut. This may result in profuse diarrhea and significant fluid and electrolyte imbalances.

More often than direct injury to the bowel itself, a short bowel syndrome may result from an injury to its blood supply. In a series of 196 adult patients evaluated at a single institution over 23 years, 8% of the patients with a short bowel syndrome had been victims of abdominal trauma.[59] Historically, 80% of trauma-related short bowel syndrome has been due to mesenteric injuries. Clinical manifestations include malabsorption, diarrhea, steatorrhea, fluid and electrolyte disturbances, and malnutrition. Late complications include cholelithiasis and kidney (oxalate) stones. Short bowel syndrome is fully manifest when the remaining jejunum and ileum are less than 200 cm in length. Plasma citrulline may be a useful

biomarker to index the remaining small bowel enterocyte mass.[60]

Physiologic adaptation of patients with a short bowel syndrome follows a distinct trajectory.[61] The acute phase occurs during the immediate postoperative weeks and may last 1 to 3 months. This time period is marked by poor absorption of almost all macronutrients and micronutrients. Ostomies, if present, may have outputs exceeding 5 L/d during the first few days. Aggressive intravenous fluid and electrolyte replacement is necessary to prevent life-threatening dehydration and electrolyte imbalances. Gastric hypersecretion is frequent in this phase and may be treated with proton pump inhibitors. Loperamide, codeine, diphenoxylate, or even tincture of opium should be used to slow gastric and intestinal transit to control diarrhea. Careful monitoring of fluid and electrolytes, particularly potassium, magnesium, and calcium, is critical. Fluid needs can be monitored by urinary and fistula output, as well as by urinary sodium and osmolarity. Depending on the amount of bowel remaining, nutrition is often a combination of full TPN with supplemental elemental enteral feedings as tolerated. An adaptation phase will occur over time (months to years) with improvements in absorption of fluids and nutrients. Enteral feeding to provide intraluminal nutrients to maintain gut mass is necessary for the adaptation response to occur. Thus, enteral nutrition remains the primary therapy in maximizing luminal nutrient absorption in the intestinal remnant.

Patients who have survived their injury but have lost most of their small bowel may be candidates for intestinal transplantation. Trauma patients seem to have equivalent long-term survival rates as compared with nontrauma patients following intestinal transplantation. A multidisciplinary approach to the treatment of intestinal failure due to short bowel syndrome appears to be the best outcome for these patients.

CONCLUSION

An algorithm reviewing the operative management of injuries to the stomach and small bowel is presented in Fig. 35-12.

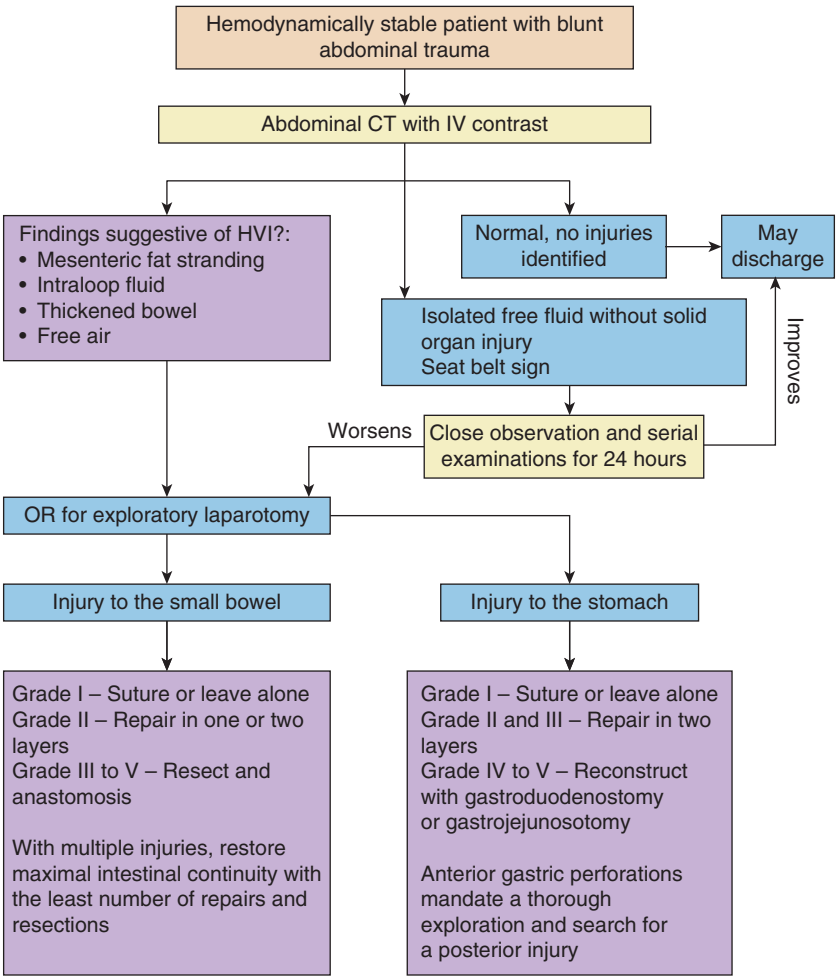

FIGURE 35-12 Algorithm reviewing the operative management of injuries to the stomach and small bowel. CT, computed tomography; HVI, hollow viscus injury; IV, intravenous.

Duodenum and Pancreas

Paula Ferrada • Ricardo Ferrada • David V. Feliciano

KEY POINTS

- The incidence of injuries to the duodenum at laparotomy is <2% with stab wounds, 5% to 6% with blunt trauma, and 10% to 11% with gunshot wounds.
- A patient with a blunt rupture of the duodenum may have minimal symptoms initially due to its retroperitoneal location, low bacterial count, and neutral pH contents.
- A computed tomography (CT) diagnosis of a ruptured duodenum is suggested by air outside the duodenum in the right upper quadrant on the "scout" film and leakage of contrast on the formal study.
- A primary transverse or oblique suture repair of a blunt rupture or penetrating wound of the duodenum is appropriate if there is no loss of tissue and no injury to the major papilla.
- Pyloric exclusion with gastrojejunostomy should be considered as an adjunct to a duodenal repair when the repair narrows the duodenum, the duodenal wall around the repair is severely contused, there has been a delay in diagnosis of the duodenal injury, or there are adjacent, but not destructive, injuries to the C-loop and head of the pancreas.
- The incidence of injuries to the pancreas at laparotomy is approximately 6% with all forms of trauma.
- When a contrast-enhanced multidetector CT study is unclear about whether an injury to the duct of Wirsung is present after blunt trauma, a magnetic resonance cholangiopancreatography and/or an endoscopic retrograde cholangiopancreatography is performed.
- The Letton-Wilson Roux-en-Y distal pancreatojejunostomy is appropriate in a highly selected group of patients with Organ Injury Scale proximal grade III and grade IV injuries.
- A damage control approach (sequential operations) is now used in the majority of patients who need a pancreatoduodenectomy after trauma.
- Combined pancreatoduodenal injuries have significantly increased postoperative complications and mortality rates when compared to injury to either organ alone.

INTRODUCTION

The duodenum and pancreas are retroperitoneal structures that are protected somewhat from injury by the spine, retroperitoneal muscles, and overlying intra-abdominal viscera. Injuries to these structures are uncommon, and many trauma surgeons have limited experience in treating them. In the United States, injuries to the duodenum and pancreas are noted at only 1.5% to 11% and 5% to 6% of all laparotomies for trauma, respectively.[1] A recent review from the Trauma Audit and Research Network of the United Kingdom and Wales found that only 4.7% of patients with abdominal trauma had injuries to the duodenum or pancreas.[2]

Isolated injuries to the duodenum and pancreas are rare, and early deaths after injury are usually due to associated vascular injuries or multiple visceral and vascular injuries in the same patient. Other factors in management include delays in patient presentation after blunt trauma, the significant leak rate after pancreatic resections, and difficult decisions with combined injuries.

Outcomes for injuries to either organ have improved in recent years secondary to increased experience and to utilization of time-tested management algorithms.[3-7]

DUODENUM[8,9]

Anatomy

The duodenum is approximately 30 cm (12 fingerbreadths) in length and has four parts. The intraperitoneal short superior duodenum (D_1) starts beyond the pyloric muscle ring

of the stomach and goes to where it crosses over the common bile duct and gastroduodenal artery in the hepatoduodenal ligament. The retroperitoneal descending duodenum (D_2) extends from the hepatoduodenal ligament to the ampulla of Vater. The retroperitoneal transverse duodenum (D_3) is from the ampulla of Vater to the superior mesenteric vein and artery at the uncinate process of the pancreas. Finally, the retroperitoneal and distal intraperitoneal ascending duodenum (D_4) extends from the mesenteric vessels to the duodenojejunal junction at the ligament of Treitz.

The duct of Wirsung, or main pancreatic duct, enters the common bile duct to form the poorly named ampulla of Vater. This empties into the medial wall of the duodenum at the papilla (junction D_2–D_3), which can be palpated through a traumatic perforation or rupture of reasonable size in this area. The duct of Santorini or accessory pancreatic duct enters at the minor papilla in D_2, which lies 2 cm proximal to the major papilla described earlier.

The vascular anatomy of the upper abdomen complicates management of duodenal and pancreatic injuries, particularly the shared blood supply of the C-loop of the duodenum and head of pancreas. The superior pancreaticoduodenal artery, a branch of the gastroduodenal artery, is the arterial supply of the upper half of the duodenum. The inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery, is the arterial supply of the lower half of the duodenum. On the venous side, the anterior branch of the superior pancreaticoduodenal vein drains into the right gastroepiploic vein, while the posterior branch drains into the portal vein. One or more branches of the inferior pancreaticoduodenal vein drain into the superior mesenteric vein.

Associated injuries in patients with duodenal trauma are most commonly to an upper abdominal vessel, liver, colon, and pancreas (approximately one-third of the time).[9] Major vessels adjacent to D_1 and D_2 include the hepatic artery, portal vein, inferior vena cava, the right renal vessels, and the left renal vein as it enters the inferior vena cava. Penetrating wounds to D_3 and D_4 may involve the underlying visceral abdominal aorta and the left renal vessels.

Mechanism of Injury

With blunt trauma, the duodenum can be compressed by a direct blow to the epigastrium such as from the handlebar of a child's bicycle. In an adult, a fist, the lower rim of the steering wheel, or a misplaced lap seat belt may be the cause. The injury that may result is a submucosal or subserosal hematoma, usually in D_2, although more extensive hematomas involving both D_2 and D_3 occur. A more extensive injury such as rupture is thought to be related to the anatomy of the duodenum (ie, the pyloroduodenal and duodenojejunal junctions, which are the two main points of fixation). It has long been hypothesized that sudden kinking of the duodenum at these points of fixation results in a sudden increase in intraluminal pressure during a deceleration-type motor vehicle crash and causes a rupture in D_2 or D_3.

In patients with penetrating thoracoabdominal, abdominal, flank, or back wounds mandating an emergency (peritonitis, hypotension, evisceration, bleeding from gastrointestinal or genitourinary tract) or urgent (delayed diagnosis, failure of nonoperative management) laparotomy, the duodenum is always exposed to see if an injury is present. Injuries to adjacent abdominal vessels and viscera, as described earlier, obviously increase the likelihood that a duodenal injury is present.

Clinical Presentation and Diagnosis

The clinical presentation of patients with *blunt* trauma to the duodenum will depend on whether a submucosal or subserosal hematoma versus rupture is present, the presence of associated injuries, and the time interval since injury.

A patient with a submucosal or subserosal hematoma of the duodenal wall will often have only minimal or moderate pain and epigastric tenderness on the initial physical examination in the emergency center. In the past, patients with minimal pain and tenderness were discharged from the emergency center without abdominal computed tomography (CT) being performed. As posttraumatic edema occurs, the patient develops a complete duodenal obstruction and persistent vomiting, usually within 6 to 12 hours. A 128-multidetector CT of the abdomen will confirm the presence of the hematoma in D_2 and/or D_3. A "coiled spring" sign or complete duodenal obstruction will be present if oral diatrizoate meglumine (Gastrografin) is administered before the CT (Fig. 36-1).

A blunt rupture of the duodenum as described earlier may also not be diagnosed on the first physical examination because the bacterial count of the duodenum is low (10^3–10^4) and pancreatic bicarbonate tends to neutralize gastric acid; hence, retroperitonitis may have a delayed presentation as compared to traditional peritonitis. When abdominal flat plate x-rays were performed routinely in patients with abdominal trauma in the past, surgeons would always look to see if there was a collection of air outlining the C-loop of the duodenum in the right upper quadrant. This finding suggested the diagnosis of a retroperitoneal duodenal rupture and would prompt an upper gastrointestinal contrast study to confirm the diagnosis. Currently, this abnormal collection of air would be noted on the preliminary scout CT or on the formal CT of the abdomen. The addition of oral Gastrografin would, once again, be used to confirm the diagnosis. An example of a CT diagnosis of a duodenal perforation is presented in Fig. 36-2.

An early diagnosis of a perforation or rupture of the duodenum is critical because a delay of 24 hours, a rare event in the modern era, led to a mortality rate of 40% in the past.[10] This is related to autodigestion of the retroperitoneum and the difficulty in repairing an edematous duodenum with everted mucosa.

In a patient undergoing an emergency laparotomy (no preoperative abdominal CT) after either blunt or penetrating

FIGURE 36-1 Duodenal hematoma at junction of D_2 and D_3.

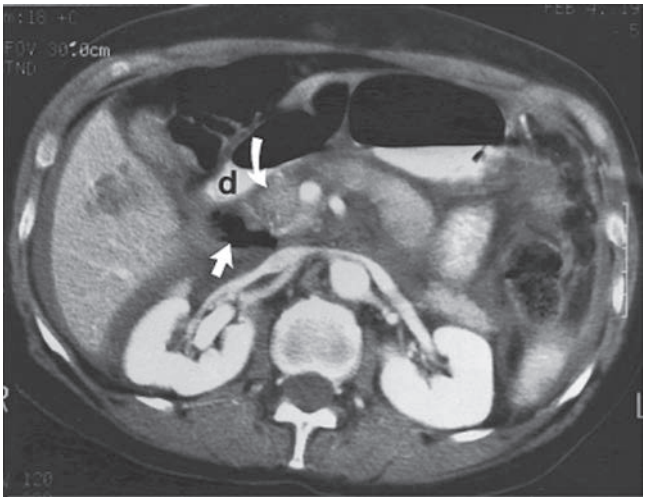

FIGURE 36-2 Computed tomography (CT) findings of retroperitoneal duodenal perforation. CT scan shows poor definition of the structures in the region of the head compared to the body. A collection of extraluminal, retroperitoneal gas (straight arrow) lies immediately posterior to the second portion of the duodenum (d), consistent with a duodenal perforation. (Reproduced with permission from Smith DR, Stanley RJ, Rue LW III. Delayed diagnosis of pancreatic transection after blunt abdominal trauma. *J Trauma*. 1996;40:1009.)

TABLE 36-1: American Association for the Surgery of Trauma Duodenum Organ Injury Scale

Grade		Injury description
I	Hematoma	Involving single portion of duodenum
	Laceration	Partial thickness, no perforation
II	Hematoma	Involving more than one portion
	Laceration	Disruption <50% of circumference
III	Laceration	Disruption 50%–75% circumference of D_2
		Disruption 50%–100% circumference of D_1, D_3, D_4
IV	Laceration	Disruption >75% circumference of D_2
		Involving ampulla or distal common bile duct
V	Laceration	Massive disruption of duodenopancreatic complex
	Vascular	Devascularization of duodenum

Source: Adapted with permission from Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling II: pancreas, duodenum, small bowel, colon, and rectum. *J Trauma.* 1990;30:1427-1429.

trauma, any area of injury in proximity to the duodenum is explored (see later in chapter).

Duodenum American Association for the Surgery of Trauma Organ Injury Scale (Table 36-1)

Management of the patient with a diagnosis of an injury to the duodenum is based on multiple factors, especially the magnitude of injury as determined by the American Association for the Surgery of Trauma (AAST) Organ Injury Scale (OIS).[11]

Nonoperative Management: Organ Injury Scale Grade I Duodenal Hematoma (Fig. 36-3)

An isolated blunt OIS grade I duodenal hematoma diagnosed on CT is managed nonoperatively. A nasogastric tube is inserted because of the total obstruction of the upper gastrointestinal tract, and the patient is maintained on total parenteral nutrition (TPN) through a central venous line. A repeat abdominal CT with upper gastrointestinal contrast is performed after 10 to 14 days to see if there has been any resolution of the hematoma. If the hematoma is still causing a complete obstruction of the duodenum, current options include another week of nasogastric suction and TPN, percutaneous drainage, or open or laparoscopic evacuation with insertion of a T-tube into the hematoma cavity.[12-15] After 21 days, failure of the hematoma to resolve or failure of the approaches mentioned earlier to drain or evacuate the hematoma should be followed by a laparoscopic or open

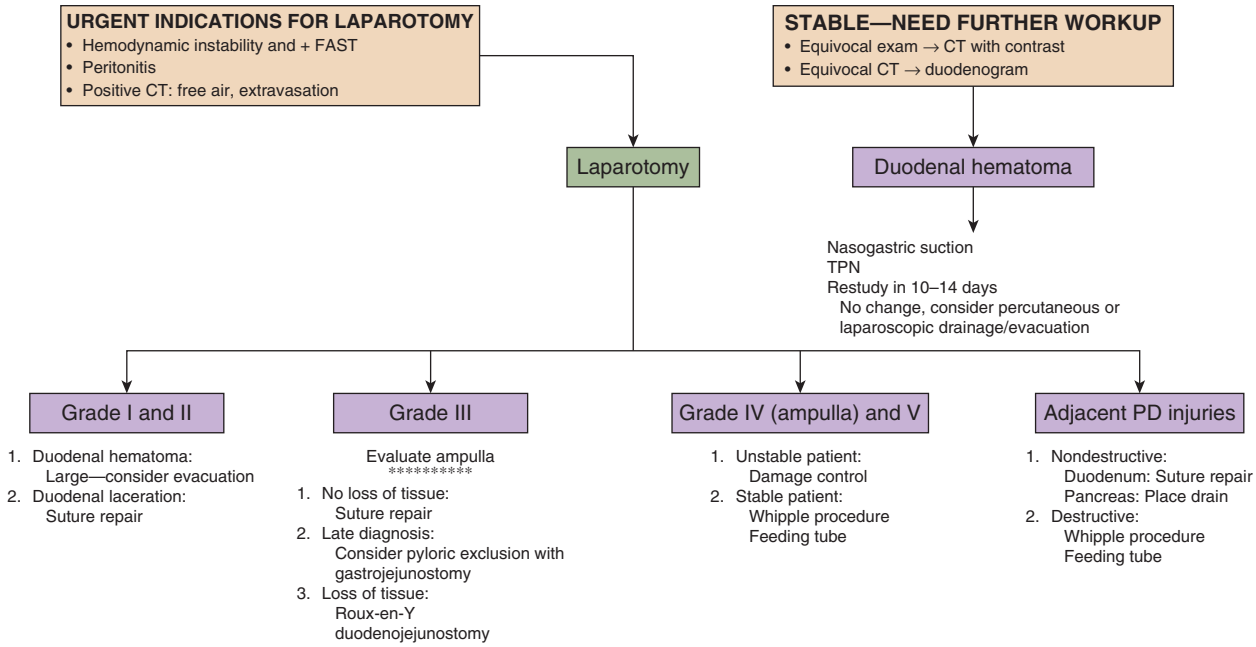

FIGURE 36-3 Algorithm for operative management of duodenal trauma. CT, computed tomography; FAST, focused assessment with sonography in trauma; PD, pancreatoduodenal; TPN, total parenteral nutrition.

gastrojejunostomy. The patient should be screened for the presence of *Helicobacter pylori* before discharge and treated if this is positive.

Operative Exposure

In patients with either blunt or penetrating trauma, areas of bleeding from viscera or vessels are controlled and gastrointestinal perforations or ruptures are repaired or resected. Exposure of the duodenum is then performed.[16] Ideally, the entire duodenum should be exposed at each laparotomy for trauma. In reality, blunt ruptures most commonly occur in D_2 and D_3 and are readily visualized by an extensive Kocher maneuver. As the track of a stab wound or civilian missile is usually straight, only the area of the duodenum in the track is usually exposed in patients with penetrating trauma.

The first step in complete exposure of the duodenum is medial mobilization of the distal ascending colon and hepatic flexure. An extensive Kocher maneuver is then performed, and this is facilitated by applying several Babcock clamps to D_2 and D_3 through the retroperitoneum and pulling these anteriorly. A scissors is used to divide the retroperitoneum just lateral to the antimesenteric edge of the C-loop of the duodenum. Gentle manual sweeping of the surgeon's hand under the elevated C-loop and head of the pancreas will allow for exposure of D_2 and a portion of D_3. In obese individuals, the middle colic vein can be used as a marker to where the superior mesenteric vein lies inferior to the pancreas.

The ligament of Treitz is then sharply divided from lateral to medial to mobilize the duodenojejunal junction until the fingers enter the space to the right where the Kocher maneuver was performed. This maneuver allows for complete visualization of D_4 and anterior D_3, whereas posterior D_3 can be palpated. The Cattell-Braasch maneuver described in 1960 can be performed to improve visualization of posterior D_3 if this is necessary to complete a duodenal repair.[17] First, the cecum, ascending colon, and hepatic flexure are mobilized medially by sharp division of the line of Toldt and traction on the colon. The retroperitoneal attachments of the mesentery of the small bowel are then sharply divided from the right lower quadrant to the duodenojejunal junction. With evisceration of the small bowel to the left, D_3 and D_4 can be visualized completely.

Operative Management: Factors in Repair

In critically injured patients, intraoperative hypotension and physiologic exhaustion secondary to associated injuries are the most important factors in operative management. Even so, an effort should be made to temporarily or permanently close the hole in the duodenum at the first damage control procedure. This is appropriate even if the temporary repair results in significant narrowing of the duodenal lumen. With near transection, both ends can be oversewn or stapled shut. Some type of closure decreases contamination and inflammation in an immunocompromised patient who will need more laparotomies.

When the patient is hemodynamically stable in the operating room, there are two important factors in choosing a technique for duodenal repair. The first is whether or not there has been a significant loss of tissue from the duodenal wall that will prevent a primary suture repair. The second is whether or not combined injuries of the duodenum and

pancreas in proximity are present, as the postoperative complication rate is always higher in such patients.[18,19]

Operative Management: Organ Injury Scale Grades II, III, and Selected Grade IV Injuries[1] (Fig. 36-3)

As previously noted, the duodenum has an excellent blood supply and reasonable mobility after an extensive Kocher maneuver is performed. Routine suture repairs of blunt ruptures (Fig. 36-4) or penetrating perforations without loss of tissue will, therefore, have a leak rate of only 1% to 3%. Repairs of such injuries away from the medial wall are performed in a transverse or oblique fashion using an inner full-thickness row of 3-0 absorbable suture and an outer seromuscular row of 3-0 silk sutures.[20] When the medial wall is part of the rupture or perforation, the hole is extended transversely toward the antimesenteric boarder. Through this hole, the major papilla is visualized and palpated to verify that it is not injured. If a hole in the medial wall is confirmed (pancreatic tissue visualized), closure is attempted using a single row of interrupted 3-0 absorbable sutures. The risk of a postoperative pancreatic fistula is significant with such an injury, and the hope would be that the fistula would drain internally into the duodenal lumen.

A repair of a longer rupture or perforation or one with contusions surrounding the area of duodenal repair is presumably at an increased risk for a postoperative leak. As a buttress to this repair, a viable pedicle of omentum can be mobilized off the right side of the transverse colon, placed on top of the repair, and held in place with interrupted 3-0 absorbable sutures.

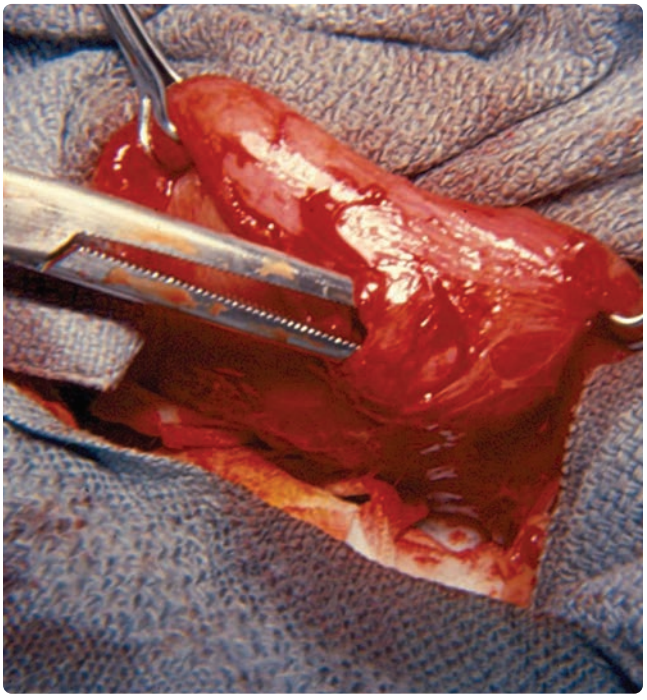

FIGURE 36-4 Blunt duodenal rupture in victim of pedestrian–motor vehicle crash.

When there is a loss of a portion of the anterior, antimesenteric, or posterior wall of the duodenum, a more complex repair is needed. The same is true in a patient with significant narrowing or an early leak after a rapid repair at the prior "damage control" laparotomy. The sutures in the duodenal wall are removed, and the edges of the open duodenal wall are debrided back to bleeding tissue. A standard jejunal Roux limb 40 cm in length is created and passed through the avascular area of the right transverse mesocolon. A side-to-end duodenojejunostomy is then performed at the site of the duodenal defect using the two-layer repair described earlier. As in general surgery procedures, the jejunal Roux limb is fixated to the window in the transverse mesocolon with circumferential 3-0 silk sutures. The final step in the procedure is to perform a sutured or stapled end-to-side or side-to-side jejunojejunostomy to restore gastrointestinal continuity.

There are few data on the use of a jejunal serosal patch to repair large defects in the wall of the duodenum as described in older publications.[21] A mucosa-to-mucosa repair is the procedure of choice in the modern era.

ADJUNCTIVE PROCEDURES: PYLORIC EXCLUSION WITH GASTROJEJUNOSTOMY

Several adjunctive operative procedures have been described over the past 113 years to lower the incidence of duodenal leaks after repair or to treat duodenal fistulas. In the modern era, these procedures are used occasionally in patients with one of the following, but in whom a Whipple procedure cannot be justified: (1) a narrowed duodenal repair; (2) a discolored or bruised duodenal repair; (3) a delayed duodenal repair in the previously mentioned presence of retroperitoneal digestion and duodenal mucosal eversion; or (4) a combined pancreatoduodenal injury.

The first adjunctive operative procedure described by Albert A. Berg, MD, at Mt. Sinai Hospital in New York City in 1907 was pyloric exclusion with gastrojejunostomy.[22] The original description was for treatment of postoperative duodenal fistulas. The procedure, however, was adopted by the trauma group at Ben Taub General Hospital (now Ben Taub Hospital)/Baylor College of Medicine in Houston, Texas, as an adjunct for the treatment of complex duodenal injuries or combined pancreatoduodenal injuries 70 years later.[18,23,24] The technique has been controversial in the trauma literature for the past 40+ years, with support from the Ben Taub group and others,[18,23-26] concerns about the addition of gastrojejunostomy,[27] and lack of improvement in overall results.[28,29] In the senior author's recent experience, the technique is used one to two times per year in a busy urban trauma center with 10% to 30% penetrating wounds. The indications have continued to be those described earlier, most commonly a delayed diagnosis of a duodenal rupture or perforation.

The procedure starts by skeletonizing approximately 10 cm of the dependent greater curve of the stomach within 6 to 10 cm of the pylorus. A dependent gastrotomy is then made through the skeletonized area. To facilitate an accurate and complete pyloric occlusion, Babcock clamps are placed

on the pyloric muscle ring, not the prepyloric antrum, at the 12 and 6 o'clock positions. By pulling these clamps superiorly and inferiorly, respectively, the pyloric outlet is converted to a vertical slit. Two rows of #1 polypropylene suture are then placed into the pyloric muscle ring to complete the exclusion. The procedure is completed by sewing or stapling an antecolic gastrojejunostomy.

Because this operative adjunct may increase the risk of a stomal ulcer over time, the patient is screened for the presence of *H pylori* before discharge. Standard treatment for *Helicobacter* is initiated if the screening is positive. In addition, an upper gastrointestinal contrast x-ray is performed to verify complete closure of the pylorus (Fig. 36-5). One older study documented that pyloric exclusions open between 14 and 21 days in 94% of patients.[24] Therefore, the exclusion will minimize output from a postrepair fistula that develops in the first 2 to 3 postoperative weeks.

Variations in the operative technique for pyloric exclusion have been reported. At the Hospital Universitario del Valle in Cali, Colombia, a feeding tube is first passed through the pylorus. Then the pyloric muscle ring is sewn closed tightly against the feeding tube through a gastrotomy, and a gastrojejunostomy is *not* performed. In Taiwan, the "controlled reopen suture technique for pyloric exclusion" was reported in 1998.[26] First, a slip knot is used at the end of the suture closing the pylorus. Then, the long suture end of the slip knot is brought out of the stomach and abdomen attached to a gastrostomy tube. If there is no evidence of a leak from the duodenal repair after 2 weeks, the slip knot is released by pulling on the long suture outside the abdomen.

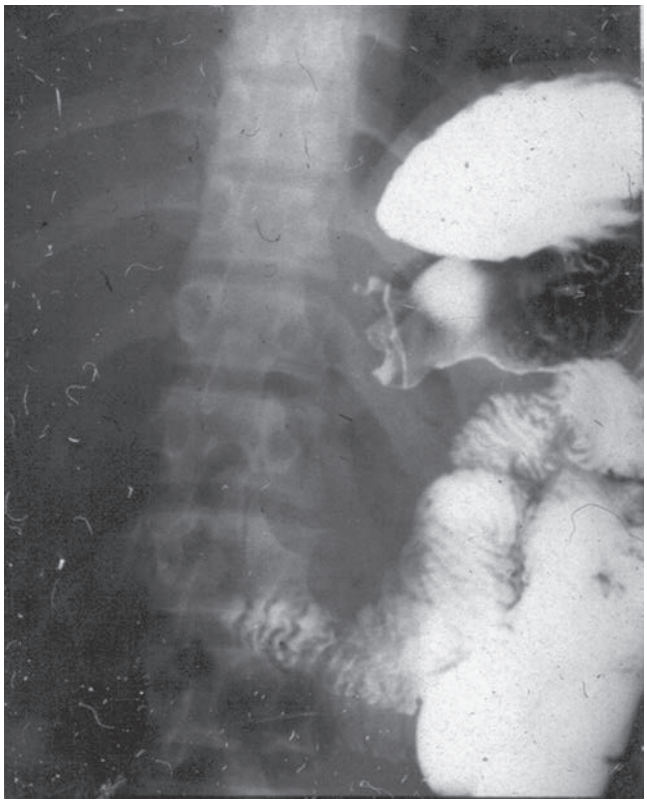

FIGURE 36-5 Postoperative upper gastrointestinal contrast x-ray documents complete pyloric exclusion.

ADJUNCTIVE PROCEDURES—DUODENAL DIVERTICULIZATION

In papers published in 1968 and 1974, the trauma group from Los Angeles County Hospital/University of Southern California described a diversion procedure for 50 patients with combined duodenal and pancreatic injuries.[30,31] The operation consisted of a truncal vagotomy, antrectomy, gastrojejunostomy, T-tube drainage of the common bile duct, and a tube duodenostomy or the insertion of drains adjacent to the duodenal repair. Although results were excellent, the technique has been used rarely in other centers over the past 40 to 50 years because of the following concerns: possible sequelae of the vagotomy; the sacrifice of normal antrum; and the difficulty in inserting a T-tube into a normal-sized common bile duct.

ADJUNCTIVE PROCEDURES: TUBE DECOMPRESSION

Originally described at Denver General Hospital (now Denver Health Medical Center) in 1978 in a small subset of patients, one to three tubes for decompression and/or feeding (gastrostomy, standard or retrograde duodenostomy, feeding jejunostomy) were inserted after the duodenal repair.[32] A subsequent report by H. Harlan Stone and Timothy C. Fabian at Grady Memorial Hospital in Atlanta, Georgia, in 1979 described 234 patients with duodenal injuries who had triple tube decompression after a duodenal repair.[33] Only one patient had a postoperative leak from the duodenal repair, and this patient had an adjacent periduodenal abscess. Although a tube duodenostomy is performed occasionally to decompress the C-loop after a tenuous repair in the modern era, the triple tube approach is used rarely. The major concern is the conversion of a solitary gastrointestinal injury, the hole in the duodenum, to four holes that must heal.

DRAINS AFTER REPAIR OF THE DUODENUM

The use of a closed suction drain adjacent to a repair of an OIS grade II laceration (<50% of circumference) of the duodenum is unnecessary. The exceptions would be when there has been a delay in diagnosis or when there are adjacent combined pancreatoduodenal injuries.[1] With OIS grade III, IV, or V lacerations, particularly those with a delay in diagnosis, contusions of the duodenal wall around the repair, or a complex repair, most, but not all, surgeons will insert a closed suction drain.

JEJUNAL FEEDING TUBE AFTER REPAIR OF THE DUODENUM

There is always a concern about passing a nasojejunal feeding tube through a duodenum that has just been repaired. Therefore, when a feeding tube is indicated (eg, multiple

intra-abdominal injuries, particularly after a first damage control laparotomy), a Witzel feeding jejunostomy away from an area of jejunal injury should be considered as an alternative. Unfortunately, with the distension of the midgut and the increased risk of intra-abdominal complications after a damage control laparotomy, some surgeons are wary of this approach as well. These concerns should not, however, prevent the insertion of a feeding tube by either approach when indicated.

Operative Management: Organ Injury Scale Grade IV Injury Involving the Ampulla or Distal Common Bile Duct and Grade V Injury (Fig. 36-3)

Destruction of the ampulla of Vater, massive disruption of the duodenopancreatic complex, and devascularization of the duodenum are all classic indications to perform a pancreatoduodenectomy. The timing of this operation will depend on whether the patient has one or more classic indications to perform a damage control laparotomy. If so, duodenal injuries should be sewn or stapled shut as previously noted, peripancreatic bleeders ligated, and closed suction drains placed adjacent to the duodenal and pancreatic injuries. The drains will remove any duodenal contents or pancreatic amylase and, should an early leak occur, act as a marker of the same should the first reoperation be delayed. In another scenario, the surgeon has been able to complete the Whipple resection, but the patient's physiologic status deteriorates. The operation should be terminated and the reconstruction completed at another operation. Reconstruction at a reoperation is usually by an end-to-end or end-to-side pancreatojejunostomy, end-to-side choledocho- or hepatodochojejunostomy, and an antecolic gastrojejunostomy. Two closed suction drains are placed adjacent to the pancreatojejunostomy.

There have been isolated reports of reimplantation of a transected ampulla back into the medial wall of the duodenum over the years. This avoids the pancreatoduodenectomy but should be performed with the assistance of an experienced hepatopancreatobiliary surgeon.

Complications After Operation for Duodenal Injuries

The incidence of postrepair duodenal fistulas with all grades of injury ranged from 4% to 16.6% with a mean of 6.6% in older reviews.[34] In a review of 29 patients with penetrating duodenal injuries (16 OIS grade IV injuries) in 2007, no patient developed a postoperative duodenal fistula.[28] A 19-year experience with 125 patients who survived longer than 24 hours after penetrating duodenal wounds (four OIS grade IV injuries) noted a fistula state of 8% in 2016.[3] In contrast, a review of 44 patients with "complex penetrating duodenal trauma" (nine OIS grade IV injuries) from four trauma centers in Colombia and the United States in 2014 described a fistula rate of 33.7%.[35]

In the comprehensive analysis of the experience at the University of Tennessee, Memphis, Schroeppel et al[3] noted that the incidence of a postoperative duodenal leak/fistula was not affected by demographics, admission variables, injury severity, location, grade of injury, or technique of repair. Some of these results seem counterintuitive, particularly when compared to the results in the Colombia–United States review. The Memphis group did note, however, that a patient was more likely to develop a duodenal fistula if a major vascular injury was present (60% vs 23%; $P = .02$), if a pancreatic injury was present (70% vs 31%; $P = .03$), or if a drain was present (90% vs 45%; $P = .008$).

The management of a suspected (no drain present but patient symptomatic or clinically deteriorates) or likely (bile in drainage) leak from the duodenal repair has remained the same for many years. An emergency abdominal CT with oral contrast is performed to confirm the leak and to see if a fluid collection is present in the periduodenal area or in Morison's pouch. A percutaneous drain is inserted into any fluid (bile) collection. The patient is then placed on NPO (nothing by mouth) status, TPN is administered, and subcutaneous injections of somatostatin analog at a dose of 200 mcg every 8 hours are considered. These latter injections are painful and expensive; however, they will lower the output of the fistula to minimize fluid and electrolyte losses and to protect the skin of the abdominal wall from leaks around a drain. If a pyloric exclusion had not been performed at the trauma laparotomy, a lateral duodenal fistula (in continuity with the gastrointestinal tract) in the absence of an associated intra-abdominal infection will take approximately 2 to 8 weeks to close. A persistent duodenal fistula beyond this time is extraordinarily rare. Should this occur, the patient is optimized nutritionally for 3 months before a difficult reoperation is considered. A repeat abdominal CT scan with oral contrast is performed again to verify that a duodenal fistula is present. At the reoperation, there are two options for repair. If the leak site is small, local debridement, suture closure, and an omental buttress are performed. A larger defect with extensive surrounding inflammation is debrided, and a Roux-en-Y side-to-end duodenojejunostomy to the defect is performed, as described previously.

Mortality

The mortality after duodenal (or pancreatic) trauma is always deceptive because most deaths are due to vascular injuries in the upper abdomen or to multiple intra-abdominal injuries, as previously noted. Overall mortality in patients with duodenal injuries ranged from 5.5% to 30%, and the mean mortality in 17 series from 1960 to 1990 was 17%.[34] Actual mortality related to the duodenal injury and its postoperative complication ranged from 0.09% to 3.9%, with a mean of 1.7%, in five series describing 942 patients from 1970 to 1985.[34]

In more recent series, the mortality in 2220 patients with isolated blunt duodenal injuries reported to the National Trauma Data Bank was 5.2%.[36] With penetrating injuries

TABLE 36-2: Mortality After Duodenal Injuries

Author	Mechanism	OIS	No. of patients	Mortality	Duodenum-related
Siboni et al,[36] 2015	Blunt	OIS ≥1; only duodenum	2220	5.2%	—
Seamon et al,[28] 2007	Penetrating	OIS ≥2	29	First repair 7% Exclusion 21%	—
DuBose et al,[29] 2008	Penetrating/blunt	OIS ≥3	147	First repair 15.1% Exclusion 10.7%	—
Schroeppel et al,[3] 2016	Penetrating	OIS ≥2	125	12%	1.6%
Phillips et al,[4] 2017	Penetrating	OIS ≥2	879	14.4%	—

OIS, Organ Injury Scale.

(most OIS grade ≥II), the mortality rate in four reviews from 2007 to 2017 including 1069 patients ranged from 7% to 21% (Table 36-2).[3,28,35,37] In two reviews, duodenum-related mortality was 1.6% and 2.8%.[3,35]

PANCREAS[8,37]

Anatomy

The pancreas has a thin mesothelial capsule and is 15 to 20 cm (6+ inches) in length, 1.0 to 1.5 cm in thickness, and approximately 3.0 cm in width. It crosses the retroperitoneum at the level of the first and second lumbar vertebrae. The head of the pancreas is within the C-loop of the duodenum and encircles the distal common bile duct. The inferior part of the head or uncinate process partially wraps around the superior mesenteric vein to the right and the superior mesenteric artery arising from the visceral portion of the abdominal aorta. The thinnest part of the pancreas, the neck, lies between the head and body and overlies the mesenteric vessels and upper lumbar spine. The longest part of the pancreas is the body, which lies between the neck and tail and is posterior to the distal stomach. To the left of the body in the left upper quadrant is the tail of the pancreas attached to the spleen.

The main ventral pancreatic duct of Wirsung passes through the entire length of the pancreas just above a line halfway between the superior and inferior edges. As previously noted, it enters the left side of the common bile duct in the head of the pancreas to form the ampulla of Vater. The accessory dorsal duct of Santorini enters the duodenal lumen at the minor papilla. In 10% of individuals, the duct of Santorini is the main drainage of the pancreas.

There is a shared blood supply of the head of the pancreas and the C-loop of the duodenum through the anterior and posterior branches of the superior and inferior pancreaticoduodenal arteries as previously noted. Therefore, a major injury to the head of the pancreas or C-loop of the duodenum usually mandates a combined resection. On the venous side, veins around the head of the pancreas drain into the portal vein, while the remainder of the pancreas is drained by the splenic vein.

Associated injuries in patients with pancreatic trauma are most commonly to the liver, stomach, an upper abdominal vessel, and spleen.[9] Penetrating wounds to the head of the pancreas may involve the underlying inferior vena cava, the right renal vessels, and the left renal vein as it enters the cava. In similar fashion, injuries to the neck and uncinate process are in proximity to the inferior pancreaticoduodenal artery, superior mesenteric vein, and superior mesenteric artery. Finally, the body of the pancreas lies over the visceral portion of the abdominal aorta, whereas the body and tail encircle or are intimately adherent to the splenic artery and vein.

Mechanism of Injury

With a blunt blow to the epigastrium or a compressive force such as a misplaced lap seat belt in the obese adult, the pancreas can be partially or completely transected at the neck and over the mesenteric vessels and lumbar spine. This location is much closer to the C-loop of the duodenum than is commonly depicted in drawings in textbooks, with 70% to 90% of the pancreatic mass to the left of the transection.

As noted in the section on injuries to the duodenum, a penetrating abdominal wound with a track through the upper abdomen mandates exposure of the possibly involved portion of the pancreas. Once again, injuries to adjacent viscera and abdominal vessels increase the likelihood that a pancreatic injury is present.

Clinical Presentation and Diagnosis

The clinical presentation of patients with *blunt* trauma to the pancreas will often depend on the magnitude of associated injuries. Even with transection over the spine at the level of the neck of the pancreas, the patient may have only modest epigastric pain and tenderness when first evaluated because of its retroperitoneal location. In one older study from the University of Louisville in Louisville, Kentucky, 34% of patients with a

documented pancreatic injury had an equivocal or negative physical examination at the time of first evaluation.[38] Moderate epigastric pain and tenderness or persistent symptoms associated with nausea and vomiting during a period of observation mandate further evaluation with a multidetector CT.

It has long been recognized that the initial serum amylase is neither sensitive nor specific enough to confirm or rule out an injury to the pancreas.[39-41] For example, salivary amylase elevations related to acute alcohol intoxication account for a significant percentage of the hyperamylasemia seen on admission to trauma centers. An elevated serum amylase level, particularly one drawn 3 hours after trauma, or a level remaining elevated or rising during a period of observation mandates further evaluation as well.[42]

There have been concerns about the accuracy of 16- or 64-slice multidetector CT scans in diagnosing pancreatic injuries, particularly one to the duct.[43-45] The sensitivity and specificity of 4-, 16-, or 64-slice multidetector CT in detecting a ductal injury by visualizing a laceration and a laceration greater than 50% of the parenchymal width in one study in 2013 was 50% and 73.2% and 50% and 95.1%, respectively.[44] At this time, there are not sufficient data to evaluate the accuracy of 128-slice multidetector CT.

Recognizing these limitations, CT findings suggestive or diagnostic of an injury to the pancreas are listed in Table 36-3 and illustrated in Fig. 36-6. If a CT is not available or the result is equivocal (unclear if ductal injury is present, with or without associated hyperamylasemia), a magnetic resonance cholangiopancreatogram (MRCP) or endoscopic retrograde cholangiopancreatogram (ERCP) is appropriate.[46] Because MRCP is noninvasive, it is theoretically the next diagnostic test of choice; however, it is disappointing how little data on the use of MRCP in this situation are available.[47,48] With either MRCP or ERCP, the goal is to see if a ductal injury (OIS grade III) is present.[49,50]

Pancreas American Association for the Surgery of Trauma Organ Injury Scale (Table 36-4)

Management of the patient with a diagnosis of an injury to the pancreas is based on multiple factors, especially the magnitude of injury.[11]

TABLE 36-3: Computed Tomography Findings Suggestive or Diagnostic of a Pancreatic Injury

Suggestive of injury

Fluid in the lesser sac
Fluid between pancreas and splenic vein
Hematoma of transverse mesocolon
Thickening of left anterior renal fascia
Duodenal hematoma or laceration
Injury to spleen, left kidney, left adrenal gland
Chance (transverse) fracture of lumbar spine, especially in a child

Diagnostic of injury

Parenchymal hematoma or laceration
Obvious transection of the parenchyma/duct with fluid in the lesser sac
Disruption of the head of the pancreas
Diffuse swelling characteristic of posttraumatic pancreatitis

Nonoperative Management: Organ Injury Scale Grade I, II, and Select Grade III Injuries (Fig. 36-7)

In the absence of associated intra-abdominal injuries mandating an emergent or urgent laparotomy, a blunt OIS grade I or II pancreatic injury on CT is managed nonoperatively.[8] Such contusions or lacerations would be expected to heal, although an occasional patient may develop a peripancreatic fluid collection or pseudocyst. A follow-up abdominal CT scan is appropriate if the patient develops new-onset epigastric pain or hyperamylasemia while being observed.

Endoscopic stent placement into the main pancreatic duct for a variety of benign pancreatic diseases (stricture, leak) has been available for over three decades.[51] Stent placement across a partially or completely transected main duct after blunt trauma is appropriate under the following circumstances: (1) when the patient has no other intra-abdominal injury mandating an urgent laparotomy; (2) when the patient has an associated injury or medical condition (severe blunt cardiac injury, new-onset myocardial infarction, early-onset adult respiratory distress syndrome) that increases perioperative risk; and (3) when a surgeon or gastroenterologist with extensive experience in ERCP and stenting of the pancreatic duct is available. Endoscopic stenting is considered to be a success when the patient's symptoms resolve, hyperamylasemia clears, the stent can be removed at 3 months, and a follow-up CT and ERCP document a normal duct.[52,53]

Operative Exposure and Evaluation for an Injury to the Pancreatic Duct

Much as with injuries to the duodenum, areas of bleeding from viscera or vessels are controlled and gastrointestinal perforations or ruptures are repaired or resected. Ideally the entire pancreas should be exposed at each laparotomy for trauma because pancreatic contusions or hematomas can occur anywhere in the pancreas. Blunt partial or complete

transections, however, most commonly occur at the thin neck of the pancreas over the mesenteric vessels and spine, as previously noted. Much as with penetrating wounds of the duodenum, only the area of the pancreas in the track of a stab or missile wound is usually exposed.

The first step in complete exposure of the pancreas is medial mobilization of the distal ascending colon and hepatic flexure. This is followed by an extensive Kocher maneuver (to the superior mesenteric vein), which will allow for visualization of the anterior and posterior aspects of the head and the anterior aspect of the neck of the pancreas. The anterior aspect of the body is visualized after division of the gastrocolic omentum. Division of the retroperitoneal attachments to the inferior border of the pancreas while carefully avoiding the inferior mesenteric vein is then performed. Bimanual gentle elevation of the inferior border of the pancreas will allow for visualization of the posterior body. Finally, division of the lienorenal and splenocolic ligaments will allow for elevation and medial mobilization of the spleen. In the absence of a history of pancreatitis, the tail of the pancreas can be elevated as well, by sweeping the surgeon's right hand under the pancreas toward the midline.[8]

A hematoma under the thin mesothelial capsule of the pancreas should always be opened because a complete transection of the pancreas may be under this. In similar fashion, a penetrating wound of the pancreas should be exposed to determine its relationship to the likely area of the duct of Wirsung.

In the distant past, a surgeon who was still unsure about whether a ductal injury was present or not at this point had two options.[54] One was to perform a duodenotomy, cannulate the orifice of the pancreatic duct in the ampulla of Vater with a 5F pediatric feeding tube, and perform an operative pancreatogram. The other was to perform a resection of the tail of the pancreas and cannulate the duct in the open proximal end of the pancreas to perform the pancreatogram. In the modern era, the operative findings suggestive of an injury to the duct of Wirsung have been found to be very accurate in assessing its integrity[5,37] (Table 36-5 and Fig. 36-8).

A routine intraoperative cholangiopancreatogram or one using methylene blue dye is still an option to assess the integrity of the duct of Wirsung.[55] A #5 pediatric feeding tube is inserted into the cystic duct. After the anesthesiologist injects fentanyl to cause spasm of the sphincter of Oddi, standard cholangiogram contrast or one ampule of methylene blue solution in 200 mL normal saline is injected through the feeding tube. The spasm should cause reflux of the dye into the pancreatic duct and, when methylene blue is injected, staining and leakage at the site of a ductal injury. The obvious disadvantage of the approach is the need for a cholecystectomy after the cystic duct has been opened to perform the cholangiopancreatogram.

TABLE 36-5: Operative Findings Suggestive of Injury to the Duct of Wirsung

Fat necrosis in the lesser sac
Blunt laceration involving half or more of the width of the gland
Central missile wound
Significant disruption of the parenchyma
Leakage of clear fluid from area of injury during 5-minute period of observation

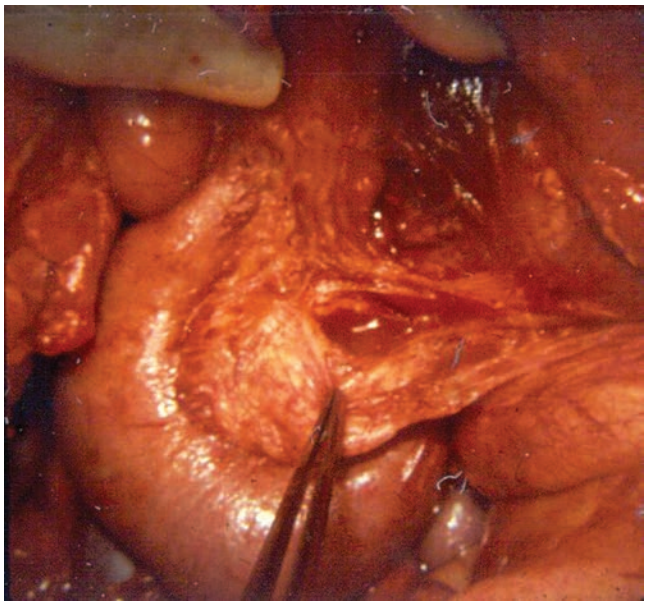

FIGURE 36-8 Stab wound of the head of the pancreas in which the surgeon believed there was no gross evidence of an injury to the main pancreatic duct. Drainage alone was performed. A pancreatic fistula developed but closed spontaneously. (Photo courtesy of Jon M. Burch, MD. Reproduced with permission from Feliciano DV. Abdominal trauma. In: Schwartz SI, Ellis H, eds. *Maingot's Abdominal Operations*. 9th ed. Norwalk, CT: Appleton & Lange; 1989:457.)

Operative Management: Factors in Repair

Much as with injuries to the duodenum, intraoperative hypotension and physiologic exhaustion are the most important factors in operative management. Once peripancreatic hemorrhage is controlled and a closed suction chain is inserted, no other operative procedure on the pancreas is necessary at a damage control operation.

A delay in diagnosis is another factor in choice of repair because autodigestion, pancreatic fistulas, and suture line leaks are more likely to occur in the postoperative period. After a delayed repair or resection, consideration should be given to inserting a feeding jejunostomy tube and peripancreatic drains as well as initiating empiric subcutaneous injections of octreotide. The value of octreotide is only that it may decrease the daily volume of any pancreatic fistula that might occur, although prospective clinical data are lacking.[56,57]

In hemodynamically stable patients with an early diagnosis and operation, the most important factor in choosing

drainage only, resection, Roux-en-Y reconstruction, and/or diversion is whether or not the duct of Wirsung has been injured.[1,8] Ductal transection mandates resection in most patients in the modern era (see later in chapter).

Finally, a combined pancreatoduodenal injury increases the complexity of management and, when the injuries are in proximity to one another, increases the fistula rate from either repair.

Operative Management: Organ Injury Scale Grade I to II Injury (Fig. 36-7)

An OIS grade I injury noted at laparotomy does not need to be drained. With an OIS grade II major laceration (Fig. 36-9), one option is to fill the laceration with a viable omental plug held in place with absorbable sutures. Although there are no data proving the value of this adjunct, theoretic benefits (based on its use in hepatic and splenic trauma) include the following: (1) tamponade of venous bleeding; (2) lower incidence of postoperative pancreatic fistulas; and (3) bringing mobile macrophages to the area of injury. Again, there are no clear-cut data regarding the need to drain OIS grade II pancreatic injuries.

Operative Management: Organ Injury Scale Grade III Injury (Fig. 36-7)

Transection of the duct of Wirsung over or to the left of the superior mesenteric vein is almost always treated with a distal pancreatectomy and splenectomy in adults.[58] Once again,

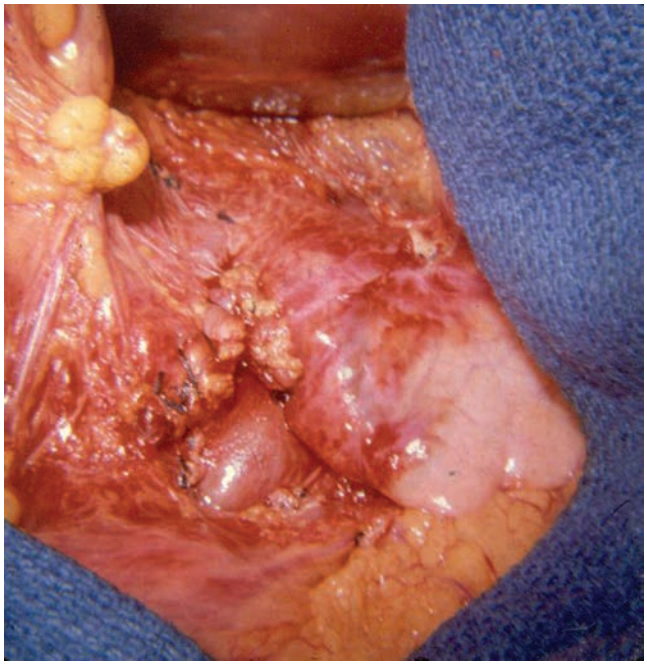

FIGURE 36-9 Organ Injury Scale grade II pancreatic laceration over superior mesenteric vein.

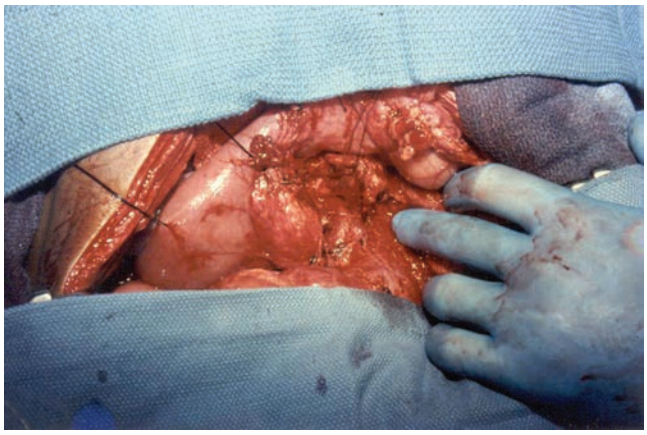

FIGURE 36-10 If this grade IV pancreatic injury is treated with distal resection, it will be a 90% pancreatectomy and splenectomy. (Reproduced with permission from Feliciano DV. Abdominal trauma. In: Schwartz SI, Ellis H, eds. *Maingot's Abdominal Operations*. 9th ed. Norwalk, CT: Appleton & Lange; 1989:457.)

this is often an 80% to 90% resection, as previously noted (Fig. 36-10). The splenic artery and vein are suture ligated separately with a 4-0 polypropylene suture 2 cm proximal to where the duct has been injured or where the pancreas is to be divided. Along with coverage of the stumps of the vessels with a viable omental pedicle, separate sites of division and ligation isolate the stumps from a distal pancreatic fistula occurring in the postoperative period.

A variety of surgical techniques have been used over the years by elective and trauma pancreatic surgeons to lower rates of postoperative pancreatic fistulas after distal resection. These have included the following: (1) fishmouth central beveled resection and horizontal mattress suture closure with or without ligation of the pancreatic duct; (2) use of transverse anastomosis or endovascular stapler; and (3) suture closure buttressed with fibrin glue, omental patch, or falciform mesothelial membrane.[59-65]

Large retrospective and prospective studies on elective and trauma pancreatectomies, some using the 2016 revised International Study Group on Pancreatic Fistula definition, have now been performed.[66] A 28% to 32% rate of fistulas has been consistent, no matter which type of closure is performed.[58-65] Therefore, a Jackson-Pratt or Blake drain is always inserted after distal pancreatectomy.[67,68]

LETTON-WILSON PROCEDURE

In highly selected patients who are hemodynamically stable and have no or few associated injuries, a Letton-Wilson procedure can be performed for an OIS grade III (or IV) injury[69] (Fig. 36-11). Originally performed in 1957 at Grady Memorial Hospital in Atlanta, Georgia, the first step in the procedure is ligation of the exposed duct of Wirsung in the open transected proximal pancreatic remnant (head or neck). This open end of the pancreas is then oversewn or stapled in the surgeon's usual fashion. The next step

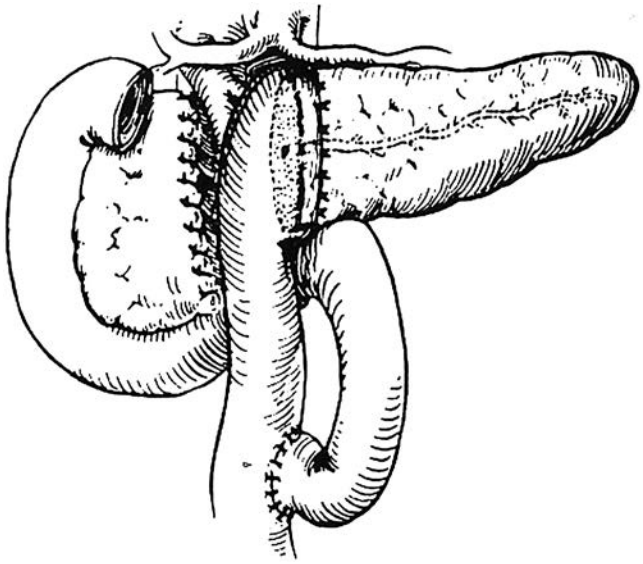

FIGURE 36-11 Letton-Wilson procedure for highly selected patients with proximal grade III or grade IV pancreatic injuries. (Reproduced with permission from Letton AH, Wilson JP. Traumatic severance of pancreas treated by Roux-Y anastomosis. *Surg Gynecol Obstet.* 1959;109:473. Copyright © Elsevier.)

is mobilization/elevation of 2 cm of the opened end of the distal pancreatic fragment (body and tail) off the splenic vessels. A 40-cm jejunal Roux limb is then created and passed through the right side of the transverse mesocolon, a two-layer invaginating end-to-end distal pancreatojejunostomy is performed,[70] and the Roux limb is fixated in the mesocolon with circumferential sutures. Finally, the standard end-to-side or side-to-side jejunojejunostomy is performed, and closed suction drains are inserted.

SPLEEN-PRESERVING DISTAL PANCREATECTOMY

Splenic immunity is critical in children, particularly those less than 2 years of age and probably in those up to 10 years of age.[71-73] For this reason, a spleen-preserving pancreatectomy for OIS grade III and IV injuries is preferred in young children.[74-76] In 2018, Schellenberg et al[76] reviewed data from 2007 to 2014 in the National Trauma Data Bank and noted that patients undergoing spleen preservation were younger, more likely to have blunt trauma, and had a lower Injury Severity Score.

Spleen-preserving distal pancreatectomy is easier in children than in adults. There is less fat obscuring pancreatic branches to the splenic vessels and less adherence of spleen to the pancreas. Using manual inferior traction on the pancreas, the small arterial and venous branches connecting the splenic vessels and pancreas are isolated over a small hemostat or right-angle clamp. A small metal clip is then placed on the pancreatic side of each vessel, while the end attached to a splenic vessel is ligated with a 4-0 silk tie. Once the pancreas is completely free from the splenic vessels, the distal pancreatectomy is completed.

LONG-TERM CONSIDERATIONS AFTER DISTAL PANCREATECTOMY

In the 1985 report by Ronald C. Jones from Parkland Memorial Hospital/University of Texas Southwestern in Dallas, Texas, 11 patients had 80% or more distal pancreatic resections for trauma.[77] Three patients developed diabetes mellitus requiring insulin, whereas three other patients had elevated blood glucose levels and abnormal glucose tolerance tests. Another patient who had a Whipple procedure for trauma developed diabetes mellitus as well.

It is worthwhile, therefore, to inform patients how much of the exocrine and islet cell masses of the pancreas are removed when a distal, hemi-, or subtotal pancreatectomy has been performed. In addition, they should be educated about the risks of alcoholism and obesity on the pancreatic remnant in the future. Finally, they should be advised to have a fasting blood sugar level checked every year in the future.

Operative Management: Organ Injury Scale Grade IV Injury

There are three options to manage the rare transection of the duct of Wirsung to the right of the superior mesenteric vein. First, a subtotal or 70% to 90% pancreatectomy and splenectomy in an adult is complicated by the need to close over the bulky proximal stump in the head-neck junction or head of the pancreas. Closure of this stump is usually with sutures because standard staplers may be too narrow to fit around it. The second option is the Letton-Wilson procedure, which is only appropriate in a highly selected group of patients, as previously described. Finally, the third option for blunt transections or destructive missile wounds through the head of the pancreas is a pancreatoduodenectomy (see next section).

Older trauma textbooks mention a fourth option, which is a Roux limb of jejunum sewn to the edges of the injury in this unusual location—a so-called "anterior" Roux-en-Y pancreatojejunostomy. This procedure should *not* be performed because it does not encompass the posterior aspect of any full-thickness transection or track of a missile and will lead to a high-output pancreatic fistula.

Operative Management: Organ Injury Scale Grade V Injury

Massive disruption of the head of the pancreas, devascularization of the C-loop of the duodenum, or destruction of the ampulla of Vater mandate a pancreatoduodenectomy. The timing will depend on the patient's hemodynamic status, the physiologic state, and the magnitude of associated injuries. In certain patients with blunt compression injuries, the trauma itself has "performed the Whipple" (ie, the head of the pancreas and C-loop of the duodenum have been devascularized and are already partially separated from surrounding structures).

The major change in operative approach in patients requiring a Whipple procedure for trauma over the past three

decades has been the use of staged procedures based on damage control principles.[78-82] If the Whipple resection cannot be performed at the first operation because of intraoperative hypothermia, metabolic acidosis, or a clinical coagulopathy, the management is as described previously in the duodenum section—the duodenal injury is closed, peripancreatic bleeders are ligated, and closed suction drains are placed. When the Whipple resection can be completed at the first operation, but reconstruction is contraindicated by "physiologic exhaustion," the following are indicated: (1) staple shut the open end of the common bile duct (prevents a bile leak and leads to dilation of the duct); and (2) staple shut the open end of the pancreas (prevents major leakage from duct, leads to dilation of the duct, and makes the gland more firm).[79] Reconstruction is performed when the patient's physiologic exhaustion has been reversed.

The mortality rate after Whipple procedures for trauma in 170 patients in 52 published reports from 1964 to 1990 was 33%.[34] In the most recent large civilian series from Harborview Medical Center/University of Washington, 12 of 15 patients (80%) undergoing Whipple procedures from trauma had a staged approach, and the mortality rate was only 13%.[82]

Summary of Operative Management for Pancreatic Injuries

In a review of 1000 patients undergoing operation for pancreatic injuries from 1980 to 1990, the following procedures were performed: (1) simple drainage, 72.6%; (2) distal resection, 16.9%; (3) Whipple procedure, 1.8%; (4) pyloric exclusions, 1.7%; and (5) other, 7.1%.[83]

Complications After Operation for Pancreatic Injuries

In older large reviews, the incidence of postoperative pancreatic fistulas with all grades of injury has ranged from 3% to 17% with a mean of 6%; however, trauma centers have used a variety of definitions of the complication over time.[66,83] In one recent series of distal pancreatectomies performed for trauma, pancreatic fistulas occurred in 29% of patients.[58] This is the exact same figure for the incidence of fistulas after elective distal pancreatectomies.

After elective pancreatic surgery, the International Study Group of Pancreatic Fistula now (as of 2016) uses the following definition: "a postoperative pancreatic fistula is now redefined as a drain output of any measurable volume of fluid with an amylase level >3 times the upper limit of institutional normal serum amylase activity, associated with a clinically relevant development/condition related directly to the postoperative pancreatic fistula."[66] Using this definition, pancreatic fistulas can be divided into clinical grades "biochemical leak" B and C. More commonly, trauma surgeons in the United States use the classic definition of intra-abdominal fistulas based on volume of output (high output, >500 mL/24 hours; moderate output, 200–500 mL/24 hours; and low output, <200 mL/24 hours).

The majority of pancreatic fistulas after a distal, hemi-, or subtotal pancreatectomy or a rare Whipple procedure for trauma are related to a soft pancreas encountered at the time of operation. They are usually self-limited in the absence of a history of preexisting benign pancreatic disease and will close within 2 to 6 weeks.

An elevated amylase level in an increased volume of fluid from a peripancreatic drain suggests that either a pancreatic or upper gastrointestinal fistula is present. A patient with a moderate- or high-output fistula associated with clinical deterioration (elevated temperature, onset of systemic inflammatory response syndrome, ileus) should undergo an abdominal CT with contrast. A fluid collection adjacent to the oversewn or stapled end of the pancreas or to a pancreatojejunostomy (or pancreatogastrostomy) can be treated with insertion of a percutaneous drain. This is controversial after distal resections because these collections are frequently sterile.[84] Appropriate antibiotic therapy is initiated should cultures of the fluid be positive.

Enteral nutrition beyond D_2 is appropriate after any left-sided resection when there is a moderate- or high-output fistula. Conversion to an oral diet is appropriate as the volume of fistula output decreases or when only a low-output fistula is present.

Much as with duodenal fistulas, the use of somatostatin analog in a patient with a postoperative pancreatic fistula remains controversial. After elective pancreatic resections, multiple reviews have failed to document a higher or earlier rate of closure of the fistula when somatostatin analog has been administered.[85,86] In a patient with a high-output fistula, however, it may be worthwhile to administer high-dose somatostatin analog for 5 to 7 days to see if the output decreases.

Much as with postoperative biliary fistulas, a persistent high-volume pancreatic fistula can be managed with ERCP, endoscopic sphincterotomy, and placement of a stent through the sphincterotomy into the pancreatic duct. One indication for an emergency reoperation is sudden catastrophic bleeding from the ligated stump of the splenic or gastroduodenal artery. An indication for a semi-elective reoperation is multiple recurrent abscesses in the left subphrenic area. Some of these patients will be found to have necrosis of the sewn or stapled stump of the pancreas and will require a re-resection.

The second most common complication after an operation for pancreatic trauma is a postoperative intra-abdominal abscess, with a range of 5% to 18% and mean of 5%. A patient with a left subphrenic abscess will usually develop an elevated temperature, onset of systemic inflammatory response syndrome, and a left pleural effusion on chest x-ray, and will have a positive abdominal CT. Percutaneous drainage is appropriate and usually effective for treatment. A rare patient has unsuccessful percutaneous drainage or recurrent abscesses, as described earlier. Rather than a formal reoperation through the midline incision, a local operative approach such as through the left flank or with resection of the left 12th rib posteriorly is appropriate.

TABLE 36-6: Forty-Year Comparison of Combined Pancreatoduodenal Injuries

Author/year	No. of patients	Penetrating mechanism	Damage control	Whipple	Mortality
Feliciano et al,[18] 1987	129	104/129 (80.6%)	0/129	13/129 (10.1%)	38/129[a] (29.4%)
Krige et al,[19] 2016	75	62/75 (82.6%)	29/75 (38.6%)	19/75 (25.3%)	21/75 (28%)

[a]One "pancreatoduodenal" death.

Mortality

Mortality after pancreatic trauma is obviously affected by the mechanism of injury, magnitude of the pancreatic injury, number and magnitude of associated injuries, and the patient's hemodynamic status on admission. Overall mortality is approximately 20%, with the following rates based on mechanism of injury: stab wound, 2.8% to 5%; gunshot wound, 15.4% to 22%; and blunt trauma, 16.9% to 19%.[31]

COMBINED DUODENAL AND PANCREATIC INJURIES[8]

Even in the busiest urban centers with penetrating wounds accounting for 25% to 30% of all trauma admissions, only 7 to 10 patients with combined injuries will be treated each year.

Operative Principles

The first principle of operative management is to treat geographically separate, but combined, injuries individually. An example would be a patient with multiple gunshot wounds and grade III injuries to the mid-pancreas and to D_2. This patient should have a distal pancreatectomy and splenectomy, a transverse repair of the duodenum, and insertion of a closed suction drain adjacent to the stump of the pancreas.

The second principle of operative management is to treat adjacent destructive injuries such as the aforementioned disruption of the head of the pancreas, devascularization of the C-loop of the duodenum, or destruction of the ampulla of Vater with a pancreatoduodenectomy.

The third principle of operative management is to consider adding a proximal diversion procedure such as a pyloric exclusion with gastrojejunostomy to treat adjacent nondestructive injuries described previously (see earlier section "Adjunctive Procedures: Pyloric Exclusion with Gastrojejunostomy").

Complications

The two largest civilian series of combined pancreatoduodenal injuries in the past 40 years are compared in Table 36-6.[18,19] In the older series (1987), 108 of 129 patients surviving longer than 48 hours had the following postoperative pancreatoduodenal-related complications: pancreatic fistula, 25.9%; intra-abdominal abscess, 16.6%; and duodenal fistula, 6.5%.[18] In the more recent series (2016), the following postoperative pancreatoduodenal-related complications were noted (number of patients surviving longer than 48 hours is unclear): 11 pancreatic fistulas and 3 cases of pancreatitis; 15 cases of "abdominal sepsis"; and 16 duodenal fistulas and 1 stenosis.[19]

Mortality

In the older series, the overall mortality rate was 29.4%, with 55% of these patients dying within 48 hours secondary to hypovolemic shock and transfusion-associated coagulopathies. Six or more intra-abdominal visceral or vascular injuries were present in 15 of the 21 patients with perioperative deaths. In the four patients who died in the perioperative period from 1981 to 1985, the average operative blood loss was 32 units.[18]

In the more recent series, the overall mortality rate was 28%, and the 21 deaths occurred at a median of 3 days after the injury (range, 1–42 days). Shock on presentation, increased composite grade of injury (see Table 1 in Krige et al[19]), associated vascular injuries overall, major visceral venous injuries, and the combination of vascular plus the total number of associated organs inured were all significantly related to mortality.[19]

Colon and Rectum

Martin A. Croce • Timothy C. Fabian

KEY POINTS

- The presence of blood on digital examination of the anorectum is highly suggestive of injury, but its absence does not rule out injury to the colon or rectum.
- Primary repair of colonic injuries is safe and is the preferred option for nondestructive wounds.
- The management of patients with destructive colon wounds is controversial, but a prudent approach would be resection and anastomosis for stable patients without shock or other major comorbidities and diversion for unstable or high-risk patients.
- Degree of fecal contamination influences the probability of developing septic complications, including intra-abdominal abscess, but is not associated with an increased risk of suture line failure (anastomotic leaks).
- Patients with intraperitoneal penetrating rectal injuries should be managed the same as those with colon injuries. In patients with blunt injuries, proximal colostomy is usually the procedure of choice, as these injuries are frequently associated with pelvic fractures or complex perineal injuries.
- Extraperitoneal rectal injuries should be managed according to the anatomy of the injury. If the injury is accessible, it may safely be repaired primarily without diversion. If it cannot be repaired, then diversion is indicated.
- The anatomy of the rectal injury should dictate whether presacral drains be placed (selective use), but the practice of rectal washout cannot be supported by contemporary data.

INTRODUCTION

The management of injuries to the colon and rectum has changed dramatically through the years. Colon-related morbidity has decreased to approximately 15% to 20%, and mortality has decreased from approximately 90% during the Civil War to around 1% in the current literature.

Much of the early description of management for patients with colon and rectal injuries was from wartime experiences. These principles were then used for civilian patients initially. Over time, surgeons realized that civilian wounds were different from military ones, and new clinical approaches were devised. These evidence-based approaches have improved morbidity and mortality for civilian patients, as noted earlier.

Controversy still exists with respect to destructive wounds, location of colonic injury, blunt injury, abbreviated laparotomy, primary rectal repair, and presacral drainage. In this chapter, we will address these controversial issues and present a workable management scheme.

INJURIES TO THE COLON

Military and Civilian Experience

In order to understand the controversies that exist with management of colon wounds, it is important to review military and civilian experiences. The first report of a colon injury is recorded in the book of Judges when Ehud killed King Eglan. "And Ehud reached with his left hand, took the sword from his right side, and thrusted into his belly. And the hilt also went in after the blade, and the fat closed over the blade, for he did not pull the sword out of his belly; and the dung came out."[1]

Little was written about the management of colon injuries until the Civil War, when colonic wounds were almost uniformly fatal. Patients were typically managed without operations during that time. Unless a patient developed a fistula, death was likely.

As wars changed, so did the weaponry and injuries. World War I brought about more sophisticated guns with higher

velocity missiles, resulting in more destructive injuries. Management evolved from nonoperative to operative. Patients underwent either primary repair or diversion, but there was no universal policy for management of colon wounds. Despite the lack of uniformity in management, mortality rates fell to approximately 70%.[2]

Improvements in triage, resuscitation, blood banking, and antibiotics were evident in World War II. There was also standardization of the management of colon wounds. Major General William Heneage Ogilvie, a British surgeon who served in both World Wars, provided the basis for mandatory colostomy for all colon wounds: "The treatment of colon injuries is based on the known insecurity of suture and the dangers of leakage. Simple closure of a wound of the colon, however small, is unwarranted; men have survived such an operation, but others have died who would still be alive had they fallen into the hands of a surgeon with less optimism and more sense. Injured segments must either be exteriorized, or functionally excluded by a proximal colostomy."[3]

The concept of mandatory colostomy was then extended to civilian populations. Woodhall and Ochsner challenged that scheme in postwar New Orleans.[4] They realized the difference in weaponry and demonstrated that low-energy colonic wounds could safely be managed with primary repair. Despite their publication, most colon wounds continued to be managed with colostomy for the next 30 years. In 1979, Stone and Fabian[5] at Grady Memorial Hospital, Atlanta, Georgia, performed the first randomized trial comparing primary colon repair versus colostomy. They demonstrated the safety and superiority of primary repair for nondestructive injuries. Since then, debate has centered around the management of destructive colon wounds and injuries in those patients with "damage control" laparotomies.

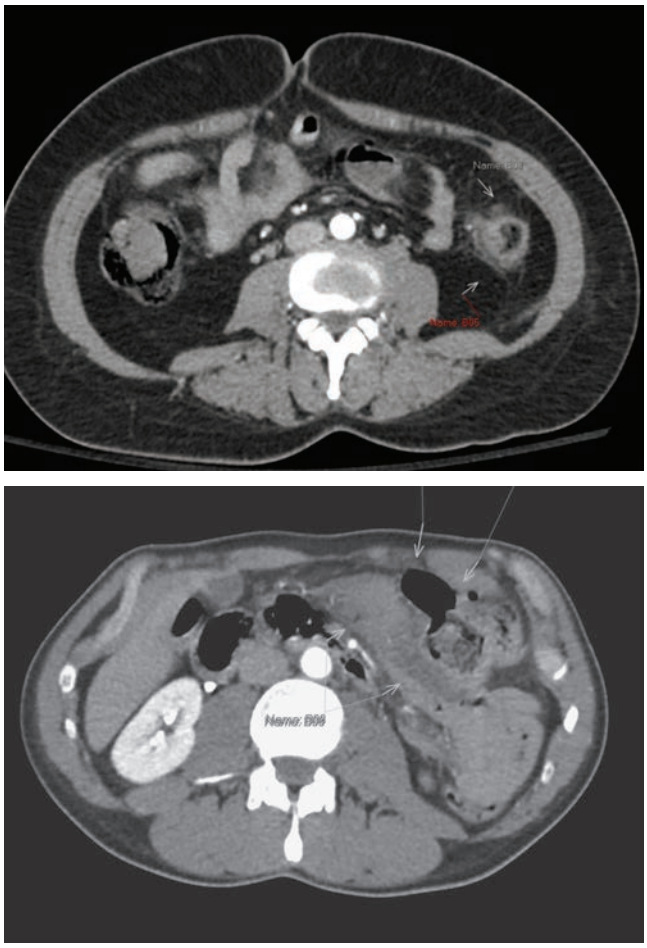

FIGURE 37-1 Thickened colon wall with small amount of surrounding fluid (top); thickened colon wall with pneumoperitoneum (bottom).

General Considerations

Following injury, the patient should undergo standard resuscitation with blood and blood products as necessary. For patients with penetrating abdominal wounds, extensive preoperative evaluation is not necessary. Selected patients with tangential wounds, wounds to the flank or back, or wounds to the right thoracoabdomen may be managed nonoperatively after appropriate imaging, but expedient operation is the best option for the majority of patients.[6]

The preoperative evaluation of patients with blunt abdominal trauma, however, is not as straightforward. Hemodynamically unstable patients with intra-abdominal fluid on a surgeon-performed ultrasound should undergo prompt operation. Stable patients are best evaluated by a contrast-enhanced computed tomography (CT) scan. An injury to the colon is suspected by a thickened colonic wall, usually with unexplained intraperitoneal fluid or even a pneumoperitoneum (Fig. 37-1). A digital rectal exam is imperative, as previously noted.[7]

The American Association for the Surgery of Trauma (AAST) has developed grading systems for various organ injuries. These Organ Injury Scales describe injury severity and allow for standardization of clinical research. In addition, management schemes may be designed based in part on the injury scales. The AAST colon injury and rectal injury scales are listed in Table 37-1.[8]

Operative Management: Nondestructive Colon Wounds

Nondestructive colon injuries include grade I and II and selected grade III injuries. Such injuries are typically low-energy wounds that do not require significant debridement. There is ample evidence that primary repair for nondestructive injuries is the optimal treatment. In the previously mentioned study by Stone and Fabian[5] in 1979, 139 patients with nondestructive colon wounds were randomized to either primary repair or colostomy. Improved outcomes with reduced intra-abdominal infection rates were documented in the primary repair group. In a follow-up study from the University of Tennessee–Memphis in 1989, George et al[9] evaluated 102 consecutive patients with penetrating colon injuries. All

TABLE 37-1: American Association for the Surgery of Trauma Organ Injury Scales for Colon and Rectum

Grade[a]	Type of injury	Description of injury
Colon Injury Scale		
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration <50% of circumference
III	Laceration	Laceration ≥50% of circumference without transection
IV	Laceration	Transection of the colon
V	Laceration	Transection of the colon with segmental tissue loss
	Vascular	Devascularized segment
Rectum Injury Scale		
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial-thickness laceration
II	Laceration	Laceration <50% of circumference
III	Laceration	Laceration ≥50% of circumference
IV	Laceration	Full-thickness laceration with extension into the perineum
V	Vascular	Devascularized segment

[a]Advance one grade for multiple injuries up to grade III.

were managed with either primary repair (83%) or resection and anastomosis (17%). There were no failures of primary repair and only one anastomotic leak. The authors identified transfusions, associated injuries, contamination, and the severity of the colon injury as independent predictors of abdominal infection, but none were risks for suture line leaks. In another randomized study, Chappuis et al[10] likewise demonstrated the safety of primary repair in 56 patients. Gonzales et al[11] randomized 109 patients to primary repair or diversion. They included patients regardless of shock, associated injuries, extent of fecal contamination, timing of surgery, and grade of colon injury. They found that primary repair was at least as successful as diversion and stated that all patients with penetrating colon injuries should undergo primary repair. A number of other prospective studies have also demonstrated that primary repair can be successfully performed in most patients with colon injuries.[12-25]

Thus, there is sufficient high-level evidence that primary repair of nondestructive colon wounds is the treatment of choice. Despite this, a survey of 342 surgeons in the United States demonstrated that colostomy was still preferred in 43% of patients with fecal contamination.[26] It appears that old habits die hard, despite the overwhelming evidence of safety for primary repair of nondestructive colon wounds.

Operative Management: Destructive Colon Wounds

As mentioned previously, destructive colon wounds include most grade III and all grade IV and V injuries.[27] Resection of injured tissue, taking care to ensure an adequate mesenteric blood supply, and anastomosis is the optimal treatment for these destructive injuries; however, whether to perform proximal diversion or even exteriorization of the injury as an end colostomy is the subject of debate. Stewart et al[27] evaluated 60 patients with destructive colon wounds managed by resection and anastomosis in 1994. They observed that patients who had significant medical comorbidities or those who received more than 6 units of blood had a suture line dehiscence rate of 42%, compared to 3% in patients who are otherwise healthy and received less than 6 units of blood. This was the first study to identify specific risk factors for anastomotic leak in patients with destructive colon injuries.

Subsequently, Cornwell et al[28] evaluated 25 patients with resection and anastomosis in 1998. They had an 8% leak rate, and these patients all had high transfusion requirements (>6 units). Murray et al[29] had similar results and conclusions in 140 patients.

In 2001, a prospective observational study sponsored by the AAST involving 297 patients from 19 centers was published.[30] All patients underwent resection; 66% had resection and anastomosis, and 34% had diversion. The authors stated that the method of colon management did not impact colon-related complications and suggested that all injuries requiring resection should be managed by anastomosis. While the concept has merit, there were differences in decision making among the 19 separate centers since there was no standardized protocol for management of the colon wound.

To evaluate a standard management protocol, the group from the University of Tennessee–Memphis performed a follow-up study 8 years after Stewart's original algorithm.[31] With adherence to the algorithm (Fig. 37-2), abdominal abscess rates decreased from 37% to 27%, suture line dehiscence dropped from 14% to 7%, and mortality decreased from 12% to 5%. An important observation was that the degree of fecal contamination was not associated with suture line failure, a finding confirming previous studies from the same institution.[9,32] Ten years later, the same group evaluated an additional 102 patients with destructive colon wounds.[30] Abscess rates further dropped to 18%, suture line failure to 5%, and mortality to 1%. The improvements over time seemed to be related to increased compliance with the algorithm, which was greater than 90% in the latest time period.

Thus, the evidence for management of patients with destructive colon wounds is somewhat less clear than for nondestructive wounds. It seems that prudent management would be resection and anastomosis for stable patients without shock or other major comorbidities and diversion for

unstable patients in shock or patients with chronic underlying illnesses.

Operative Management: Blunt Colon Wounds

Injuries to the colon following blunt abdominal trauma are uncommon, occurring in 0.1% to 0.5% of patients.[33,34] These injuries demand special consideration since they can be devastating. The degree of trauma imparted to the colon causing it to rupture is substantial, making these injuries particularly susceptible to ischemia. Approximately 50% of blunt colon injuries are grade III to V, thus necessitating resection.[35] Typical injuries include extensive serosal tears, mesenteric rents with devascularization, and perforations.

Sharpe et al[35] evaluated 151 patients with blunt colon injuries over a 13-year period. The management scheme was based on the original algorithm described by Stewart et al[27] (Fig. 37-2). Seventy-eight patients underwent primary repair, 44 had resection and anastomosis, and 29 underwent diversion. Compliance with the algorithm resulted in a suture line leak rate of 2%, compared to 13% in patients not managed according to the algorithm. These values are comparable to those following destructive penetrating wounds and compare favorably to other series of patients with blunt colon injuries.[36-38] Thus, even though the algorithm was developed for patients with penetrating injuries, it appears to be appropriate for patients with blunt injuries as well.

Operative Management: Abbreviated Laparotomy

In 1983, H. Harlan Stone described the concept of a limited laparotomy in unstable patients following initial control of hemorrhage and gastrointestinal contamination and then with temporary abdominal closure and transfer to the intensive care unit.[39] He termed the strategy *abbreviated laparotomy*. This was later referred to as *damage control laparotomy* by Rotondo et al.[40] This approach has been shown to be beneficial and to improve survival in patients with hypothermia, a metabolic acidosis, and/or a clinical coagulopathy.[39-45] Although this approach can be lifesaving, management of hollow organ wounds at a reoperation, especially the colon, can be challenging. Typically, these destructive wounds are resected, and the colon is left in discontinuity. After correction of "physiologic exhaustion," the surgeon must decide how to manage the colon at the time of a repeat laparotomy.

Miller et al[46] from Wake Forest described 11 patients with delayed anastomosis of the colon. None had suture line dehiscence, but almost half died during their hospitalization, making interpretation difficult. Weinberg et al[47] described 56 patients with abbreviated laparotomy over a 7-year period. A delayed anastomosis of the colon was performed in 33 and ostomy in the remaining 23, with a 12% leak rate. The authors cautioned against delayed anastomosis in the setting of abbreviated laparotomy. Another study from Denver Health described 25 patients with delayed anastomoses.[48] Their leak rate of 16% was higher than those reported earlier, but the authors concluded that delayed anastomosis was safe after a damage control laparotomy. In a larger series, Ott et al[49] reported 44 patients with delayed anastomosis with a failure rate of 27%. They concluded that the risk of leak was too high to justify delayed anastomosis. Other studies[50-53] have drawn fairly disparate conclusions following delayed anastomosis (Table 37-2).

The group from the University of Tennessee–Memphis reported a 17-year experience of 149 patients with colon wounds and abbreviated laparotomy.[54] Of these, 42 patients had a delayed anastomosis. No specific risk factors were identified in the 17% who developed leaks; however, the authors noted that 55% of the patients with delayed anastomoses were managed according to Stewart's protocol (Fig. 37-2). For patients not managed by the algorithm, the leak rate was 32%, compared to only 4% for those who were managed according to the algorithm (P = .03). Thus, a management

Sharpe *with* algorithm	23	4

scheme initially described for penetrating colon injuries in patients with a single laparotomy has been shown to be effective for patients with blunt colon injuries and those with delayed anastomoses following abbreviated laparotomy.

Risk Factors for Abdominal Complications

The overall incidence of abdominal septic complications in patients with colon injuries is approximately 20%. There are a number of risk factors for infection and suture line failure, and this distinction is critical.

LOCATION OF COLON WOUND

Historically, there has been concern that left-sided colon wounds carry an increased risk of colon-related complications, and suture lines should be avoided. In a multicenter study sponsored by the AAST, it was noted that over half of left-sided colon wounds were managed by diversion compared to only one-third of right-sided ones.[30] Military data have demonstrated a similar ratio in management of colon wounds; however, these data were not controlled.[53] A Western Trauma Association observational trial reported leak rates of 3% for right colon wounds, 20% for transverse colon wounds, and 45% for left colon wounds.[55] Similarly, these data were not controlled, making interpretation difficult, since it is unclear whether there is a true cause and effect or this is simply a measurement of surgeon preference. Dente et al[56] evaluated 217 patients with penetrating colon wounds and determined that injuries around the splenic flexure should be managed with caution due to the sometimes tenuous blood supply to this area. The group from Memphis evaluated 469 colon wounds and analyzed injury location and outcome.[57] They found that neither suture line dehiscence nor intra-abdominal abscess was associated with location of the colon injury. After adjusting for shock, injury severity, and operative management, location was still not associated with adverse outcomes (Table 37-3).

ASSOCIATED ABDOMINAL INJURIES

Despite the opinion that multiple associated injuries should mandate colostomy, there is sufficient evidence that these are associated with development of postoperative intra-abdominal abscesses, but *not* failure of the suture line in the colon.[5,9,11,27,28,32,35]

TRANSFUSIONS

Multiple blood transfusions are associated with the development of postoperative intra-abdominal abscesses[5,9,27,30,32,35] but are not associated with suture line failure for patients with primary repair of nondestructive colon wounds.[30,32,35] As mentioned previously, transfusions do influence the integrity of the suture line for patients with resection and anastomosis.[27,30,35,36,54]

FECAL CONTAMINATION

Peritoneal fecal contamination is associated with postoperative abdominal infection[5,9,11,27,28,32,35,36,58-60]; however, many surgeons have interpreted this fact to mean the contamination is also associated with dehiscence of the colon suture line. There are no data to suggest that fecal contamination is associated with failure of the colon suture line.[5,10,30,35,36] Thus, the practice of colostomy for fecal contamination alone following a penetrating injury to the colon should be abandoned. A summary of risk factors is shown in Table 37-4.

Technical Tips

As with all laparotomies for penetrating trauma, the initial primary goal is to control hemorrhage and limit contamination. After this is accomplished, injuries should be explored and prioritized. Colon injuries should be adequately mobilized, taking care to dissect the fat off the colon wall so that the full extent of the wound is visualized and debrided to viable tissue. For injuries amenable to primary repair, the authors prefer a two-layer closure with an inner layer of full-thickness 3-0 absorbable suture and an outer seromuscular closure with interrupted 3-0 silk Lembert sutures. For destructive wounds, the sites of resection should be chosen to ensure an adequate blood supply to the anastomosis; however, it is not necessary to adhere to oncologic principles. The exception to this principle is a destructive injury to the right colon. Segmental resection of the right colon is not advised due to its thin wall and marginal blood supply. Either a two-layer end-to-end or side-to-side handsewn anastomosis or a side-to-side stapled anastomosis may then be performed.

TABLE 37-3: Adjusted Odds Ratios and Confidence Intervals for Suture Line Failure and Abdominal Abscess Based on Colon Anatomy

INJURIES TO THE RECTUM

Accepted management of penetrating rectal injuries evolved from the military experience in World War II and Vietnam.[3,61,62] These principles include routine fecal diversion, injury repair (if possible), distal rectal washout, and presacral drainage. As experience with civilian rectal injuries has increased, the utility of war-based principles has been challenged.

Anatomy

It is important to consider the anatomy of the rectum since it can influence management of the injury and outcome. The rectum is approximately 15 cm in length, and only the proximal two-thirds is intraperitoneal and covered with serosa. The lower one-third is extraperitoneal and technically difficult to expose, making primary repair difficult. The entire posterior aspect of the rectum is without a serosa to varying degrees.

General Considerations

The presence of blood on a digital anorectal examination is suggestive of an injury, as previously noted, and should trigger further investigation unless the patient is hemodynamically unstable and an immediate operation is indicated. Stable patients with blunt injury and selected patients with penetrating trauma should undergo CT scanning with contrast. If an injury is identified, prompt operation is indicated. If the CT clearly demonstrates no injury, a period of observation is appropriate in case of a false-negative study.

For stable patients with a penetrating injury and blood present on digital rectal exam, further investigation with sigmoidoscopy is indicated to possibly localize the injury.

Operative Management (Fig. 37-3)

Patients with intraperitoneal penetrating rectal injuries should be managed the same as those with colon injuries (ie, nondestructive wounds should be repaired primarily without proximal fecal diversion). As previously noted, proximal colostomy is usually the procedure of choice in patients with blunt injuries because these are often associated with pelvic fractures or complex perineal injuries.

Patients with extraperitoneal injuries should be managed according to the anatomy of the injury.[63,64] If the injury is accessible, it may safely be repaired primarily without diversion. If it cannot be repaired, then diversion is indicated.[63-69]

The literature suggests that the anatomy of the injury should dictate the use of presacral drains.[63,67] A large multicenter AAST

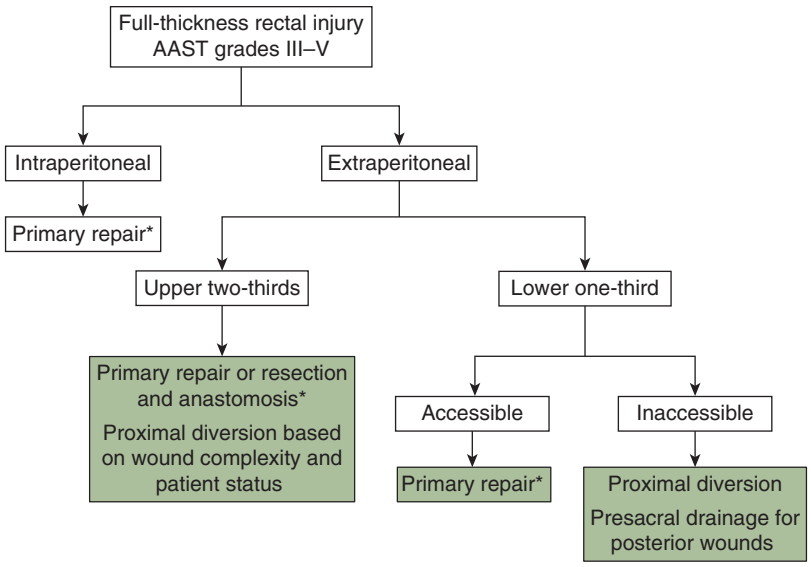

FIGURE 37-3 Management algorithm for full thickness rectal injuries. AAST, American Association for the Surgery of Trauma. *Primary repair for nondestructive wounds or destructive wounds in the absence of greater than 6 units of transfused blood or medical comorbidities.

study suggested that presacral drains were not indicated; however, the use of such drains was not controlled, making interpretation difficult.[65] Weinberg et al[64] also emphasized rectal anatomy as the primary determinant of presacral drain placement, following up a study by McGrath et al.[63] Wounds to the anterior part of the distal rectum will not benefit from posterior placement of presacral drains. Extraperitoneal wounds that are explored and repaired will effectively become intraperitoneal, thus precluding the need for presacral drainage. Extraperitoneal posterior wounds that are not explored are the injuries that will benefit from presacral (retrorectal) drainage.[64] This scheme is both intuitive and anatomically consistent, and the lack of benefit of presacral drainage from other studies is likely explained by this anatomic distinction.

The use of distal rectal washout was once part of the standard management of rectal injuries. There is no compelling evidence that it reduces morbidity, and this practice should be abandoned.[70,71]

Technical Tips

When performing preoperative sigmoidoscopy (either with a rigid or flexible scope), it is important to be prudent with insufflation. Too much insufflation makes subsequent abdominal exploration more difficult and potentially increases contamination from associated injuries, while too little will inhibit identification of the injury.

When the injury is located at the subsequent laparotomy, it is imperative to debride back to healthy tissue. All surrounding fat must be cleared to adequately evaluate the wound edges. A two-layer suture repair is appropriate, as previously described for colon wounds.

Placement of presacral drains, if anatomically indicated, should be done with the patient in the lithotomy position. A curvilinear incision between the anal sphincter and coccyx is made. Using a long clamp, the muscles of the pelvic floor and endopelvic fascia are penetrated until the sacral hollow is easily felt. Penrose drains are then placed in the presacral space and secured at the skin incision. These drains are gradually removed over several days beginning around postoperative day 3.

Ostomy

If a colostomy is deemed necessary, it is the authors' preference to perform a loop colostomy. There is no difference in function relative to an end colostomy if the loop is placed over a rod and the colotomy is made on the down side of the loop.[72] Creation of a loop allows for easier closure when the patient is ready. Timing of closure is debatable but typically occurs after 6 to 8 weeks.

Antibiotic Prophylaxis

As with all patients with penetrating abdominal trauma, preoperative antibiotics are mandatory. The choice of antibiotics must provide coverage against enteric aerobes and anaerobes including *Bacteroides fragilis*. Efficacy for single- or dual-agent therapy is equivalent as long as the regimen has coverage against enteric organisms. The duration of antibiotic prophylaxis is 24 hours.[32,73]

Management of the Incision

Primary skin closure following laparotomy in patients with colon or rectal injuries is not advised. Although tempting, primary skin closure is associated with significantly increased rates of wound infection and fascial dehiscence. All of these incisions are contaminated regardless of the amount of fecal spillage. In a prospective randomized trial, primary skin closure doubled the risk of infection when compared to delayed primary closure.[74] Newer agents and techniques, such as absorbable antimicrobials and negative-pressure wound dressings, may be promising, but controlled trials are necessary.

SUMMARY

The management of trauma to the colon and rectum can be quite challenging. Evidence-based practices have changed from mandatory colostomy to primary repair of nondestructive wounds and resection and anastomosis for destructive wounds in appropriate patient populations. Simplified management algorithms are effective and have been shown to improve patient outcomes.

Abdominal Vessels

David V. Feliciano • Juan A. Asensio

KEY POINTS

- Patients with gunshot wounds to the abdomen will have injury to a named abdominal vessel 20% to 25% of the time.
- Abdominal vessel injuries will present with intraperitoneal hemorrhage; a contained mesenteric, retroperitoneal, or portal hematoma; thrombosis; or some combination of these.
- Options for management of abdominal vessel injuries include nonoperative (intimal flap on computed tomography angiogram), endovascular (hostile abdomen, delayed diagnosis, or failed prior repair), and operative.
- A midline supramesocolic hematoma is approached with a left-sided medial mobilization maneuver, whereas hemorrhage is approached directly through the lesser sac to the diaphragmatic aorta.
- The proximal superior mesenteric artery and common and external iliac arteries should always be shunted and *never* ligated during damage control operations.
- Ligation of the infrarenal inferior vena cava after a severe injury is more commonly practiced in the modern era and is usually well tolerated in young patients.
- Endovascular stents or stent grafts are commonly placed to cover intimal defects or restore arterial flow after blunt injury of the renal artery.
- An end-to-end anastomosis or interposition graft in the common or external iliac artery in the presence of significant enteric or colonic contamination has an increased rate of postoperative infection and subsequent arterial blowout.
- Survival rates after abdominal arterial injuries are as follows: suprarenal aorta, 8% to 24%; infrarenal aorta, 34% to 58%; superior mesenteric artery, 40% to 61%; and iliac artery, 60% to 80%.
- Survival rates after abdominal venous injuries are as follows: infrarenal inferior vena cava, 46% to 76%; superior mesenteric vein, 35% to 71%; iliac vein, 74% to 91%; and portal vein, 50%.

INTRODUCTION

Abdominal vessel injuries are among the most lethal injuries encountered by trauma surgeons because the vast majority of these patients arrive at trauma centers in profound hemorrhagic shock.[1-4] Patients sustaining abdominal vessel injuries best exemplify the lethal vicious cycle of shock, with secondary hypothermia, acidosis, and a coagulopathy.

The major sites of hemorrhage in patients sustaining blunt or penetrating abdominal trauma are the viscera, the mesentery, and the major abdominal vessels. The term *abdominal vascular or vessel injury* generally refers to injury to major intraperitoneal or retroperitoneal vessels and is classified into four zones described as follows and in Table 38-1:

- Zone 1: Midline retroperitoneum
  - Supramesocolic region
  - Inframesocolic region
- Zone 2: Upper lateral retroperitoneum
- Zone 3: Pelvic retroperitoneum
- Zone 4: Porta hepatis/retrohepatic inferior vena cava

Because most of the vessels in these areas are in the retroperitoneum, they are difficult to quickly access via a midline laparotomy incision. Therefore, a systematic operative approach is required to adequately diagnose and manage these potentially devastating injuries. A general discussion of epidemiology and methods of diagnosis, with subsequent descriptions of the operative management of abdominal vessel injuries within each region of the abdomen, follows.

EPIDEMIOLOGY

In reviews of vascular injuries sustained in older military conflicts, abdominal vascular injuries have been extraordinarily rare. For example, the classic article by DeBakey and Simeone

TABLE 38-1: Classification of Abdominal Vessel Injury

Zone	Major arterial branches	Major venous branches	Operative maneuvers[a]
1 (Supramesocolic)	Suprarenal aorta Celiac axis Superior mesenteric artery Proximal renal artery	Superior mesenteric vein	Left medial visceral rotation Midline suprarenal aortic exposure
1 (Inframesocolic)	Infrarenal aorta	Infrahepatic inferior vena cava	Midline infrarenal aortic exposure Right medial visceral rotation
2	Renal artery	Renal vein	Midline control of the renal hilum Lateral control of the renal hilum
3	Common, external, and internal iliac arteries	Common, external, and internal iliac veins	Midline control of iliac arteries and veins Isolation and control of common iliac vein/vena caval confluence Total pelvic isolation
4	Hepatic artery	Portal vein Retrohepatic vena cava	Portal exposure Exposure and control of retrohepatic inferior vena cava

[a]Discussed in sections titled "Exposure and Vascular Control."

on 2471 arterial injuries during World War II included only 49 that occurred in the abdomen, an incidence of 2%.[5] Reporting on 304 arterial injuries from the Korean conflict, Hughes[6] noted that only seven, or 2.3%, occurred in the iliac arteries. In the review by Rich et al[7] of 1000 arterial injuries in the Vietnam War, only 29, or 2.9%, involved abdominal vessels.

During Operation Iraqi Freedom and Operation Enduring Freedom (Afghanistan), the overall incidence of vascular injuries in American troops has been approximately 12%.[8] This figure is significantly higher than the 1% to 3% documented in the older military conflicts listed earlier. The incidence of abdominal vascular injuries increased significantly as well, accounting for 9.1% (143/1570) of all vascular injuries reported from both conflicts from January 2002 through September 2009.[9]

The data from civilian trauma centers are quite different. A review from Ben Taub Hospital in Houston, Texas, in 1982 revealed that 31.9% of all vascular injuries occurred in the abdomen, including 18.5% of all arterial injuries and 47.5% of all venous injuries.[10] A 30-year review (1958–1988) at the same hospital in 1989 documented that 33.8% of 5760 cardiovascular injuries occurred in the abdomen.[11] In the last 5 years of the period covered by the report (1984–1988), abdominal vascular injuries accounted for 27.3% of all cardiovascular injuries.

Over the past 30 years, many patients with abdominal vascular injuries have continued to be treated in civilian centers. Asensio et al[12] reported a series of 302 patients with 238 (47%) abdominal arterial and 266 (53%) abdominal venous injuries who underwent operative repair at the Los Angeles County Hospital (University of Southern California) from 1992 to 1997. Similarly, there were 300 patients with 205 abdominal arterial and 284 abdominal venous injuries who underwent operative repair at the Grady Memorial Hospital (Emory University) from 1989 to 1998 as reported by Davis et al.[13] Finally, there were 470 patients with 731 abdominal vascular injuries treated at Detroit Receiving Hospital (Wayne State University) from 1980 to 1997 as reported by Tyburski et al.[14]

The significantly higher number of abdominal vascular injuries treated in civilian as opposed to military practice likely reflects the modest wounding capacity of many handguns when compared with military ordnance, as well as the shorter prehospital transit times in most urban areas of the United States. Advances in torso-protecting military armor and the changing tactics of modern warfare have led to a shift in injuries to the extremities rather than the torso as well, although noncompressible (torso) hemorrhage remained the leading cause of combatant death from hemorrhage in one review.[15]

At present, the estimated incidence of injury to major abdominal vessels in patients sustaining blunt abdominal trauma is thought to be about 5% to 10%.[16,17] This is compared to patients with penetrating stab and gunshot wounds to the abdomen who will sustain a major abdominal vascular injury 10% and 20% to 25% of the time, respectively.[18]

PATHOPHYSIOLOGY

Blunt Trauma

Rapid deceleration in motor vehicle collisions may cause two different types of vascular injuries in the abdomen. The first is avulsion of small branches from major vessels, with subsequent *hemorrhage*. A common example of this is the avulsion of intestinal branches from either the proximal or distal superior mesenteric artery at sites of fixation. A second type

of vascular problem seen with deceleration injury is the development of an intimal tear with secondary *thrombosis* of the lumen, such as is seen in patients with renal artery thrombosis, or a full-thickness tear with a secondary traumatic false aneurysm of the renal artery.[19]

Crush injuries to the abdomen, such as by a lap seat belt, posterior blows to the spine, and any mechanism that causes significant anterior-to-posterior compression may cause two different types of vascular injury, also. The first is an intimal tear or flap with secondary *thrombosis* of a vessel, such as the superior mesenteric artery,[20-22] infrarenal abdominal aorta,[23,24] or iliac artery.[25-27] Direct blows can also completely disrupt exposed vessels, such as the left renal vein over the aorta[28] or the superior mesenteric artery or vein at the base of the mesentery,[29] leading to massive intraperitoneal *hemorrhage*, or they may even partly disrupt the infrarenal abdominal aorta, leading to the development of a traumatic false aneurysm.[23,24]

Penetrating Trauma

In contrast, penetrating injuries create the same kinds of abdominal vessel injuries as seen in the vessels of the extremities, producing blast effects with intimal flaps and secondary *thrombosis*, lateral wall defects with *hemorrhage* or pulsatile *hematomas* (early false aneurysms), or complete transection with either *free hemorrhage* or *thrombosis*.[30] On rare occasions, a penetrating injury may produce an arteriovenous *fistula* involving the portal vein and hepatic artery, renal vessels, iliac vessels, or superior mesenteric vessels.

Iatrogenic injuries to major abdominal vessels are an uncommon but persistent problem. Reported iatrogenic causes of abdominal vascular injury include diagnostic procedures (angiography, cardiac catheterization, laparoscopy), abdominal operations (pelvic and retroperitoneal procedures), spinal operations (removal of a herniated disk), and adjuncts to cardiac surgery (cardiopulmonary bypass, intraaortic balloon assist).[31-33]

DIAGNOSIS

History and Physical Examination

An abdominal vessel injury may present in one of four ways including free intraperitoneal *hemorrhage*; a contained mesenteric, retroperitoneal, or portal *hematoma*; *thrombosis* of the vessel; or some combination of these. As such, patients can be quickly divided into two major groups: those with ongoing hemorrhage and those without ongoing hemorrhage (contained hematoma or thrombosis). Thus, the presenting symptoms are variable based on both presentation and the involved vessel. After blunt trauma, for example, free intraperitoneal hemorrhage may be seen with avulsion of mesenteric vessels and lead to secondary hypovolemic shock. Conversely, when thrombosis of the renal artery is present, the patient will be hemodynamically stable but may complain of upper abdominal and flank pain and will commonly have hematuria (70%–80%).[34] Thrombosis of the infrarenal abdominal aorta will obviously cause pulseless lower extremities.

Penetrating truncal wounds between the nipples and the upper thighs remain the most common cause of abdominal vessel injuries. The exact vessel injured is generally related to the track of the missile or stab wound. For example, gunshot wounds directly on the midline most commonly involve the inferior vena cava or abdominal aorta. Gunshot wounds traversing the pelvis will often injure branches of the iliac artery or vein, while gunshot wounds in the right upper quadrant may involve the renovascular structures, vascular structures within the porta hepatis, or the infrahepatic or retrohepatic inferior vena cava.

On physical examination, the findings in patients with abdominal vessel injury will depend on whether a contained hematoma or active hemorrhage is present. Patients with contained hematomas at the base of the mesentery, in the retroperitoneum, or in the hepatoduodenal ligament, particularly those with injuries to abdominal veins, may be hypotensive in transit but often respond rapidly to the infusion of fluids. They may remain remarkably stable until the hematoma is opened at the time of laparotomy. These patients are potential candidates for the imaging studies mentioned in the next section. Conversely, patients with active hemorrhage, particularly those with injuries to abdominal arteries, generally have a rigid abdomen and unrelenting hypotension. Most of these patients will have an admission base deficit of –10 to –25 and will need 10 to 15 units of packed red blood cell transfusion in the perioperative period.[35] These patients should obviously undergo immediate laparotomy without further evaluation.

The other major physical finding that may be noted in patients with abdominal vascular injury is loss of the pulse in the femoral artery in one lower extremity when the ipsilateral common or external iliac artery has been transected or is thrombosed. In such patients, the presence of a transpelvic gunshot wound associated with a wavering or an absent pulse in a femoral artery is pathognomonic of injury to the ipsilateral iliac artery.

Imaging

In both stable and unstable patients, a rapid surgeon-performed ultrasound (focused assessment for the sonographic evaluation of the trauma patient [FAST]) is useful in ruling out an associated cardiac injury with secondary tamponade or an associated hemothorax mandating the insertion of a thoracostomy tube.[36-39] In a *stable* patient with an abdominal gunshot wound, a routine flat-plate x-ray of the abdomen is of diagnostic value, so that the track of the missile can be predicted from markers placed over the wounds or from the position of a retained missile.

In patients with blunt abdominal trauma, hematuria, modest hypotension, and peritoneal signs in the emergency department, computed tomography (CT) scanning of the abdomen has documented that the absence of renal enhancement and excretion and the presence of a cortical rim sign are

diagnostic of thrombosis of the renal artery; therefore, selective renal arteriography is no longer indicated for this diagnosis. Similarly, any stable patient with blunt trauma who does not require an immediate laparotomy and who has significant hematuria should undergo a CT cystogram as well.

In other patients with blunt trauma, CT angiography is used to diagnose and treat deep pelvic arterial bleeding associated with fractures and to diagnose unusual injuries such as the previously mentioned intimal tears with or without thrombosis in the infrarenal aorta, the superior mesenteric artery, the renal artery, or the iliac artery.

As the technology of CT scanning has advanced, many surgeons and radiologists are comfortable making therapeutic decisions based on data acquired from multiplanar scanning and formal CT angiography.[40] In one study in 2007, contrast-enhanced CT alone had a 94% sensitivity and 89% specificity for the diagnosis of active hemorrhage when compared with angiography.[41] Most of the positive scans involved branches of the internal iliac artery with a concomitant pelvic fracture or injuries to solid organs, and thus were not necessarily diagnostic of true *abdominal vessel injury.* Still, in the stable patient with blunt trauma, findings on CT that are suggestive of injury to the retroperitoneal great vessels mandate nonoperative management with CT angiographic follow-up, endovascular management, or operation.

INITIAL MANAGEMENT AND RESUSCITATION

Prehospital Resuscitation

Resuscitation in the field in patients with possible penetrating or blunt abdominal vessel injuries should be restricted to basic airway maneuvers such as intubation or cricothyroidotomy and decompression of a tension pneumothorax at the scene. Insertion of intravenous lines for infusing crystalloid solutions and blood products is best attempted during transport to the hospital. Restoration of blood pressure to reasonable levels is critical to neurologic recovery in patients with associated blunt intracranial injuries and possible abdominal injuries.[42] In contrast, there is no consistent evidence to support the aggressive administration of crystalloid solutions during the short prehospital times in urban environments. Although the data on permissive hypotension in injured patients with shock after penetrating trauma are encouraging, its role in multisystem blunt trauma and its effect on coagulation are unclear. Even so, a key component of "damage control resuscitation" as espoused by the US military and discussed later is minimization of early crystalloid resuscitation.[43-46]

Emergency Department Resuscitation

In the emergency department, the extent of resuscitation clearly depends on the patient's condition at the time of arrival. In the agonal patient with a rigid abdomen after penetrating or blunt (if the admission chest x-ray is not suggestive of an injury to the descending thoracic aorta) trauma, resuscitative endovascular balloon occlusion of the aorta (REBOA) is now performed in trauma centers around the world in preference to emergency department thoracotomy (see Chapter 13).

A REBOA device inserted through a 7F sheath mimics a cross-clamp on the descending thoracic aorta in the following ways: (1) preserves available blood supply to the coronary and carotid arteries; (2) decreases arterial bleeding from injuries to the abdomen, pelvis, and lower extremities; and (3) possibly decreases bleeding from abdominal venous injuries.[47-52]

In the patient arriving with blunt abdominal trauma, significant hypotension, and a positive surgeon-performed FAST or penetrating abdominal trauma and hypotension, peritonitis, or evisceration, a *time limit of less than 5 minutes in the emergency department is mandatory.* An identification bracelet is applied; an airway and thoracostomy tube are inserted if necessary to maintain vital signs, especially if the operating room is geographically distant; and a blood sample for type and cross-match is obtained with the insertion of the first intravenous catheter. Whether more intravenous lines should be inserted in the emergency department or after arrival in the operating room is much debated. The authors have always believed that patients needing an emergency laparotomy should be in the operating room as soon as the identification bracelet has been applied and a blood specimen has been sent to the blood bank.

With short, large-bore (10-gauge or number 8.5F) catheters in peripheral veins for resuscitation, flow rates of 1400 to 1600 mL/min of crystalloid solutions can be obtained when an external pressure device is exerting 300 mm Hg of pressure. Blood replacement during resuscitation is usually with type-specific blood, although universal donor type O negative blood may be used when there is no time for even a limited cross-match.

Measures in the emergency department that will diminish the hypothermia of shock in patients with abdominal vessel injuries include the following: a heated resuscitation room, the use of prewarmed (37–40°C or 98.6–104.0°F) crystalloid solutions if blood is not available, passage of all crystalloids and blood through high-flow warmers, and covering the patient's trunk and extremities with prewarmed blankets or heating units.

Damage Control Resuscitation and Massive Transfusion

In the past 15 years, based mostly on the military experience during the conflict in Iraq, there has been a dramatic change in the resuscitation philosophy of critically injured patients in many centers. The military resuscitation philosophy of damage control resuscitation is seen as an extension of the concepts of damage control surgery, a term first used in 1993 by Rotondo et al.[53] The cornerstone of damage control resuscitation is the initial use of either fresh whole blood or an idealized ratio of packed red blood cells to fresh frozen plasma to platelets of 1:1:1. With control of hemorrhage or the onset of an intraoperative coagulopathy, further infusion of blood and

components is guided by thromboelastography or rotational thromboelastometry (see Chapters 13, 15, and 16).

OPTIONS FOR MANAGEMENT OF INJURIES TO ABDOMINAL VESSELS

In patients with possible abdominal trauma, especially blunt, and no obvious indication for a laparotomy, a CT is usually performed in those with the following: (1) equivocal physical examination; (2) altered consciousness secondary to acute alcohol intoxication or use of illicit drugs; (3) associated injuries to the brain or spinal cord; and (4) associated injuries to lower ribs, thoracolumbar spine, or pelvis. Even in patients requiring continuous transfusion to maintain a "reasonable" blood pressure after multisystem blunt trauma, particularly when a pelvic fracture is present, a contrast-enhanced CT is performed.[54,55] Such a study will document an intimal injury or thrombosis of a major named artery, as mentioned previously.

An early diagnosis of an injury to a major named abdominal vessel in a hemodynamically stable or reasonably stable patient allows for several options in management.

Nonoperative

Much as in trauma to cervical, thoracic, and peripheral vessels, an intimal flap or mural hematoma that is not flow limiting may be observed in selected patients (ie, not every wall injury needs to be stented or undergo operation). The risk is progression of the wall injury and secondary thrombosis of the artery. Should observation be chosen, one option is to perform an early (48 hours) repeat CT angiogram to see if there has been further progression of the injury. Otherwise, a repeat CT angiogram should be performed in the asymptomatic patient before discharge. With either repeat CT angiogram, evidence of progression of the injury and a decrease in arterial flow mandate choosing an endovascular or operative approach.

Endovascular

There has been extensive experience with the insertion of endostents for intimal flaps, intramural hematomas, and luminal thromboses in major named abdominal vessels after trauma for over two decades.[56] In similar fashion, endostent grafts have been used to treat wall defects resulting in early pulsatile hematomas, traumatic false aneurysms, and arteriovenous fistulas. Finally, interventional vascular surgeons routinely embolize bleeding vessels in solid organs and the pelvis in the modern era.

Endovascular approaches for injuries to abdominal vessels are particularly appealing in patients without another indication for laparotomy in the following circumstances: (1) associated injury to the brain, associated extensive burns, or early organ failure; (2) "hostile" abdomen from prior laparotomies; (3) delayed diagnosis; or (4) patient returns with failed operative repair or chronic missed vessel injury.

Operative

Detailed descriptions of injuries to major abdominal vessels have been available for 100 years.[57] Operative exposures and/or options for management in civilians have been described and refined since the classic wartime papers by the following: (1) Michael E. DeBakey and Fiorindo Simeone in 1946 (World War II)[5]; (2) Carl W. Hughes, John M. Howard, and Frank C. Spencer from 1954 to 1958 (Korean War)[6,58-60]; and (3) Norman M. Rich in 1970 (Vietnam War).[7]

OPERATIVE PREPARATIONS

Draping and Incisions

In the operating room, the entire trunk from the chin to the knees is prepared and draped in the usual manner. Before making the midline incision for a laparotomy, the trauma surgeon should confirm that the following items are available: blood components for transfusion, blood salvaging device, autotransfusion apparatus, a thoracotomy tray, an aortic compressor, a complete tray of vascular instruments, intravascular shunts, sponge sticks with gauze sponges in place for venous compression, and appropriate vascular sutures.

Maneuvers to Prevent or Decrease Hypothermia

In addition to the maneuvers previously described for preventing hypothermia in the emergency department, operative maneuvers with the same purpose include the following: warming the operating room to more than 85°F (29.4°C); covering the patient's head; covering the upper and lower extremities with a heating unit (Bair Hugger Normothermia System, 3M Company, Maplewood, MN); irrigation of nasogastric tubes, thoracostomy tubes, and open body cavities with warm saline; and use of a heating cascade on the anesthesia machine.[61]

General Principles

Insertion of a REBOA device (in aortic zone 1 for abdominal bleeding or in aortic zone 3 for pelvic bleeding) should be considered in any injured patient with a systolic blood pressure of less than 90 mm Hg who is a partial responder or nonresponder to initial resuscitative attempts. A resuscitative thoracotomy would still be indicated in the following situations: (1) REBOA device is not available or cannot be passed into the thoracic aorta; (2) failure of the patient's blood pressure to respond to REBOA; or (3) ultrasound diagnosis of pericardial tamponade or exsanguination through a thoracostomy tube.

A midline abdominal incision from xiphoid to pubis is made, and all clots and free blood are manually evacuated or removed with suction. A rapid inspection is performed to visualize contained hematomas or areas of hemorrhage in the retroperitoneum, base of the mesentery, or porta hepatis. Active hemorrhage from solid organs is controlled by packing, while standard techniques of vascular control are used to control the active hemorrhage from major intra-abdominal vessels. Digital pressure, compression with laparotomy pads, grabbing the perforated artery with a hand (common or external iliac artery), or formal proximal and distal control is needed to control any actively hemorrhaging major artery. Similarly, options for control of bleeding from major veins such as the inferior vena cava, superior mesenteric vein, portal vein, renal veins, or iliac veins include digital pressure, compression with laparotomy pads or sponge sticks, grabbing the perforated vein with a hand, applying Judd-Allis clamps to the edges of the perforation,[62] and the application of vascular clamps. Once hemorrhage from the vascular injury is controlled in a patient with a penetrating wound, it may be worthwhile to rapidly apply Babcock clamps, Allis clamps, or noncrushing intestinal clamps or to rapidly use a surgical stapler to control as many gastrointestinal perforations as possible. This avoids further contamination of the abdomen during the period of vascular repair. The abdomen is irrigated with an antibiotic–saline solution, the vascular repair is then performed, a soft tissue cover is applied over the repair, and the remainder of the operation is directed toward repair of injuries to the bowel and solid organs.

Conversely, if the patient has a nonexpanding retroperitoneal, mesenteric, or portal hematoma at the time of laparotomy, the surgeon occasionally has time to first perform necessary gastrointestinal repairs, change gloves, and irrigate with an antibiotic–saline solution. The surgeon can then open the retroperitoneum, mesentery, or porta hepatis to expose the underlying abdominal vessel injury. The magnitude of injury is best described using the Organ Injury Scale (OIS) of the American Association for the Surgery of Trauma (AAST).[63]

MANAGEMENT OF INJURIES IN ZONE 1: SUPRAMESOCOLIC REGION

Exposure and Vascular Control

The midline retroperitoneum of zone 1 is divided by the transverse mesocolon into a *supramesocolic* region and an *inframesocolic* region. If a hematoma or hemorrhage is present in the midline supramesocolic area, injury to the *diaphragmatic aorta, suprarenal aorta, celiac axis, proximal superior mesenteric artery*, or *proximal renal artery* should be suspected. In such patients, there are several techniques for obtaining proximal vascular control of the aorta at the aortic hiatus of the diaphragm. When a contained *hematoma* is present, as it may be with wounds to the aorta in the aortic hiatus (diaphragmatic aorta), the surgeon usually has time to reflect all left-sided intra-abdominal viscera, including the colon, kidney, spleen, tail of the pancreas, and fundus of the stomach to the midline

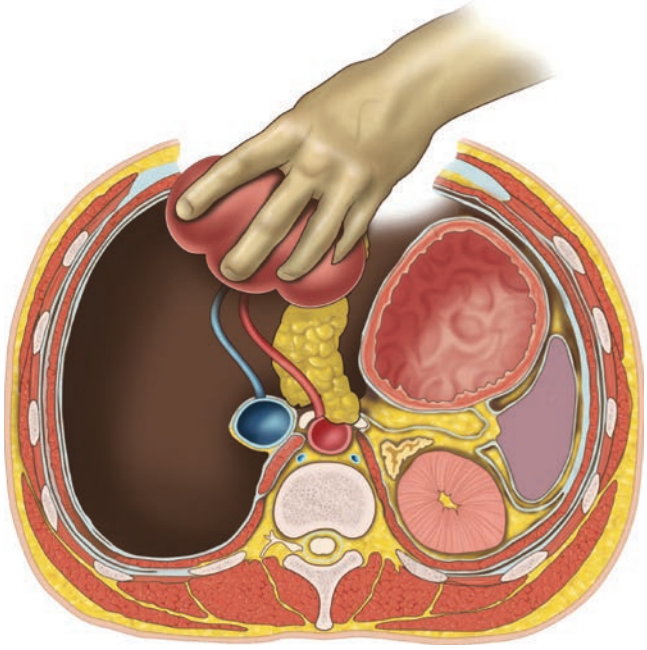

FIGURE 38-1 Completion of left medial visceral mobilization after elevation of left colon, left kidney, spleen, tail of the pancreas, and fundus of the stomach.

(left-sided medial visceral rotation). This maneuver was originally described by DeBakey et al,[64] applied by Elkins et al,[65] and modified by Mattox et al[66] (Fig. 38-1). The advantage of this technique is that it provides extensive visualization of the entire abdominal aorta from the aortic hiatus of the diaphragm to the aortic bifurcation. Disadvantages include the time required to complete the maneuver (5–7 minutes); risk of injury to the spleen, left kidney, or posterior left renal artery during the maneuver; and a fold in the aorta that results when the left kidney is rotated anteriorly.[67] One alternative is to leave the left kidney in its fossa, thereby eliminating potential damage to the kidney or decreasing renal blood flow resulting from rotation of this structure.

Because of the dense nature of the celiac plexus of nerves connecting the right and left celiac ganglia as well as the lymphatics that surround the supraceliac aorta, it is frequently helpful to transect the left crus of the aortic hiatus of the diaphragm and the adjacent diaphragm at the 2 o'clock position to allow for exposure of the distal descending thoracic aorta superior to the hiatus.[67,68] With the distal descending thoracic aorta in the hiatus exposed, a supraceliac aortic clamp such as a DeBakey or DeBakey-Crafoord can be applied. This allows for the extra few centimeters of exposure that are essential for complex repair of the vessel within this tightly confined anatomic area.

Conversely, if active *hemorrhage* is identified from this area, the surgeon may attempt to control it manually or with one of the aortic compression devices. An alternate and rapid approach is to divide the lesser omentum manually, retract the stomach and esophagus to the left, and digitally separate the muscle fibers of the aortic hiatus of the diaphragm from

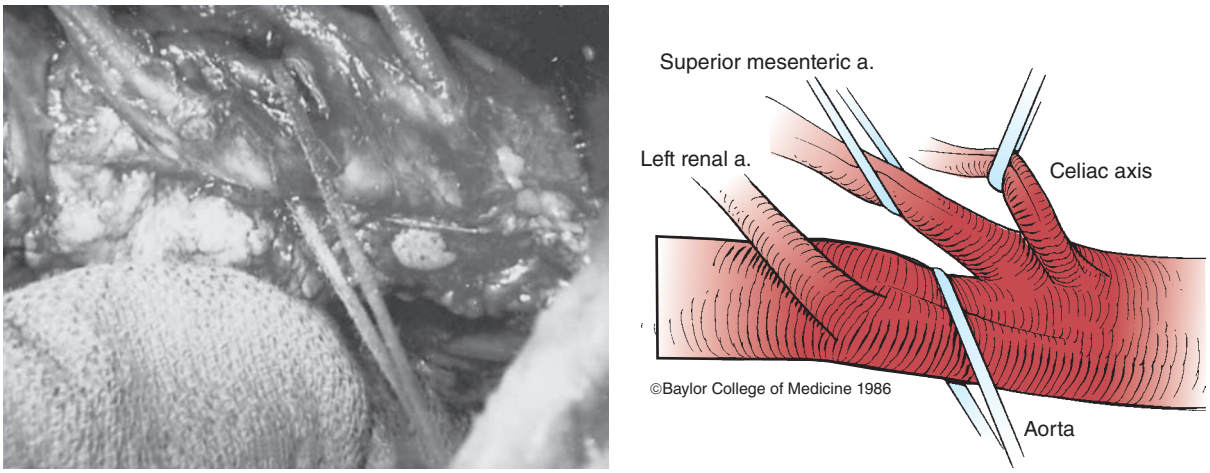

FIGURE 38-2 (**A**) View of suprarenal aorta and major branches after left-sided medial mobilization maneuver. (**B**) Diagrammatic representation of structures with labels. (Reproduced with permission from Baylor College of Medicine.)

the diaphragmatic aorta. This allows for anterior exposure for application of an aortic cross-clamp rather than the left-sided exposure from medial visceral rotation.[69] After either approach to the suprarenal abdominal aorta, cross-clamp time should be minimized to avoid the primary fibrinolytic state that occurs, presumably due to hepatic hypoperfusion.[70] Therefore, the time of placement of the clamp should be noted. Distal control of the aorta in this location is awkward because of the presence of the celiac axis and superior mesenteric artery (Fig. 38-2). In some patients with injury confined to the supraceliac aorta, the celiac axis may have to be divided and ligated to allow for more space for the distal aortic clamp and subsequent vascular repair. Necrosis of the gallbladder is a likely sequela, and cholecystectomy is generally warranted, although this may be performed at repeat exploration when damage control techniques are required.[71]

Suprarenal Aorta

With small perforating wounds to the aorta at this level, lateral aortorrhaphy with 3-0 or 4-0 polypropylene suture is preferred. If two small perforations are adjacent to one another, they should be connected by incising them with a Potts scissors and the defect closed in a transverse fashion, if possible, with polypropylene sutures. When closure of the perforations results in significant narrowing or if a portion of the aortic wall is missing, patch aortoplasty with polytetrafluoroethylene (PTFE) is indicated.

On occasion, a profoundly hypotensive patient with an extensive injury to the diaphragmatic or supraceliac aorta will require insertion of a thoracostomy tube as a temporary intraluminal shunt.[1] If the patient is hemodynamically stable at a reoperation, options for a synthetic interposition graft include Dacron, albumin-coated Dacron, or PTFE.[72,73] When there are concerns about placing a synthetic vascular graft in the presence of extensive gastrointestinal contamination, options described in the literature have included the following: (1) portion of infrarenal inferior vena cava[74]; (2) handmade spiral vein graft[75]; and (3) handmade bovine pericardium tubular graft. There is lack of follow-up data on the few patients who have survived insertion of a prosthetic graft into an injured suprarenal (or infrarenal) abdominal aorta, so the infection rate is unknown.

As previously noted, repairs of the intestine and the aorta with a significant injury should not be performed simultaneously. Once the perforated bowel has been packed away and the surgeon has changed gloves, the aortic prosthesis is sewn in place with 3-0 or 4-0 polypropylene suture. After appropriate flushing of both ends of the aorta and removal of the distal aortic clamp, the proximal aortic clamp should be removed very slowly as the anesthesiologist rapidly infuses fluids. If a long aortic clamp time has been necessary, the prophylactic administration of intravenous bicarbonate is indicated to reverse the "washout" acidosis and hyperkalemia from the previously ischemic lower extremities. The retroperitoneum is then copiously irrigated and closed in a watertight fashion with an absorbable suture.

Cross-clamping of the abdominal aorta at any level in a patient with hemorrhagic shock results in severe ischemia of the lower extremities. Restoration of arterial inflow will then cause a reperfusion injury with its physiologic consequences. In a patient who is hemodynamically stable after repair of the suprarenal (or infrarenal) abdominal aorta, measurement of compartment pressures below the knees should be performed before the patient is moved from the operating room. Pressures in the range of 30 to 35 mm Hg should be treated with below-knee, two-incision, four-compartment fasciotomies.[76] Measurement of the pressure in the anterior compartments of the thighs is worthwhile, as well.

The survival rate of patients with penetrating injuries to the suprarenal abdominal aorta in the distant past was 35%[77-83]; however, more recent reviews have documented a decline in survival (Table 38-2). In one series from 2001 in which injuries to the suprarenal and infrarenal abdominal aorta were

TABLE 38-2: Survival with Injuries to the Abdominal Aorta[a]

	Asensio et al[12]	Davis et al[13]	Tyburski et al[14]	Deere et al[84]
Abdominal aorta overall	36.1 (13/63)	39.1% (25/64)	21.9% (15/71)	33.8% (16/42)
Isolated	21.7% (10/46)	—	—	—
With other artery	17.6% (3/17)	—	—	—
Suprarenal	—	—	8.3% (3/36)	24% (6/25)
Infrarenal	—	—	34.2 (12/35)	58.8% (10/17)

[a]Excludes patients with exsanguination before repair or ligation.

separated, the survival rate in the suprarenal group was only 8.3% (3/36).[14] Another review from 2007 noted that the survival rate in 24 patients (80% penetrating wounds) with injuries to the "subdiaphragmatic" or "suprarenal" aorta was 24% if patients who were dead on arrival were excluded.[84] The reasons for this decrease in survival figures are not defined in the reviews described, although the most likely cause is the shorter prehospital times secondary to improvements in emergency medical services. This brings many patients who would otherwise not survive transit to the trauma center to die in the same.[85]

Celiac Axis

Injury to the celiac axis is rare. In the 2005 review by Asensio et al,[86] only 13 patients with this uncommon injury were treated. Penetrating injuries were the cause in 12 patients, and overall mortality was 62%. Eleven patients were treated with ligation and one with primary repair, with the final patient exsanguinating prior to treatment. Of the five survivors, four had undergone ligation, and all deaths occurred in the operating room. This group also performed an extensive literature review and could only document 33 previously reported cases, all the result of penetrating trauma. Furthermore, they could find no survivor treated with any sort of complex repair. Given these results, patients with injuries to the celiac axis that are not amenable to simple arteriorrhaphy should undergo ligation, which should not cause any short-term morbidity other than the aforementioned risk of gallbladder necrosis.[71] The collateral circulation between the celiac axis and the superior mesenteric artery will maintain viability of the viscera in the foregut. If in doubt, a second look laparotomy should be performed.

When branches of the celiac axis are injured, they are often difficult to repair because of the dense neural and lymphatic tissue in this area and the small size of the vessels in patients with profound shock and secondary vasoconstriction. There is clearly no good reason to repair major injuries to either the left gastric or proximal splenic artery in the patient with trauma to this area. In both instances, these vessels should be ligated. The common hepatic artery may have a larger diameter than the other two vessels, and an injury to this vessel may occasionally be amenable to lateral arteriorrhaphy, end-to-end anastomosis, or the insertion of a saphenous vein or prosthetic graft. In general, however, one should not worry about ligating the hepatic artery proximal to the origin of the gastroduodenal artery, since the extensive collateral flow from the midgut through this vessel will maintain the viability of the liver.

Superior Mesenteric Artery

Injuries to the superior mesenteric artery are managed based on the level of injury. In 1972, Fullen et al[87] described an anatomic classification of injuries to the superior mesenteric artery that has been used intermittently by subsequent authors in the trauma literature.[21,22] If the injury to the superior mesenteric artery is beneath the pancreas (Fullen zone 1), the pancreas may have to be transected between Glassman or Dennis intestinal clamps or GIA or TA staplers to locate and control the bleeding points. Because the superior mesenteric artery has few branches at this level, proximal and distal vascular control is relatively easy to obtain once the overlying pancreas has been divided. Another option is to perform medial rotation of the left-sided intra-abdominal viscera, as previously described, and apply a clamp directly from the left side of the aorta to the proximal superior mesenteric artery at its origin. In this instance, the left kidney may be left in the retroperitoneum as the medial rotation is performed. It is important to remember that the celiac axis and superior mesenteric artery have a "v" conformation when approached from the left side (Fig. 38-2).

Injuries to the superior mesenteric artery also occur beyond the pancreas at the base of the transverse mesocolon (Fullen zone 2, between the pancreaticoduodenal and middle colic branches of the artery). Although there is certainly more space in which to work in this area, the proximity of the pancreas and the potential for pancreatic leaks near the arterial repair make injuries in this location almost as difficult to handle as the more proximal injuries.[22,88] If the superior mesenteric artery has to be ligated at its origin from the aorta or beyond the pancreas (Fullen zone 1 or 2), collateral flow from both the foregut and hindgut should theoretically maintain the viability of the midgut in the distribution of this vessel.[89] Profound vasoconstriction of the visceral vessels, however, may compromise the viability of distal segments of the small bowel and the right colon. In the hemodynamically unstable patient with hypothermia, acidosis, and a coagulopathy, the

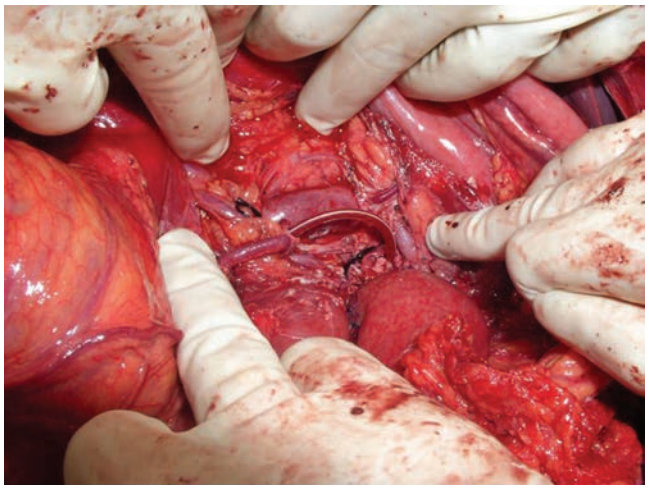

FIGURE 38-3 Argyle shunt in proximal superior mesenteric artery of patient with gunshot wound to upper abdomen.

insertion of a temporary intraluminal shunt into the debrided ends of the superior mesenteric artery is most appropriate and fits the definition of *damage control*[90] (Fig. 38-3). If replacement of the proximal superior mesenteric artery is necessary in a more stable patient or at a reoperation after a damage control procedure, it is safest to place the origin of the saphenous vein or prosthetic graft on the inframesocolic distal infrarenal aorta, away from the pancreas and other upper abdominal injuries (Fig. 38-4). A graft in this location should be tailored so that it will pass through the posterior aspect of the mesentery of the small bowel and then be sutured to the superior mesenteric artery in an end-to-side fashion without significant tension. It is mandatory to cover the aortic suture line with retroperitoneal fat or a viable omental pedicle to avoid an aortoduodenal or aortoenteric fistula at a later time. This is much easier to perform if the proximal origin of the graft is located on the distal aorta. Injuries to the more distal superior mesenteric artery (Fullen zone 3, beyond the middle colic branch, and zone 4, at the level of the enteric branches) should be considered for repair, since ligation in this area is distal to the connection to collateral vessels from the foregut and the hindgut.[91] Because this may require microsurgical techniques, however, it is essentially never performed, and ligation may mandate extensive resection of the ileum and right colon.[92]

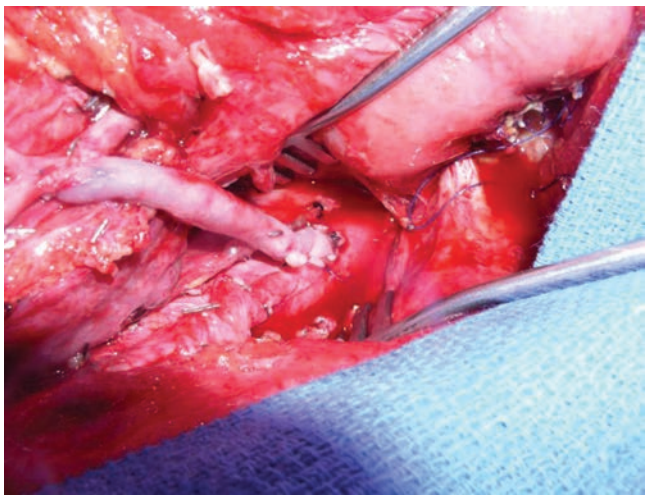

FIGURE 38-4 Same patient as in Fig. 38-3. Shunt has been removed, proximal superior mesenteric artery has been ligated, and view is of aorto-superior mesenteric artery (posterior aspect) bypass graft with autogenous saphenous vein.

The survival rate of patients with penetrating injuries to the superior mesenteric artery in the distant past was 57.7% (Table 38-3).[80,82,87,88,93-95] In four separate reviews from 2001, including a large multi-institutional study,[22] the mean survival was 58.7%.[12-14,22] In one of the older series, survival decreased to 22% when any form of repair more complex than lateral arteriorrhaphy was performed.[88] Independent risk factors for mortality in the multi-institutional study by Asensio et al[22] included injury to Fullen zone 1 or 2, transfusion of 10 units of packed red blood cells, intraoperative acidosis or dysrhythmias, and multisystem organ failure.

ENDOVASCULAR

Most injuries to the proximal superior mesenteric artery are perforations or blunt avulsions with hemorrhage or early pulsatile hematomas. Therefore, endovascular stent grafts have been used most commonly for treatment after late diagnosis of intimal flaps, stenoses, or superior mesenteric arteriovenous fistulas.[96-98]

Proximal Renal Arteries

Injuries to the proximal renal arteries may also present with a zone 1 supramesocolic hematoma or with hemorrhage in this area. The left medial visceral rotation maneuver described earlier allows visualization of much of the left renal artery from the aorta to the kidney. This maneuver does not, however, allow for visualization of the proximal right renal artery. The proximal vessel is best approached through the base of the mesocolon beneath the left renal vein and between the infrarenal abdominal aorta and inferior vena cava. Vascular control may be achieved with DeBakey or Henly clamps. Options for repair of either the proximal or distal renal artery are described later in this chapter (see section "Management of Injuries in Zone 2").

Superior Mesenteric Vein

One other major abdominal vessel, the proximal superior mesenteric vein, lying to the right of the superior mesenteric artery, may be injured at the base of the mesocolon. Injury to the most proximal aspect of this vessel near its junction with the splenic vein is difficult to manage. The overlying pancreas, proximity of the uncinate process, and close association with the superior mesenteric artery often preclude easy access to proximal and distal control of the vein. Therefore, as with injuries to the proximal superior mesenteric artery, the neck

TABLE 38-3: Survival with Injuries to the Superior Mesenteric Artery

		7 (with other artery)	2	28.6
Asensio et al[22] (multi-institutional)	2001	223	143	61
Davis et al[13]	2001	15	8	53.3
Tyburski et al[14]	2001	41	20	48.8

of the pancreas may have to be transected between noncrushing vascular or intestinal clamps or GIA and/or TA staplers to gain access to a distal injury to the vein. More commonly, the surgeon will find an injury to this vessel inferior to the lower border of the pancreas. Vascular control may be achieved with a small Cooley or Satinsky partial occlusion clamp. Often, the vein can be compressed manually or squeezed between the surgeon's fingers as an assistant places a continuous row of 5-0 polypropylene sutures into the edges of the perforation. If a posterior perforation is present, multiple collaterals entering the vein at this point will have to be ligated to roll the perforation into view. Occasionally, the vein will be nearly transected, and both ends will have to be controlled with vascular clamps. With an assistant pushing the small bowel and its mesentery back toward the pancreas, the surgeon can reapproximate the ends of the vein without tension.

When multiple vascular and visceral injuries are present in the upper abdomen and the superior mesenteric vein has been severely injured, ligation can be performed. After ligation of the superior mesenteric (or portal) vein, there is immediate swelling and discoloration of the midgut. Patients who have had rapid control of hemorrhage and stabilize quickly will usually not develop areas of necrosis of the small bowel in the postoperative period. In patients with a prolonged period of perioperative shock and need for pressor agents in the postoperative period, however, there is a risk of significant necrosis of segments of small bowel.

On occasion, there is prolonged splanchnic hypervolemia after ligation of the superior mesenteric vein. The massive distension of the midgut prevents closure of the midline abdominal incision, and the continuous leak of transudative fluid mandates vigorous daily fluid resuscitation. There are two reoperative options to decompress the splanchnic venous circulation in such patients. One is splenic vein turndown to the stump of the ligated superior mesenteric vein, whereas the other is use of a segment of the femoral vein as a conduit to the splenic vein or portal vein.[99,100]

In one 1988 review of injuries to the superior mesenteric vein, survival was 85% among 33 patients treated with ligation versus 64% in 77 patients who underwent repair.[101] Stone et al[102] have emphasized the need for vigorous postoperative fluid resuscitation in these patients as splanchnic hypervolemia leads to peripheral hypovolemia for at least 3 days after ligation of the superior mesenteric vein. The survival rate of patients with injuries to the superior mesenteric vein in four series in the distant past was 72.1% (Table 38-4).[80,95,102,103] Three more recent reviews in 2001 showed a mean survival rate of 58.3%.[12-14] One review in 2009 noted a survival rate of 55% in 11 patients.[104]

Asensio et al[105] reported the largest series in the literature, consisting of 51 injuries to the superior mesenteric vein. The mean Injury Severity Score was 25 ± 12, the mechanism of injury was penetrating for 38 patients (76%) and blunt for 13 patients (24%), and 4 patients (8%) required emergency department thoracotomy. Surgical management consisted of ligation in 30 patients (59%) and primary repair in 16 patients (31%), and 5 patients (10%) exsanguinated before repair. The overall survival rate excluding patients undergoing emergency department thoracotomy was 51%. The survival rate excluding patients who sustained greater than three to four

TABLE 38-4: Survival with Injuries to the Superior Mesenteric Vein

Reference	Year	No. of patients	No. of survivors	Survival (%)

Tyburski et al[14]	2001	32	18	56.3
Asensio et al[105]	2007	51	26	51
Fraga et al[104]	2009	11	6	55

associated injured vessels was 65%. The survival rates were 55% for patients with combined superior mesenteric vein and artery injuries, 40% for patients with injuries to the superior mesenteric vein and portal vein, and 55% for patients with isolated injuries to the superior mesenteric vein. When mortality was stratified to AAST-OIS grade, survival was 44% for grade III and 42% for grade IV. Survival rates stratified to method of management were 60% for primary repair versus 40% for ligation.

MANAGEMENT OF INJURIES IN ZONE 1: INFRAMESOCOLIC REGION

Exposure and Vascular Control

The second major area of hematoma or hemorrhage in the midline is the inframesocolic area. In this location, abdominal vascular injuries include those to the *infrarenal abdominal aorta* or *inferior vena cava.* Exposure of an inframesocolic injury to the aorta is obtained by duplicating the maneuvers used to gain proximal aortic control during the elective resection of an abdominal aortic aneurysm. The transverse mesocolon is displaced up toward the patient's head, the small bowel is eviscerated toward the right (surgeon's) side of the table, and the midline inframesocolic retroperitoneum is opened until the left renal vein is exposed. A proximal aortic clamp such as a DeBakey or Crafoord-DeBakey should then be placed immediately inferior to the left renal vein. When a large retroperitoneal hematoma is present and proximal inframesocolic control is difficult to obtain, it should always be remembered that the injury in the aorta is under the highest point of the hematoma ("Mount Everest phenomenon"). Therefore, rapid digital dissection of the hematoma will generally bring the surgeon directly to the area of injury. Exposure to allow for application of the distal vascular clamp is obtained by dividing the midline retroperitoneum down to the aortic bifurcation, carefully avoiding the left-sided origin of the inferior mesenteric artery. This vessel, however, may be sacrificed whenever necessary for exposure.

If the aorta is intact and an inframesocolic hematoma appears to be more extensive on the right side of the abdomen than on the left or if there is active hemorrhage coming through the base of the mesentery of the ascending colon or hepatic flexure of the colon, injury to the inferior vena cava caudad to the liver should be strongly suspected. Although it is possible to visualize the vena cava through the midline retroperitoneal incision previously described, most trauma surgeons are more comfortable in visualizing the inferior vena cava by performing an extensive right-sided medial visceral rotation. This consists of mobilizing the right half of the colon and C-loop of the duodenum via an extensive Kocher maneuver and leaving the right kidney in situ (Fig. 38-5). This permits the entire vena caval system from the confluence of the iliac veins to the suprarenal vena cava inferior to the liver to be visualized. This maneuver must be carefully performed to avoid an iatrogenic injury to the right gonadal vein. It is often difficult to define precisely where a hole is in a large vein of the abdomen, such as the inferior vena cava, until much of the loose retroperitoneal fatty tissue is stripped away from the wall of the vessel. Once this is done, the site of hemorrhage can be localized.

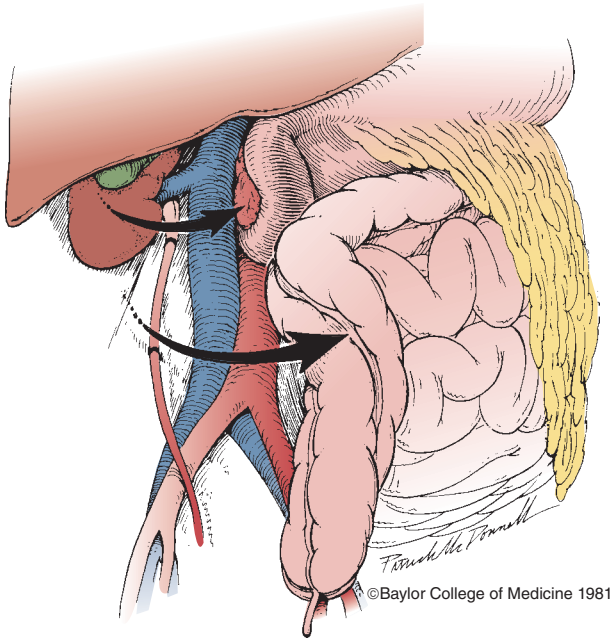

FIGURE 38-5 Medial mobilization of right-sided intra-abdominal viscera except the kidney allows for visualization of the entire infrahepatic inferior vena cava. (Reproduced with permission from Baylor College of Medicine.)

If active hemorrhage appears to be coming from the anterior surface of the inferior vena cava, a Satinsky-type vascular clamp should be applied directly to the perforation as it is elevated by a pair of vascular forceps or Allis clamps. When the inferior vena cava has been extensively lacerated and partial occlusion cannot be performed, it is often helpful to compress the proximal and distal vena cava around the partial transection or extensive laceration using gauze sponges placed in straight sponge sticks. Because of back-bleeding from lumbar veins, it may be necessary to use large DeBakey aortic clamps and completely occlude the vena cava above and below some injuries. This maneuver carries a risk in the already hypotensive patient since venous return to the right side of the heart is significantly impaired. For this reason, one should consider simultaneous clamping of the infrarenal abdominal aorta.

The two areas in which proximal and distal control of the inferior vena cava below the liver is especially difficult to obtain are at the confluence of the common iliac veins and at the caval junction with the renal veins. Although sponge-stick compression of the common iliac veins and the vena cava superiorly may control hemorrhage at the confluence, visualization of perforating wounds in this area is compromised by the overlying aortic bifurcation. In the case of difficult exposure, one technique is to divide and ligate the right internal iliac artery, which may allow for lateral and cephalad

retraction of the right common iliac artery to expose the venous injury. An alternate and interesting approach, but one that is rarely necessary, is the temporary division of the overlying right common iliac artery itself, with mobilization of the aortic bifurcation to the left.[106] This technique provides wide exposure of the confluence of the common iliac veins and the proximal vena cava, and the venous injury can be repaired or ligated in the usual fashion. The right common iliac artery is then reconstituted by an end-to-end anastomosis. Another option is to dissect the common iliac veins with Kittner dissectors and separate them or the external and internal iliac veins with Cushing vein retractors to locate the area of injury.

When the perforation occurs at the junction of the renal veins and the inferior vena cava, it should be directly compressed either digitally or with sponge sticks. An assistant then clamps the infrarenal vena cava and the suprarenal infrahepatic vena cava and loops both renal veins individually with vascular tapes or vessel loops to allow for the direct application of angled vascular clamps. When time does not allow for this dissection, medial mobilization of the right kidney may allow for the application of a partial occlusion clamp across the inferior vena cava at its junction with the right renal vein. This medial mobilization maneuver is useful for exposing posterior perforations in the suprarenal infrahepatic vena cava also.[107] Should this latter maneuver be performed, care must be taken to divide and ligate but not avulse the first lumbar vein on the right, as it frequently enters the junction of the right renal vein and inferior vena cava. One other useful technique for controlling hemorrhage from the inferior vena cava in all locations is to use a Foley balloon catheter for tamponade.[108,109] Either a 5-mL or a 30-mL balloon catheter can be inserted into a caval laceration, the balloon inflated in the lumen, and traction applied to the catheter. Once the bleeding is controlled, either a purse-string suture is inserted or a transverse venorrhaphy is performed, taking care not to rupture the underlying balloon with the needle. The balloon catheter is then deflated and removed just before completion of the suture line.

Over the past 15 years, balloon catheters have been inserted percutaneously in the preoperative or intraoperative period to control hemorrhage from the inferior vena cava and/or iliac veins as well.[110,111]

Infrarenal Aorta

As with injuries to the suprarenal aorta, penetrating or blunt injuries in the infrarenal abdominal aorta are repaired primarily with 3-0 or 4-0 polypropylene sutures or by patch aortoplasty, end-to-end anastomosis, or insertion of a woven Dacron graft, albumin-coated Dacron graft, or a PTFE graft, none of which require preclotting. Because of the small size of the aorta in young trauma patients, it is unusual to be able to place a tube graft larger than 12, 14, or 16 mm in diameter if one is required, as previously noted. The principles of completing the suture lines, sequence of clamp release, and flushing are exactly the same as for aortic repairs in the suprarenal area. Since the retroperitoneal tissue is often thin in young patients, it may be worthwhile to cover an extensive aortic repair or the suture line of a prosthesis with mobilized omentum before closure of the retroperitoneum.[112] After mobilization of the gastrocolic omentum off the transverse colon, it can be placed into the lesser sac superiorly and then brought down through an opening in the transverse mesocolon over the repair or graft in the infrarenal aorta. An alternate approach is to mobilize the gastrocolic omentum off the left side of the transverse colon and then bring the mobilized pedicle around the ligament of Treitz to once again cover the aortic repair or graft. This vascularized pedicle of omentum should prevent a postoperative aortoduodenal fistula.

Although the vast majority of injuries to the infrarenal aorta are penetrating in nature, a small number occur after blunt trauma. The largest review to date is the Western Trauma Association multicenter study by Shalhub et al[24] in 2014. There were 113 patients with a blunt abdominal aortic injury, 60% from motor vehicle collisions, and 44% of patients had associated spinal fractures. Injuries noted included intimal tears (18%), large intimal flaps (34%), pseudoaneurysms (16%), and free aortic rupture (32%). While 89% of intimal tears were managed nonoperatively, more serious lesions underwent open repair (43%) or endovascular repair (15%). Mortality was 39% overall, with 68% of deaths in the first 24 hours due to hemorrhage and shock.

The survival rate of patients with injuries to the infrarenal abdominal aorta in six series in the distant past was 46.2% (Table 38-2).[77,79-82,113] As previously noted in the discussion of recent decreases in survival figures for injuries to the suprarenal abdominal aorta, the same has been true for injuries to the infrarenal abdominal aorta. In the one series published in 2001 in which injuries to the suprarenal and infrarenal abdominal aorta were separated, the survival rate in the infrarenal group was only 34.2%.[14] Another review in 2007 in which 11 of 20 patients had shock on admission documented a survival of 27.3%.[84]

ENDOVASCULAR

Endovascular stent grafts have been successfully used to treat intimal flaps, wall injuries, traumatic false aneurysms, and contained transections of the infrarenal abdominal aorta since 1997.[114-117]

Infrahepatic Inferior Vena Cava

Anterior perforations of the inferior vena cava are best repaired in a transverse fashion using a continuous suture of 4-0 or 5-0 polypropylene. If vascular control is satisfactory and a posterior perforation can be visualized adequately by extending the anterior perforation, the posterior perforation can be repaired from inside the vena cava, with the first suture knot outside the lumen. When a significant longitudinal perforation is present, especially when adjacent perforations have been joined, the repaired vena cava will often take on the appearance of an hourglass. This narrowing may lead to slow postoperative occlusion of the inferior vena cava.

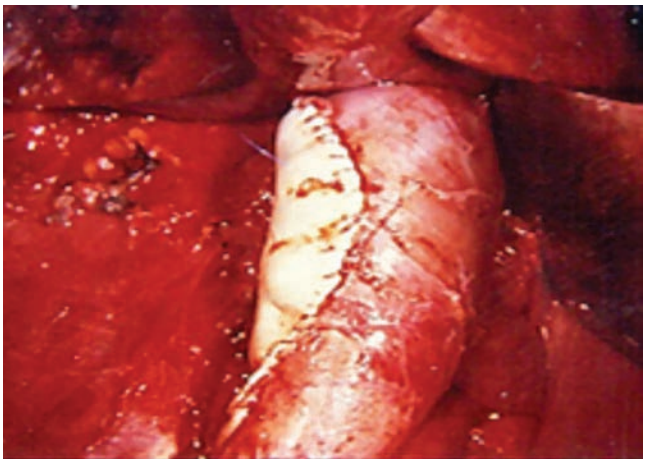

FIGURE 38-6 Polytetrafluoroethylene patch venoplasty of infrarenal inferior vena cava after mid-abdominal gunshot wound.

In the unstable patient who has developed a coagulopathy, no further attempt should be made to modify the repair. In the stable patient, there may be some justification for applying a large venous patch taken from either the resected inferior mesenteric vein or an ovarian vein, or applying a thin-walled PTFE patch (Fig. 38-6).

In a patient who is exsanguinating and in whom extensive repair of the infrarenal inferior vena cava appears to be necessary, ligation of this vessel is usually well tolerated as long as certain precautions are taken (Fig. 38-7). The first of these is to measure the pressures in the compartments of the legs and thighs at the first operation and to perform bilateral below-knee four-compartment fasciotomies if the pressure is 30 to 35 mm Hg, depending on the patient's hemodynamic status. Bilateral thigh fasciotomies may be necessary as well, within the first 48 hours after ligation. The second is to maintain circulating volume in the postoperative period through infusion of the appropriate fluids. The third is to apply

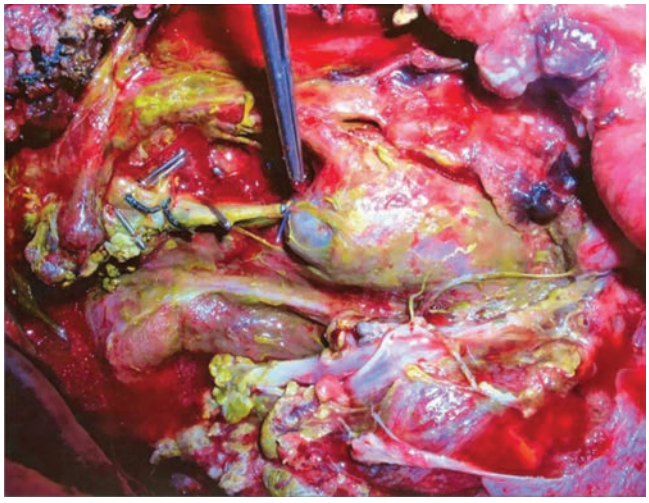

FIGURE 38-7 One day after ligation of the infrarenal inferior vena cava in patient with paraumbilical gunshot wound. Note extensive fat necrosis related to associated injury to the head of the pancreas.

elastic compression wraps to both lower extremities and keep them continuously elevated for approximately 5 to 7 days after operation. Patients should wear the wraps when they start to ambulate, as well. If there is some residual edema even with the wraps in place at the time of hospital discharge, the patient should be fitted with full-length, custom-made support hose.

A 2005 review from Groote Schuur Hospital (University of Cape Town, South Africa) emphasizes the significant increase in the use of ligation for injuries to the infrarenal inferior vena cava over the past two decades.[118] In 41 patients with such injuries, ligation was performed in 29 (70.7%).

In a 2010 review of 100 injuries to the inferior vena cava treated at Grady Memorial Hospital (Emory University) in Atlanta, 25 underwent ligation, including 22 of 54 (40.7%) with injuries to the infrarenal vena cava.[119] Survival to hospital discharge was 41%; 1-year follow-up was available in seven of nine survivors after ligation, and no patient had more than trace lower extremity edema. While the majority of patients, therefore, seem to have no or minimal long-term edema, there have been occasional reports of severe edema in the postoperative period that has required later interposition grafting.[120,121]

Ligation of the suprarenal inferior vena cava is performed only when the patient has an extensive injury at this location and appears to have terminal shock at operation.[122,123] In the previously mentioned series from Grady Memorial Hospital, three patients underwent ligation of the suprarenal inferior vena cava with only one long-term survivor. This patient required dialysis over his hospital course but gradually experienced a return of his renal function and was discharged without renal insufficiency. One-year follow-up in this patient revealed minimal lower extremity edema and normal renal function.[119] In order to avoid the risk of acute renal failure and massive edema of the lower half of the body that would ordinarily be associated with ligation at this level, several innovative approaches have been used. These include suprarenal insertion of a femoral vein graft, a saphenous vein composite interposition graft, insertion of a Dacron or ringed PTFE interposition graft, insertion of a cavo–right atrial Dacron or PTFE bypass graft, or a hybrid approach with transcaval insertion of an endostent graft.[120,121,124,125] Although long-term data are lacking for both Dacron and PTFE interposition or bypass grafts in the major veins of the abdomen, the use of an externally supported PTFE graft in combination with chronic anticoagulation would presumably offer the best long-term patency.

Survival rates for patients with injuries to the inferior vena cava obviously depend on the location of injury (Table 38-5). If one eliminates injuries to the suprahepatic and retrohepatic vena cava (to be discussed) from seven series published in the distant past, the average survival for 515 patients with injuries to the infrahepatic vena cava was 72.2%.[80,82,107,126-129] Further eliminating juxtarenal injuries, the average survival for 318 patients with true infrarenal caval injuries was 76.1%.[80,82,107,126-129] Two more recent series (2001 and 2010), in which injuries are stratified by location, show lower overall survival rates (46.1% and 59.2%) for injuries to the infrarenal

TABLE 38-5: Survival with Injuries to the Inferior Vena Cava

	Seven series, 1978–1994[80,82,107,126-129]	Tyburski et al[14]	Sullivan et al[119]
Infrahepatic inferior vena cava	72.2% (372/515)	40.3% (31/177)	57.3% (43/75)
Infrarenal inferior vena cava	76.1% (242/318)	46.1% (30/65)	59.2% (32/54)

inferior vena cava.[14,119] Finally, short-term patency of repair of the inferior vena cava was studied by Porter et al[130] in 1997. In 28 patients with prior lateral venorrhaphy of the inferior vena cava, patency of the cava was documented by sonography, CT scan, or both in 24 patients (86%).

ENDOVASCULAR

In the rare patient with a contained hematoma around a perforation or rupture of the inferior vena cava noted on a screening or preoperative CT of the abdomen, an endovascular stent graft can be inserted as definitive treatment.[131,132]

MANAGEMENT OF INJURIES IN ZONE 2

Exposure and Vascular Control

If a hematoma or hemorrhage is present in the upper lateral retroperitoneum, injury to the *renal artery, renal vein*, or *both*, as well as injury to the *kidney*, should be suspected. Most patients with penetrating trauma to the abdomen are explored prior to extensive radiologic workup; however, in selected patients who are hemodynamically stable after sustaining penetrating wounds to the flank, CT scanning has been used to document an isolated renal injury and operation has been avoided.[133] Conversely, patients found to have a perirenal hematoma at the time of exploration for a penetrating abdominal wound should have unroofing of the hematoma and exploration of the wound track. If the hematoma is not rapidly expanding and there is no free intra-abdominal bleeding, some surgeons will loop the ipsilateral renal artery with vessel loops or a vascular tape in the midline at the base of the mesocolon.[134] The left renal vein can be looped with vessel loops or a vascular tape in the same location; however, vascular control of the proximal right renal vein will have to wait for mobilization of the C-loop of the duodenum and unroofing of the inferior vena cava at its junction with the renal veins. It should be noted that obtaining proximal vascular control prior to exploration of a perirenal hematoma is controversial. Indeed, in one study, preliminary vascular control of the renal hilum had no impact on nephrectomy rate, transfusion requirements, or blood loss.[135]

Conversely, if there is active bleeding from the kidney through Gerota's fascia or from the retroperitoneum overlying the renal vessels, central renovascular control is not obtained. The surgeon should simply open the retroperitoneum lateral to the injured kidney and manually elevate the kidney directly into the wound. A large vascular clamp can be applied proximal to the hilum either at the midline on the left or just lateral to the inferior vena cava on the right to control any further bleeding.

Patients who present after blunt trauma may have either a renovascular or renal parenchymal injury, also. Patients in the former group, however, generally present with renovascular occlusion, which will be discussed later. In patients who have suffered blunt abdominal trauma and have undergone a duplex ultrasound of the renal artery or a CT of the abdomen that has demonstrated flow to the kidney and/or a low AAST-OIS grade of injury, there is no justification for exploring the perirenal hematoma should an emergency laparotomy be indicated for other reasons.

Renovascular Injuries: Renal Artery

Renovascular injuries are difficult to manage, especially when the renal artery is involved. It is a small vessel that is deeply embedded in the retroperitoneum. Occasionally, small perforations of the artery from penetrating wounds can be repaired by lateral arteriorrhaphy or resection with an end-to-end anastomosis. Interposition grafting using a saphenous vein graft for extensive injuries is indicated only when the injury leads to a solitary kidney. Alternatively, borrowed or substitute arteries, such as the splenic artery to replace the left renal artery and the hepatic artery to replace the right renal artery, have been used rarely but are not often indicated in hypotensive trauma patients with significant renovascular injuries from penetrating wounds. In these patients and in those with multiple intra-abdominal injuries or a long preoperative period of ischemia, nephrectomy may be a better choice, as long as intraoperative palpation has confirmed a normal contralateral kidney. The survival rate of patients with injuries to the renal arteries from penetrating trauma in two studies in the distant past was approximately 87%, with renal salvage in only 30% to 40%.[134,136] In the three large series from 2001, the survival rate was 65.1%.[12-14]

Intimal tears in the renal arteries may result from deceleration in motor vehicle crashes, automobile–pedestrian accidents, and falls from heights. These can lead to secondary thrombosis of the vessel and complaints of upper abdominal and flank pain in some patients, as previously noted. One older literature review noted that only 30% of patients with intimal tears in the renal arteries had gross hematuria, 43% had microscopic hematuria, and 27% had no blood in the urine.[137] Hence, the diagnosis may be missed because a duplex ultrasound or CT scan may not be performed expeditiously in a stable patient with a normal abdominal examination.

If either duplex ultrasound or a CT scan documents occlusion of a renal artery, the surgeon must decide on the need

for operation, endovascular intervention, or observation. Intuitively, the time interval from the episode of trauma to restoration of arterial flow would appear to be the most critical factor in saving the affected kidney. In one older study, there was an 80% chance of restoring some renal function at 12 hours, but this significantly decreased to 57% at 18 hours after the onset of occlusion.[137] A Western Trauma Association multicenter review in 2000[138] and a literature review in 2017,[19] however, did not demonstrate a clear relationship between time of occlusion and eventual function of the kidney after vascular repair.

A laparotomy to repair an isolated blunt stenosis or thrombosis of a renal artery is no longer performed in the modern era. Even in patients undergoing a needed laparotomy for other intra-abdominal injuries, a postoperative endovascular approach is used.[19]

It is of interest that some older case reports in the literature have documented either spontaneous recovery or the late successful revascularization of one or both kidneys after presumed blunt thrombosis of the renal artery.[139] The authors of the report suggest that attempts at late revascularization may be occasionally rewarding and advise that early nephrectomy is unnecessary because of the low incidence of chronic hypertension in cases of renal artery thrombosis.

In patients who are critically ill after multisystem trauma, isolated thrombosis of one renal artery may be observed if the contralateral artery and kidney are normal on imaging. Obviously, patients with bilateral renal artery injuries or those with injury to a solitary renal artery should be strongly considered for endovascular revascularization. In addition, prolonged follow-up should be arranged for all patients to see if hypertension develops.[19,34]

In the 2006 review of 517 patients with blunt renal artery injuries in the National Trauma Data Bank, only 13 patients had insertion of an endovascular stent.[140] The kidney was not explored in 376 patients (73%), 95 patients (18%) had nephrectomy, and only 45 patients (9%) had surgical revascularization. Patients who had surgical revascularization had longer stays in the intensive care unit and hospital on multiple regression analysis. The recommendation by the authors was that "nonoperative management should be considered as an acceptable therapeutic option."[140]

ENDOVASCULAR

As noted earlier, endovascular stents are commonly placed to cover intimal defects or restore arterial flow after blunt injury of the renal artery. The endovascular approach is one of the oldest and most commonly performed of such procedures in abdominal vessel trauma.[141,142]

Renovascular Injuries: Renal Vein

A patient with a penetrating wound to the renal vein may be quite stable as a result of the previously described retroperitoneal tamponade. Either digital compression or the direct application of a Satinsky or Henly vascular clamp can be used to control bleeding after exposure of the injured vein. Lateral venorrhaphy remains the preferred technique of repair. If ligation of the right renal vein is necessary to control hemorrhage, nephrectomy should be performed either at the initial operation or at the reoperation if damage control has been necessary. The medial left renal vein, however, can be ligated as long as the left adrenal and gonadal veins are intact. In one review of 36 patients followed more than 1 year after elective ligation of the left renal vein during complex surgery on the abdominal aorta, only two developed elevation of creatinine levels over 2 years later.[143] The survival rate for patients with penetrating injuries to the renal veins has ranged from 42% to 88% in the older literature, with the difference presumably due to the magnitude and number of associated visceral and vascular injuries.[135,144] In the three 2001 reviews, survival ranged from 44.2% to 70%, with a mean of 60.4%.[12-14]

Injuries to the renal parenchyma are discussed in Chapter 40.

MANAGEMENT OF INJURIES IN ZONE 3

Exposure and Vascular Control

The fourth major area of hematoma or hemorrhage is the pelvic retroperitoneum. In this location, the *iliac artery, iliac vein*, or *both* may be injured. Furthermore, the vascular injury may be in combination with an injury to the *ureter.* The majority of injuries reported in major series are the result of penetrating trauma. It is of interest, however, that major blunt abdominal trauma or pelvic fractures, particularly of the open type, have become a more frequent cause of occlusion or laceration of the iliac arteries in the past 30 years than previously noted.[26,27] In fact, a 2009 review from the National Trauma Data Bank noted a 3.5% rate of blunt iliac artery injury in 6377 patients with Abbreviated Injury Scale 3 or 4 pelvic fracture.[25] The presence of a blunt iliac arterial injury in combination with a pelvic fracture was associated with a significantly higher hospital mortality (40% vs 15%) and a 7.7% amputation rate.[25]

If a hematoma or hemorrhage is present after penetrating trauma, digital compression, compression with a laparotomy pad, or simply grabbing the bleeding vessel with a hand after opening the pelvic retroperitoneum should be performed until proximal and distal vascular control is attained. The proximal common iliac arteries are exposed by eviscerating the small bowel to the right and dividing the midline retroperitoneum over the aortic bifurcation. In young trauma patients, there is usually *no adherence* between the common iliac artery and vein in this location, and vessel loops or vascular tapes can be passed rapidly around the proximal arteries. Distal vascular control is obtained at the point at which the external iliac artery comes out of the pelvis proximal to the inguinal ligament. The artery is readily palpable under the retroperitoneum and can be rapidly elevated into the field of view with a vessel loop or a vascular tape. A Cushing vein retractor is useful in pulling the adjacent external iliac vein away during this maneuver. The major problem in this area is continued back-bleeding from the internal iliac artery. This artery can be exposed by further opening the retroperitoneum on the side of the pelvis, elevating the vessel loops or vascular tapes

on the proximal common iliac and distal external iliac arteries, and looking for the large branch of the iliac artery that descends into the pelvis.

When bilateral iliac vascular injuries are present, one of the former coauthors of this chapter (Jon M. Burch, MD) has used the technique of total pelvic vascular isolation. This includes proximal cross-clamping of the abdominal aorta and inferior vena cava just above their bifurcations and distal cross-clamping of both the external iliac artery and vein with one clamp on each side of the pelvis. Back-bleeding from the internal iliac vessels is minimal with this approach.

Injuries to the iliac veins are exposed through a technique similar to that described for injuries to the iliac arteries. It is not usually necessary to pass vessel loops or vascular tapes around these vessels, however, because they are readily compressible with either sponge sticks or fingers. As previously noted, the partially covered location of the right common iliac vein has led to the suggested temporary transection of the right common iliac artery in order to improve exposure at this location.[106] Similarly, transection and ligation of the internal iliac artery on the side of the pelvis will allow for improved exposure of an injured ipsilateral internal iliac vein.[145]

Common, External, and Internal Iliac Arteries

Injuries to the common or external iliac artery should be repaired or temporarily shunted. Ligation of either vessel in the hypotensive patient will lead to progressive ischemia of the lower extremity and the need for a high above-knee amputation or a hip disarticulation in the later postoperative course. In fact, in World War II, ligation of these vessels led to amputation rates of approximately 50%.[5] Furthermore, in a large review by Burch et al[146] in 1990, mortality associated with ligation was 90%. In patients with severe shock, insertion of a temporary intraluminal shunt is a better choice for damage control. Ball and Feliciano[147] compared the results of ligation (1 common and 14 external iliac arteries) versus temporary intraluminal shunts (2 common and 5 external iliac arteries). Patients treated with shunts had fewer amputations (0% vs 47%), less distal fasciotomy procedures (43% vs 93%), and lower mortality rates (43% vs 72%). In contrast, an injured internal iliac artery can be ligated with impunity even with injuries that occur bilaterally.

Options in the management of more stable patients with injuries to the common or external iliac artery include the following: lateral arteriorrhaphy; completion of a partial transection and end-to-end anastomosis; resection of the injured area and insertion of a saphenous vein or PTFE graft[148,149]; mobilization of the ipsilateral internal iliac artery to serve as a replacement for the external iliac artery; or transposition of one iliac artery to the side of the contralateral iliac artery for wounds at the bifurcation.[150]

Extensive injuries to the common or external iliac artery in the presence of *significant* enteric or colonic contamination in the pelvis remain a serious problem for the trauma surgeon. Both end-to-end repairs and vascular grafts in this location have suffered postoperative formation of postrepair false aneurysms and even blowouts secondary to pelvic infection from the original intestinal contamination. Therefore, the authors have occasionally avoided an end-to-end anastomosis or the insertion of a saphenous vein or PTFE graft in either the common or external iliac artery in such a situation. Rather, the artery is divided just proximal to the injury, closed with a double-running row of 4-0 or 5-0 polypropylene sutures, and covered with noninjured retroperitoneum or a vascularized pedicle of omentum. If the patient's lower extremity on the side of the ligation appears to be in jeopardy at the completion of the abdominal operation in the reasonably stable patient, an extra-anatomic femorofemoral crossover graft should be performed to return arterial inflow to the extremity.[72] If the surgeon chooses not to perform a femorofemoral crossover graft until the patient's condition has been stabilized in the surgical intensive care unit, an ipsilateral four-compartment below-knee fasciotomy should be performed, since ischemic edema below the knee will often lead to a compartment syndrome. The thigh compartments should be monitored for increased ischemic edema as well.

The survival rate among patients with injuries to the iliac arteries will vary with the number of associated injuries to the iliac vein, aorta, and vena cava, but was approximately 61% in 189 patients reviewed in four large series published in the distant past (Table 38-6).[95,146,151,152] When patients with other vascular injuries, especially to the iliac vein, were eliminated, the survival rate among 57 patients in three older series was 81%.[146,151,152] If the injury is large and free bleeding from the iliac artery into the peritoneal cavity has occurred during the preoperative period, the survival rate in one older series was only 45%.[151]

In one of the largest series in the literature, published in 2003, Asensio et al[153] reported on the predictors of outcome for 148 patients sustaining a total of 185 iliac vessel injuries. In this series, the authors reported a 95% incidence of penetrating injuries with a mean estimated blood loss of 6246 ± 6174 mL. Of the 185 injured vessels, 71 (99%) of 72 iliac arteries were repaired, 101 (89%) of the 113 iliac veins were ligated, and overall survival was 51% (76/148). Mortality was 82% in patients with exsanguination (49/72). Survival by vessel included the following: iliac artery, 57% (20/35); iliac vein, 55% (42/76); and iliac artery and vein combined, 38% (14/37). Significant predictors of outcome were thoracotomy in the emergency department, associated injury to the abdominal aorta or inferior vena cava, combined injuries to the iliac artery and vein, intraoperative arrhythmia, and intraoperative coagulopathy. On logistic regression, independent risk factors for survival were absence of thoracotomy in the emergency department, surgical management, and arrhythmias. When mortality was stratified according to the AAST abdominal vascular injury grade, grade III was 35% (33/95), grade IV was 71% (23/34), and grade V was 79% (15/19).

The survival rates in two of the 2001 reviews for patients with injuries to the common iliac artery (other vascular injuries not specified) ranged from 44.7% to 55.5%, with a mean of 46.8% (Table 38-6).[13,14] In the same reviews, the survival rate with injuries to the external iliac artery was a mean of 64.1%

TABLE 38-6: Historic Survival with Injuries to the Iliac Artery and Vein

[a]Isolated injury to iliac artery.
[b]Isolated injury to iliac vein.

(Table 38-6).[13,14] In the comprehensive review of data from the National Trauma Data Bank in 2013 by Lauerman et al,[26] survival rates were as follows: penetrating iliac artery, 60.8%; and penetrating iliac artery and vein, 48.2% (Table 38-7).[26]

Blunt trauma to the iliac arteries is still less common as they are protected by the bony pelvis and lie deep in the retroperitoneum. Partial transections, avulsions, and intimal injuries with secondary thrombosis have all been reported in association with pelvic fractures, particularly in recent years, as previously noted. Despite the low amputation rates described previously,[25,26] the amputation rate in 24 patients with blunt injuries to the common or external iliac artery (pelvic fractures in 89% of all iliac artery injuries) was 50% in a 2014 review from the Shock Trauma Center/University of Maryland, Baltimore.[27]

ENDOVASCULAR

Endovascular stents and stent grafts have been widely used in patients with complications after repair of penetrating wounds to the common and external iliac arteries and to restore flow in patients with blunt thrombosis.

Common, External, and Internal Iliac Veins

Injuries to the common or external iliac vein are treated either with lateral repair using 4-0 or 5-0 polypropylene suture or with ligation. Ligation in young patients has been well tolerated in the authors' experience and that of others if the same precautions used after ligation of the inferior vena cava are applied.[154] When significant narrowing of the common or external iliac vein results from a lateral repair, postoperative anticoagulation is appropriate to lessen the risk of thrombosis and/or pulmonary embolism.

The survival rate of patients with injuries to the iliac veins is variable but was approximately 70% in 404 patients reviewed in five large series published in the distant past (Table 38-6).[95,146,151,152,155] When patients with other vascular injuries, especially to the iliac artery, were eliminated, the survival rate among 137 patients in three series was 95%.[146,151,152] The survival rate in the three 2001 series in patients with injuries to the iliac vein (not otherwise specified or common/external/internal combined) was a mean of 65.1%.[12-14]

TABLE 38-7: Survival with Injuries to the Iliac Artery and Vein—National Trauma Data Bank

Reference	Year	Penetrating artery	Penetrating vein	Penetrating combined
Lauerman et al[26]	2013	60.8% (124/204)	74.5% (190/255)	48.% (76/157)
Reference	**Year**	**Penetrating/blunt artery**	**Penetrating/blunt vein**	**Penetrating/blunt combined**
Magee et al[156]	2018	80.7%% (1562/1936)	83.5% (740/886)	51.3% (286/557)
Reference	**Year**	**Iliac vein repair**	**Iliac vein ligation**	
Magee et al[156]	2018	91.2% (206/226)	81.3% (156/192)	

In more recent reviews from the National Trauma Data Bank in 2013 and 2018, the survival rates after injury to the iliac vein (but not the artery) were 74.5% and 83.5%, respectively, whereas the survival rates after combined arterial and venous injuries were 48.4% and 51.3%[26,156] (Table 38-7). In the latter review, the survival rate was 91.2% after venous repair versus 81.3% after ligation.[156]

Pelvic Fractures and Injury to Pelvic Vessels

The management of pelvic fractures is comprehensively reviewed in Chapter 39. Trends in the management of hemorrhage from the iliac vessels and branches over the past 15 years have included the following: (1) REBOA positioned at zone 3 (infrarenal aorta)[157,158]; (2) preperitoneal packing[159]; (3) endovascular stent graft for major arterial injury[157]; (4) angioembolization with access through either common femoral or radial arteries[157]; and (5) return of operative ligation of bilateral internal iliac arteries.[160]

Transpelvic Gunshot Wounds and Presacral Bleeding

A number of techniques, including some from colorectal surgeons, are available to control presacral bleeding after transpelvic gunshot wounds. These include the following: (1) sterilized metallic thumbtacks[161,162]; (2) endoscopic mesh stapler[163]; (3) electrocautery passed through muscle fragments[164]; (4) tamponade with Sengstaken-Blakemore balloon[165]; (5) tamponade with breast implant sizer[166]; (6) free rectus muscle piece for tamponade[167]; and (7) external fixator to hold direct compression.[168]

MANAGEMENT OF INJURIES IN THE PORTA HEPATIS AND TO THE RETROHEPATIC VENA CAVA

Exposure and Vascular Control

If a hematoma or hemorrhage is present in the area of the portal triad in the right upper quadrant, there may be injury to the *portal vein, hepatic artery*, or *both.* Furthermore, the vascular injury may be in combination with an injury to the *common bile duct.* When a hematoma is present, the proximal hepatoduodenal ligament should be encircled with a vessel loop or vascular tape or a noncrushing vascular clamp should be applied (the Pringle maneuver) before the hematoma is entered. If hemorrhage is occurring, finger compression of the bleeding vessels will suffice until the vascular clamp is in place. The Pringle maneuver clamps the distal common bile duct as well as the bleeding vessels but led to only one stricture of the common bile duct in one older series of hepatic injuries from the Ben Taub Hospital in Houston, Texas, in 1986.[169] Because of the short length of the porta in many patients, it may be difficult to place a distal vascular clamp right at the edge of the liver. In such patients, manual compression with forceps may allow partial distal vascular control until the area of injury can be isolated. Because of the proximity of the common bile duct, no sutures should be placed into the porta until the vascular injury is precisely defined.

Injuries to the portal vein in the hepatoduodenal ligament are isolated in much the same fashion as injuries to the hepatic artery. The posterior position of the vein, however, makes the exposure of these injuries more difficult. Mobilization of the common bile duct to the left and of the cystic duct superiorly, coupled with an extensive Kocher maneuver, will usually allow for excellent visualization of any suprapancreatic injury after proximal (and, if possible, distal) vascular control has been obtained. As with proximal wounds to the superior mesenteric artery or vein, division of the neck of the pancreas is necessary on rare occasions to visualize perforations in the retropancreatic portion of the portal vein. With the assistant compressing the superior mesenteric vein below and a vascular clamp applied to the hepatoduodenal ligament above, the surgeon should open both ends of the retropancreatic tunnel over the anterior wall of the portal vein by gently spreading a clamp or scissors. This maneuver may be prevented above by the position of the gastroduodenal artery, which should then be divided and ligated. When the tips of the surgeon's index fingers touch under the neck of the pancreas, two straight noncrushing intestinal (Glassman or Dennis) or slightly angled vascular (Glover) clamps are placed across the entire neck of the pancreas. The pancreas is divided between the clamps and retracted away until the perforations in the portal vein or distal superior mesenteric or splenic veins are visualized. Alternatively, the neck of pancreas may be divided with a GIA or TA stapler as previously noted.

Hepatic Artery

Due to its short course, injury to any portion of the hepatic artery is rare. Replacement of the injured common hepatic artery with a substitute vascular conduit is rarely indicated, since most patients with a portal hematoma or hemorrhage have significant injuries to the liver, right kidney, or inferior vena cava also. As previously noted, ligation of the hepatic artery appears to be well tolerated in the young trauma patient. This is true even when performed beyond the origin of the gastroduodenal artery, owing to the extensive collateral arterial flow to the liver[170]; however, extensive necrosis of any repair of an associated injury to the liver may occur. Because of the small size of the right or left hepatic artery, lateral repairs are often difficult and will frequently be followed by occlusion of the vessel in the postoperative period.

Because of its rarity, few large studies have been performed on injuries to the hepatic artery. A relatively large multicenter experience was published in 1995 by Jurkovich et al,[171] which documented the course of 99 patients with injury to the portal triad. Of this group, 28 patients had 29 injuries to a segment of the hepatic artery. Nineteen patients underwent ligation, with eight survivors (mortality 42%). Only one patient developed hepatic necrosis requiring debridement, and this patient had an associated extensive injury to that lobe. Seven patients

TABLE 38-8: Survival with Injuries to the Portal Vein

Reference	Year	No. of patients	No. of survivors	Survival (%)
Graham et al[103]	1978	38	18	48.6
Petersen et al[174]	1979	28	17	60.7
Stone et al[102]	1982	41	22	53.7
Kashuk et al[80]	1982	9	3	33.3
Ivatury et al[175]	1987	14	7	50.0
Jurkovich et al[171]	1995	44[a]	20	45.4
Fraga et al[104]	2009	15	8	53.3
Overall		188	95	50.5

[a]Only patients who had repair or ligation; also, one patient had two injuries to portal vein.

had attempts at repair with only one survivor, and two other patients exsanguinated prior to therapy. It should be noted, again, that selective ligation of the right hepatic artery warrants a cholecystectomy.

Portal Vein

As noted earlier, injuries to any portion of the portal vein are more difficult to manage than are injuries to the hepatic artery, owing to the posterior location of the vein, the friability of its wall, and the greater blood flow through it. Techniques for repair of the vein are varied, but lateral venorrhaphy with a 4-0 or 5-0 polypropylene suture is preferred. More extensive maneuvers that have occasionally been used with success include the following: (1) resection with an end-to-end anastomosis; (2) interposition grafting; (3) transposition of the splenic vein down to the superior mesenteric vein to replace the proximal portal vein; (4) an end-to-side portacaval shunt; and (5) a venovenous shunt from the superior mesenteric vein to the distal portal vein or inferior vena cava.[80,100,172-174] Such vigorous attempts at restoration of blood flow have resulted from the concern about viability of the midgut if the portal vein is ligated. Unfortunately, any type of portal–systemic shunt may have the undesirable effect of causing hepatic encephalopathy because the direction of splanchnic venous flow with the shunt would mimic that in the patient with cirrhosis and hepatofugal flow in the obstructed portal vein. Ligation of the vein is compatible with survival, as Pachter et al,[173] Stone et al,[102] and Asensio[12] have emphasized. In the 1979 review of the literature on this subject by Pachter et al,[173] one of six survivors of ligation of the portal vein developed portal hypertension. The 1982 series by Stone et al[102] included 9 survivors among 18 patients who underwent ligation of the portal vein. In essence, ligation of the portal vein should be performed if an extensive injury is present and the patient is hypothermic, acidotic, and/or coagulopathic (damage control indicated). As previously noted, the surgeon must then be prepared to infuse significant amounts of fluids to reverse the transient peripheral hypovolemia secondary to splanchnic hypervolemia.[102]

To apply some perspective to the somewhat controversial area of injuries to the portal vein, a review of techniques for management is helpful. In the 1978 review by Graham et al[103] of 37 patients with injuries to the portal vein, 26 underwent lateral venorrhaphy, 5 had packing or clamping only, 4 had ligation (none of whom survived), 1 had an end-to-end anastomosis, and 1 had a portacaval shunt. In contrast, the aforementioned 1982 review by Stone et al[102] of 46 patients included 17 who had lateral venorrhaphy, 18 who had ligation (9 survived), 7 who had no repair, 3 who underwent an end-to-end anastomosis, and 1 who had a portacaval shunt.[102] Ivatury et al[175] reported on 14 patients with injuries to the portal vein in 1987, among whom exsanguination occurred in 3, venorrhaphy was performed in 10 (of whom 6 survived), and ligation was done in 1 (who survived). In 1995, Jurkovich et al[171] reported on 56 injuries to the portal vein with 33 patients undergoing primary repair (42% mortality), 1 undergoing complex repair (died), and 10 undergoing ligation (90% mortality). In 2009, Fraga et al[104] described primary suture repair in 15 patients with injury to the portal vein with an overall survival of 53%. Ten of these patients had stab wounds, and the survival rate was 60%.[104] An additional 11 patients died prior to definitive ligation and/or repair. In the seven series with greater than nine patients from 1978 to 2009, the mean survival rate was 50.5%[80,102-104,171,174,175] (Table 38-8).

Retrohepatic Vena Cava

The management of injuries to this vessel is described in Chapter 33. Newest approaches have included the following: (1) resuscitative balloon occlusion; (2) endovascular stent grafts for repair; (3) hybrid open and endovascular approaches; and (4) recognition of variability in length and diameter of suprarenal-to-suprahepatic caval segments as customized fenestrated endografts are developed.[176-179]

COMPLICATIONS

The complications of vascular repairs in the abdomen are much the same as those elsewhere in the body. They include postoperative thrombosis, dehiscence of a suture line, and infection.[180] Occlusion is not uncommon when small, vasoconstricted vessels, such as the superior mesenteric artery or renal artery, undergo lateral arteriorrhaphy. In such patients,

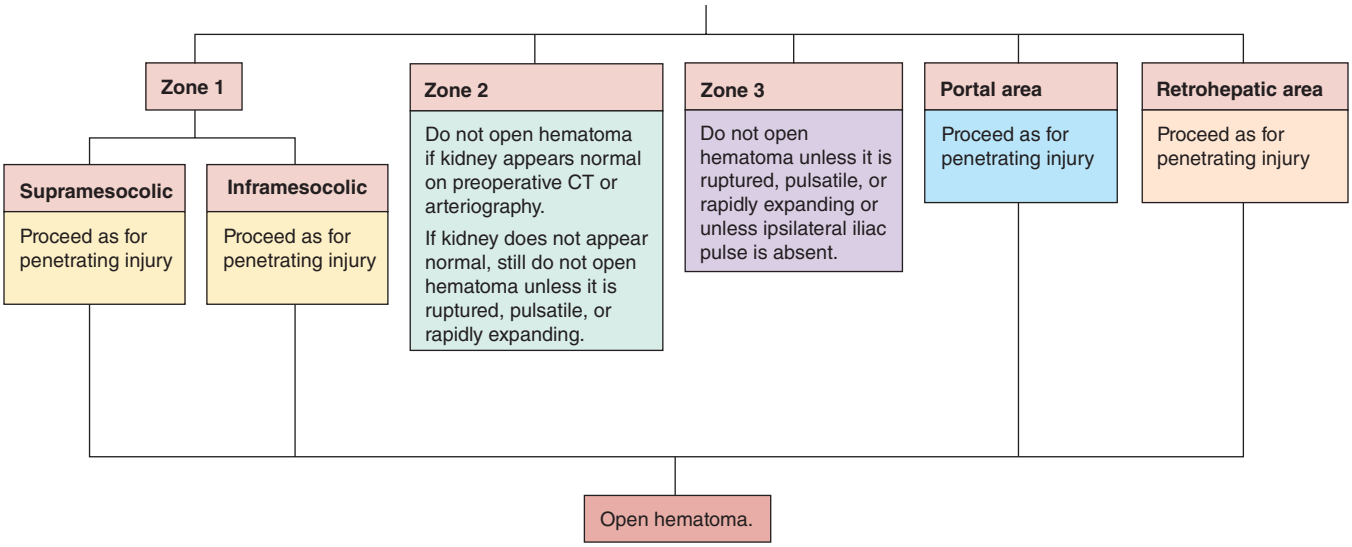

FIGURE 38-8 Blunt abdominal vascular injury algorithm. CT, computed tomography.

it may be valuable to perform a second-look operation within 12 to 24 hours after the patient's temperature, blood pressure, and coagulation abnormalities have returned to normal. When this is done, correction of an early vascular thrombosis may be successful.

Dehiscence of vascular suture lines in the abdomen has occurred in two locations in the authors' experience, and both have been previously discussed. First, a substitute vascular conduit inserted in the superior mesenteric artery near a pancreatic injury may be disrupted if a small pancreatic leak occurs in the postoperative period. For this reason, the proximal anastomosis of such a graft should be on the infrarenal abdominal aorta inferior to the transverse mesocolon and far away from the pancreas as previously noted. Second, the dehiscence of end-to-end anastomoses and graft-artery suture lines in the iliac arteries can be avoided by limiting the extent of repair if there is significant enteric or colonic contamination in the pelvis and considering an immediate or early femorofemoral bypass if the patient's limb is threatened, as described earlier.

Finally, a vascular complication unique to the abdomen is the postoperative development of vascular–enteric fistulas. This will occur most commonly in patients who have anterior aortic repairs, aortic interposition grafts, or grafts to the superior mesenteric artery from the aorta. Again, this problem can be avoided by proper coverage of suture lines on the aorta with retroperitoneal tissue or a viable omental pedicle and on the recipient vessel with mesentery. [112]

SUMMARY

Abdominal vessel injuries are most commonly seen in patients with penetrating wounds to the abdomen but occur after blunt abdominal trauma as well (Figs. 38-8 and 38-9). They

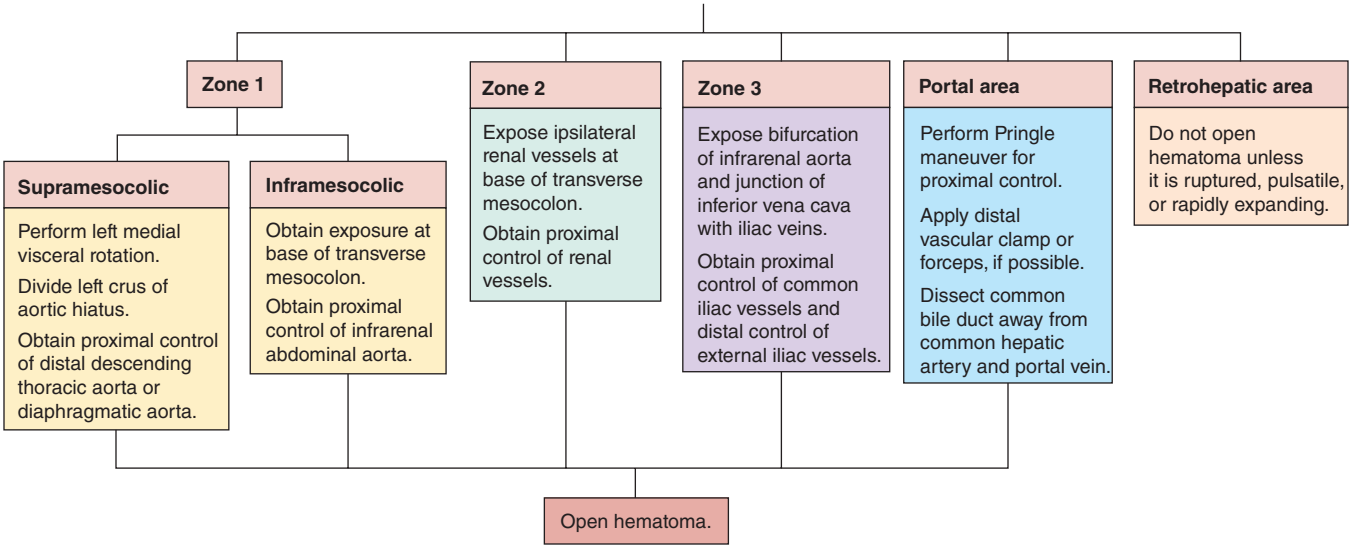

FIGURE 38-9 Penetrating abdominal vascular injury algorithm.

present either with a contained retroperitoneal, mesenteric, or portal hematoma; active hemorrhage; thrombosis; or a combination of these. When tamponade is present, proximal and distal vascular control should be obtained before opening the hematoma causing the tamponade. If active hemorrhage is present, direct compression of the bleeding vessels with a finger, hand, laparotomy pad, or sponge stick at the site of injury is necessary until proximal and distal vascular control can be obtained. Vascular repairs are generally performed with polypropylene sutures and can range from simple arteriorrhaphy or venorrhaphy to the insertion of substitute vascular conduits, much as in vascular injuries in the extremities. Also, in the occasional patient who presents with normal hemodynamics and angiographic evidence of a major vessel injury, thrombosis of a repair or other postoperative complication, or in a delayed fashion after an abdominal vessel injury, endovascular techniques have a role in management. Overall, if hemorrhage can be rapidly controlled and distal perfusion restored, many patients with major abdominal vessel injuries can be salvaged with the techniques described in this chapter.[73]

Endovascular Commentary to Chapter 38: Abdominal Vessels

Joseph J. DuBose

The authors do an outstanding job of outlining the diagnosis of these injuries as well as their open management. Where does endovascular management fit in the contemporary care of these injuries? This is an important question that is made all the more important by the rapidly emerging capabilities of endovascular technologies. In order to adequately provide guidance on the potential utility of these approaches, one must present both the potential promise and the paradox of endovascular therapies in the current era.

First, I will touch on the potential of endovascular management for select patients. In a variety of emerging studies using multi-institutional data, patients managed with endovascular modalities versus traditional open approaches for vascular injury at noncompressible locations (including abdominal and iliac vessels) have been shown to have improved outcomes. It is also clear that these modalities are being employed more aggressively in this regard based on these findings.[1-3] The technologies are commonly available to modern vascular surgeons, who have become ever more facile with their expedient employment for a variety of vascular pathologies, including trauma.

While these findings are promising, the results of these efforts must be considered in the context of the significant limitations of present endovascular capabilities for trauma management. In outlining these limitations, it must first be acknowledged that the aforementioned promising results have been noted almost exclusively among patients with a major arterial injury confined to the aorta, iliac arteries, and the pelvic vasculature.[4] Additionally, these results are largely achieved only at high-volume centers with the right combination of both trauma volume and vascular expertise. Accordingly, the results of these efforts must be considered in context and

are not fair to extrapolate to a wider variety of environments. In addition, what are the most significant limitations of endovascular approaches?

First, a stable patient is almost universally required for endovascular management. Advanced imaging capabilities must be employed, appropriate vascular access achieved, specialized technicians to assist with device selection called in, and the appropriate providers summoned. The latter, at present, typically consist of formally trained vascular surgeons or interventionalists who are not present when the unstable patient demanding emergent hemorrhage control arrives. The delays required in mustering these capabilities are neither practical nor appropriate in the care of an unstable patient.

Second, endovascular technologies are not well suited to the care of patients with multiple pressing injuries that demand urgent attention. Open exposure within the abdomen allows for the rapid intervention for a variety of potentially life-threatening injuries. A facile trauma surgeon can pack a liver and remove a spleen in relatively short order. Endovascular procedures are confined to the intravascular space alone and require focus on one portion of the arterial tree at a time. The use of these technologies simply limits the ability to rapidly address multiple injuries in the same fashion as can be achieved by open means.

Third, there remains a need to define the long-term durability of endovascular approaches. Although embolization of the pelvis or solid organs is now a mature practice that has demonstrated its worth, the endovascular repair of a major vascular injury with a stent graft is a newer capability comparatively. Although efforts are underway to obtain longitudinal data on endovascular repair of traumatic arterial injuries after treatment, the known durability of these devices remains a matter of needed examination. This is especially true when suggesting they replace the "tried and true" open repair modalities (interposition repair with native or synthetic conduits) available for use.

Even among stable patients, the urge to overtreat certain injuries must be avoided. Among more minor aortic abdominal injuries, for example, it has been shown that the majority of these injuries will heal without sequalae when managed nonoperatively.[5] The aggressive employment of endovascular stent grafts for these injuries may, therefore, introduce unnecessary risk for the patient.

There are, however, areas where endovascular potential is possibly clearer. The stable patient with a "hostile" or reoperative abdomen and a lesion amenable to the existing capabilities of endovascular technologies would seem an ideal candidate. So too might the delayed diagnosis of specific injuries such as a traumatic false or true aneurysm or an arteriovenous fistula. Many delayed pseudoaneurysms of larger arteries likely behave clinically in a fashion similar to pathologies familiar to vascular surgeons facile with endovascular treatment.

Moving forward, there may even be a potential future for the adoption of "hybrid" approaches in select patients. In this fashion, the traditional "open versus endovascular" considerations give way to an evolved consideration of these technologies as complementary in specific situations. Resuscitative endovascular balloon occlusion of the aorta (REBOA) represents one such "hybrid" facilitator. Although still a matter of active investigation, this technology has already demonstrated its potential in affording emergent proximal aortic control prior to entry into the abdomen to surgically address injuries using traditional approaches.[6] Theoretically, among more stable patients, hybrid partnerships between endovascular and open providers might afford proximal arterial control in a similar fashion at a variety of intra-abdominal locations of arterial injury. These hybrid techniques are already used commonly at several high-volume academic centers. Further study is required, however, to guide optimal patient selection and occlusion practices using this modality.

And so, endovascular capabilities do demonstrate significant potential for improving outcomes in select patients after abdominal vascular injury. In stable patients with appropriate capabilities and expertise present, they can be employed in staged or hybrid approaches to good effect. In order to optimally define these capabilities (and limitations), however, significant additional study is required.

Pelvis

Aussama Nassar • Lisa Knowlton • David A. Spain

KEY POINTS

- The anterior elements of the pelvis, including the pubic rami and pubic symphysis, only contribute to approximately 40% of pelvic stability.
- In the Tile classification of pelvic fractures, type A are stable, type B are vertically stable but rotationally unstable, and type C are vertically and rotationally unstable.
- In the Young-Burgess classification of pelvic fractures, the three types are anteroposterior compression (APC), lateral compression, and vertical shear.
- Pelvic binders are indicated for APC ("open book") fractures when first diagnosed, but not for lateral compression fractures.
- Early external fixation stabilizes the fractured elements, decreases the pelvic volume, and allows clot to form.
- For the patient who is exsanguinating from a closed pelvic fracture, embolization of the bilateral internal iliac arteries is considered to be the "damage control" procedure of choice.
- In the technique of preperitoneal pelvic packing for hemorrhage, three laparotomy pads are placed on either side of the bladder in the retroperitoneum.
- APC III, most lateral compression II, and vertical shear pelvic fractures typically require posterior stabilization by internal fixation.
- The mean Injury Severity Score (ISS) for patients with pelvic fractures is 18, reflecting the significant number of patients with associated injuries to the brain, thorax, abdomen, and long bones.
- Control of bleeding in open pelvic fractures includes packing through the laceration, application of a pelvic binder, angiographic embolization, and definitive bony fixation.

INTRODUCTION

Pelvic ring fractures (PRFs) are frequent, particularly after blunt trauma (9% of all blunt trauma patients), and range from clinically insignificant minor pelvic fractures to life-threatening injuries that can lead to exsanguination (0.5% of all blunt trauma patients). The overall mortality rate of patients with PRFs is approximately 8%.[1] Anterior-posterior compression and vertical shear injury mechanisms are associated with a higher incidence of pelvic vascular injury and hemorrhage. Pelvic fractures are one of the insidious, unrecognized sources of shock and death in polytrauma patients with other distracting injuries. This is largely due to the fact that an actively bleeding pelvis is not usually appreciated on clinical exam or focused abdominal sonography for trauma (FAST) and occasionally does not present with active extravasation of contrast on computed tomography (CT) of the pelvis. These complicating factors make the management of an exsanguinating pelvic fracture challenging, with lack of consensus on a single best management approach. The recent evolution of rapid pelvic stabilization by pelvic binding or external fixation during the trauma primary survey, combined with a selective approach to preperitoneal pelvic packing and angiographic embolization, has significantly decreased the mortality rates of devastating PRF. Resuscitative endovascular balloon occlusion of the aorta (REBOA) has been introduced as a promising hemorrhage control modality in the immediate management of exsanguinating PRF, which will be discussed later in this chapter. A multidisciplinary coordinated approach is crucial in managing patients with PRF, as there is no single treatment modality that has been shown to be the gold standard.

PELVIC ANATOMY

The pelvic ring comprises the sacrum and the two innominate bones, all attached with strong ligaments. The innominate bones join the sacrum at the sacroiliac joints and each other

anteriorly at the pubic symphysis. The anterior and posterior sacroiliac ligaments include shorter and longer elements that extend over the sacrum and to the iliac crests, and provide vertical stability across the sacroiliac joints. The pelvic floor is bridged by the sacrospinous and sacrotuberous ligaments that connect the sacrum to the ischial spine and the ischial tuberosity, respectively. The anterior elements, including the pubic rami and pubic symphysis, contribute to approximately 40% of pelvic stability, but the posterior elements are more important, as shown by biomechanical studies.[2]

The internal iliac (hypogastric) arteries provide blood supply to the organs, bones, and soft tissues of the pelvis. The anterior division includes the inferior gluteal, obturator, inferior vesicular, middle rectal, and internal pudendal arteries. The posterior division includes the iliolumbar, lateral sacral, and superior gluteal arteries. The largest branch is the superior gluteal artery, which is the most commonly injured major arterial branch after pelvic fractures. Pelvic veins run parallel to the arteries and form an extensive plexus that drains into the internal iliac veins. The sacral venous plexus is adhered to the anterior surface of the sacrum and is often shredded after major pelvic fractures. Thus, venous bleeding or bleeding from bony fragments accounts for approximately 85%, with the remainder stemming from an arterial source.[3]

The sciatic nerve is formed by the nerve roots of L4 to S3 and exits the pelvis under the piriformis muscle. The anterior roots of L4 and L5 cross the sacroiliac joints and can be injured in sacral ala fractures or sacroiliac joint dislocations.

All pelvic organs are at risk of injury following severe PRF, with the bladder and urethra being the most frequently injured. The extraperitoneal rectum and vagina are also at risk of injury from the sharp pelvic bone fragments and convert the type of fracture to an open pelvic fracture.

CLASSIFICATION OF PELVIC FRACTURES

Despite multiple classification systems described, the two most commonly used are those described by Tile[3] and Young and Burgess.[4,5]

The Tile classification categorizes pelvic fractures in three groups based on stability, as evaluated primarily by clinical examination and plain radiographs (Table 39-1):

- Type A fractures are stable, as the posterior ligaments are intact. These fractures include transverse sacral, iliac wing, pubic rami, pure acetabular, and chip and avulsion fractures.
- Type B fractures are caused by internal and external rotational forces and are "partially" stable (vertically stable but rotationally unstable). They include open-book and bucket-handle fractures (Figs. 39-1 to 39-3).
- Type C fractures are vertically and rotationally unstable, as they involve a complete disruption of the sacroiliac complex (Fig. 39-4).

The Young-Burgess classification divides pelvic fractures according to the vector of the force applied into anteroposterior compression (APC), lateral compression (LC), and vertical shear fractures (Table 39-2):

- APC injuries are produced by forces applied in the sagittal plane, as is usually the case with motor vehicle crashes. APC-I injuries may result in a small widening of the pubic symphysis (<2.5 cm), but the posterior ligaments are intact. APC-II injuries include tearing of the anterior sacroiliac ligaments as well as the sacrospinous and sacrotuberous ligaments, but the posterior sacroiliac ligaments are intact. The pubic symphysis diastasis may be more than 2.5 cm. Rotational instability is usually present and hemorrhage more likely. APC-III injuries are caused by high-energy transfer, and the posterior sacroiliac ligaments are disrupted, causing full instability of the hemipelvis with a high likelihood of bleeding, nerve damage, and organ injuries.
- LC injuries are produced from lateral impacts across the horizontal plane, also common with motor vehicle crashes. LC-I injuries include transverse fractures of the anterior ring or impacted sacral fractures, and are typically stable. LC-II injuries are caused by higher-energy forces that produce tearing of the posterior sacroiliac ligament and displacement of the sacroiliac joint or an oblique fracture of the ilium, the superior part of which remains attached to the sacrum, while the inferior is mobile (crescent fracture). Depending on the force applied, this fracture can be stable or unstable. LC-III injuries are severely unstable fractures, as the lateral force continues to compress and rotate the hemipelvis to the point of complete destruction of the sacroiliac joints, as well as the sacrospinous and sacrotuberous ligaments. Neurovascular and organ injuries are common.
- Vertical shear injuries are typically produced by a fall from a height and involve anterior (pubic rami, pubic symphysis) and posterior (sacroiliac complex) fractures. Typically, they are unstable.
- Combinations of the above types produce a variety of fracture patterns, most commonly involving LC and vertical shear injuries. Nearly one-third of PRF patients have combination injuries.

DIAGNOSIS

Physical examination occasionally establishes the diagnosis for a PRF. Before the availability of sophisticated imaging, the optimal bedside physical exam maneuver was by the examiner placing his or her hands on the anterior iliac spines of the patient, then exerting gentle compression toward the midline, followed by a mild divergent movement of the hands toward the outside; these combined maneuvers would assess for pelvic instability. This was done by an experienced physician who would interrupt the motion immediately if instability or a fracture was felt so as not to produce pain and aggravate bleeding. Careful, detailed inspection of the perineum and skin overlying the pelvic bones is critical to diagnose lacerations or hematomas that might aid in the diagnosis of severe PRF. In addition to assessing the perineum, there must be a

TABLE 39-1: Tile Classification of Pelvic Fractures

Type			Characteristics	Hemipelvis displacement	Stability
Type A, posterior arch intact	A1, pelvic ring fracture (avulsion)	A1.1	Anterior iliac spine avulsion	None	Stable
		A1.2	Iliac crest avulsion		
		A1.3	Ischial tuberosity avulsion		
	A2, pelvic ring fracture (direct blow)	A2.1	Iliac wing fracture	None	Stable
		A2.2	Unilateral pubic rami fracture		
		A2.3	Bilateral pubic rami fracture		
	A3, transverse sacral fracture	A3.1	Sacrococcygeal dislocation	None	Stable
		A3.2	Nondisplaced sacral fracture		
		A3.3	Displaced sacral fracture		
Type B, incomplete posterior arch disruption	B1, anteroposterior (AP) compression	B1.1	Pubic diastasis, anterior sacroiliac (SI) joint disruption	External rotation	Rotationally unstable, vertically stable
		B1.2	Pubic diastasis, sacral fracture		
	B2, lateral compression	B2.1	Anterior sacral buckle fracture	Internal rotation	Rotationally unstable, vertically stable
		B2.2	Partial SI joint fracture/subluxation		
		B2.3	Incomplete posterior iliac fracture		
	B3.1, AP compression	B3.1	Bilateral pubic diastasis, bilateral posterior SI joint disruption	External rotation	Rotationally unstable, vertically stable

thorough exam of the genitalia for any evidence of urethral injury, especially in males. A careful vaginal exam should be performed in women to assess for possible lacerations. In a study of 66 patients with a Glasgow Coma Scale score over 12, a focused physical examination protocol, including posterior palpation of the sacrum and sacroiliac joint, anteroposterior and lateral iliac wing compression, active hip range of motion, and a digital rectal examination, resulted in 98% sensitivity and 94% specificity for the detection of posterior pelvic fractures.[6]

The plain anteroposterior pelvic film is an important adjunct to the primary survey. Some studies indicate that pelvic films are unnecessary in patients with a negative clinical exam for PRF. In a review of 743 blunt trauma patients with no pain or other clinical findings of PRF, only three patients (0.4%) had a pelvic fracture.[7] In all cases it was a single, nondisplaced pubic ramus fracture that required no treatment. In another study of 686 blunt trauma patients, 311 received a pelvic film, which carried a false-negative rate of 32%.[8] Although plain films of the pelvis have their limitations and patients often undergo more detailed evaluation by CT, they have a useful role in screening for pelvic disruption early in the assessment of a trauma patient.[9] This is of particular importance since bleeding from a pelvic source is often missed on FAST. In the hemodynamically stable patient with a negative FAST but abdominal or pelvic tenderness on exam, this film may be omitted because an abdominopelvic CT will be performed.

CT scan with reconstructions (and recently three-dimensional reconstructions) is routinely performed to accurately characterize pelvic fractures and associated pelvic hematomas, as well as identify associated pelvic organ injuries (Fig. 39-5). Intravenous contrast is routinely administered unless there is a contraindication. Oral and rectal contrast are not necessary for blunt trauma.

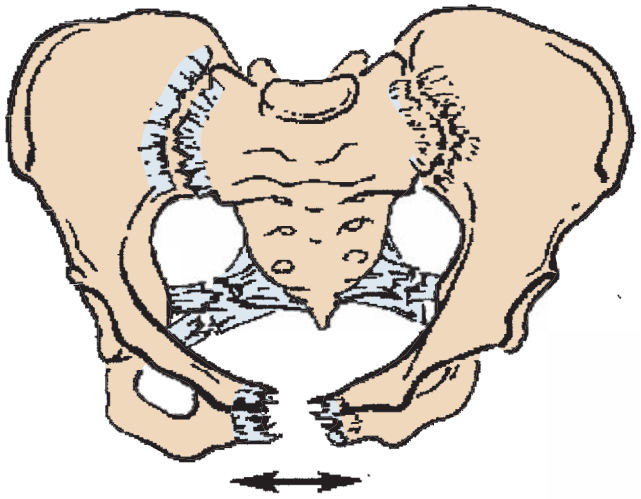

FIGURE 39-1 Type B1 open-book injury. Diastasis of the pubic symphysis and fracture of the superior or inferior pubic rami may occur.

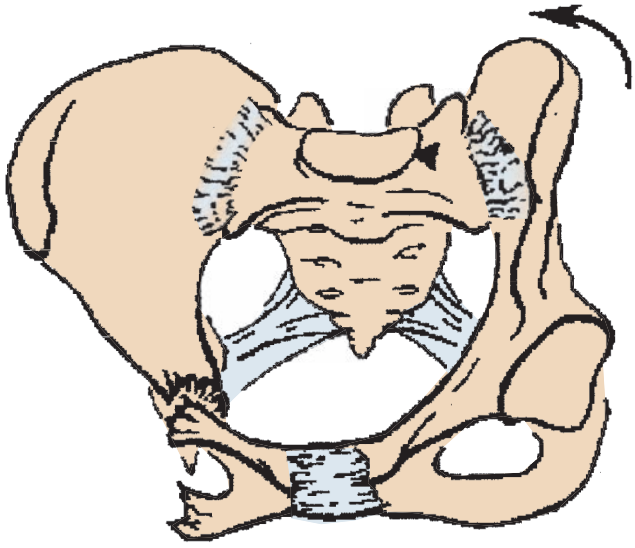

FIGURE 39-3 Type B3 lateral compression (contralateral) or bucket-handle injury. Note anterior rami fracture with contralateral posterior sacroiliac injury.

Magnetic resonance imaging (MRI) does not offer a distinct advantage over CT scan and is only rarely considered if radiation exposure becomes an issue, as it is with nonemergent cases of pediatric patients, pregnant patients, or repeat imaging. On occasion, the ligaments need to be evaluated in more detail, and this can be done with higher accuracy by magnetic resonance. It is important to remember, however, that MRI has limited usefulness in the acute diagnosis of pelvic trauma, as trauma patients would be at undue risk for hemorrhagic complications and shock during their evaluation in the MRI suite.

The FAST exam has become a routine part of the primary survey and initial assessment of trauma patients. FAST exam is only able to confirm the presence of intraperitoneal fluid with limited assessment of the retroperitoneal space and inability to qualify the nature of the intraperitoneal fluid. In PRF, a number of FAST exam findings can be useful: (1) the absence of intraperitoneal fluid in a hemodynamically unstable patient should raise the possibility of a major retroperitoneal hemorrhage from PRF (if no other obvious sites of bleeding and no nonhemorrhagic reasons for shock); (2) a distorted bladder contour indicates the presence of a compressing pelvic hematoma; and (3) the presence of intraperitoneal fluid indicates that intraperitoneal organ injury must be excluded by additional diagnostic methods or laparotomy. However, there can be false-negative or equivocal

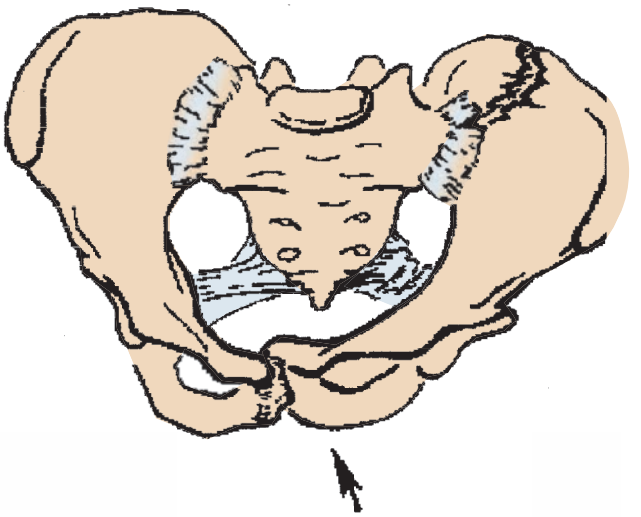

FIGURE 39-2 Type B2 lateral compression (ipsilateral) injury. Note overriding of the left hemipelvis and crush injury to ipsilateral sacrum and ipsilateral iliac fracture.

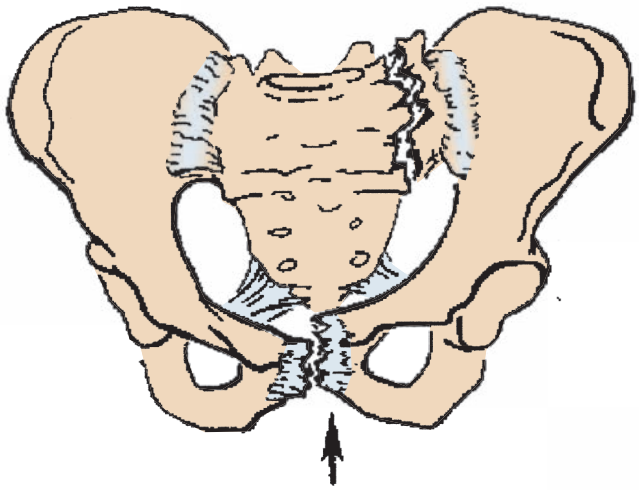

FIGURE 39-4 Type C1 unilateral injury with vertical instability. Involves symphysis disruption or rami fracture with ipsilateral sacroiliac joint or sacral injury.

TABLE 39-2: The Young-Burgess Classification of Pelvic Fractures

Mechanism and type	Characteristics	Hemipelvis displacement	Stability
Anteroposterior (AP) compression, type I	Pubic diastasis <2.5 cm	External rotation	Stable
AP compression, type II	Pubic diastasis >2.5 cm, anterior sacroiliac (SI) joint disruption	External rotation	Rotationally unstable, vertically stable
AP compression, type III	Type II plus posterior SI joint disruption	External rotation	Rotationally unstable, vertically unstable
Lateral compression, type I	Ipsilateral sacral buckle fractures, ipsilateral horizontal pubic rami fractures (or disruption of symphysis with overlapping pubic bones)	Internal rotation	Stable
Lateral compression, type II	Type I plus ipsilateral iliac wing fracture or posterior SI joint disruption	Internal rotation	Rotationally unstable, vertically stable
Vertical shear	Vertical pubic rami fractures, SI joint disruption ± adjacent fractures	Vertical (cranial)	Rotationally unstable, vertically unstable

FAST exams with PRF. Thus, although diagnostic peritoneal lavage has nearly completely disappeared from algorithms in most modern trauma centers, diagnostic peritoneal aspiration (DPA) does have a role on rare occasions with hemodynamically unstable PRF patients and negative or equivocal FAST. In addition, some use the aspiration portion of it only (DPA) to further characterize the nature of the free peritoneal fluid (blood, succus, or ascites).[10] In patients with PRF, the procedure should be performed above the umbilicus to avoid pelvic hematoma.

MANAGEMENT OF BLEEDING PELVIC RING FRACTURES

The management approach to acutely bleeding PRF focuses on reducing pelvic volume to secondarily reduce the amount of bleeding, stabilize the fractured segments, and prevent clot dislodgement. Hemodynamically unstable patients with suspected PRF should be assumed to be bleeding from a pelvic fracture source until proven otherwise. Patients should be resuscitated as per Advanced Trauma Life Support (ATLS) protocol. The concept of permissive hypotension (ie, accepting a lower than normal blood pressure during the early phases of resuscitation in order to prevent ongoing bleeding and other known sequelae of overzealous resuscitation) has been adequately established for penetrating trauma; however, it is not universally accepted for blunt trauma despite the encouraging reports.[11,12] The coexistence of neurologic injuries, which have been shown to produce worse outcomes in the presence of hypotension, is the main deterrent to allow a low blood pressure in a hemodynamically unstable blunt trauma patient. In a recent prospective randomized study from 19 emergency medical services of the Research Outcomes Consortium, 192 hypotensive trauma patients were assigned in the prehospital setting to receive crystalloid resuscitation to maintain a blood pressure above 70 mm Hg (controlled resuscitation group) or above 110 mm Hg (standard resuscitation group). There was no difference in most outcomes, but patients with blunt trauma in the controlled resuscitation group had a lower 24-hour mortality (3%) compared to the standard resuscitation group patients (18%). Although we still need phase III studies to evaluate the different resuscitation regimens, this study offers some evidence to suggest that at least there is no harm from limiting the initial crystalloid resuscitation and it may arguably be beneficial in hypotensive trauma patients regardless of the type of injury.[13] We advocate the principles of permissive hypotension (assuming no concern for traumatic brain injury), even in blunt trauma, with limited use of crystalloids and early use of blood products for resuscitation. There is no proven gold standard intervention for managing bleeding pelvic fractures. A multimodality approach with a combination of pelvic binders, interventional radiology, and operative management should be considered.

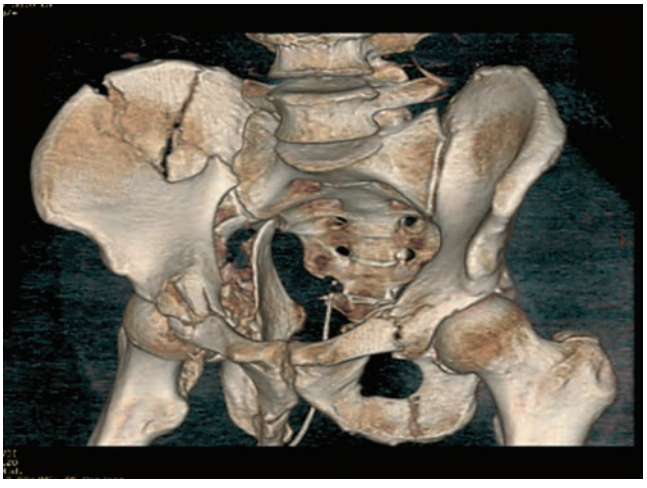

FIGURE 39-5 Three-dimensional computed tomographic reconstructions provide a realistic assessment of the anterior and posterior elements in pelvic fractures.

FIGURE 39-6 Pelvic binder.

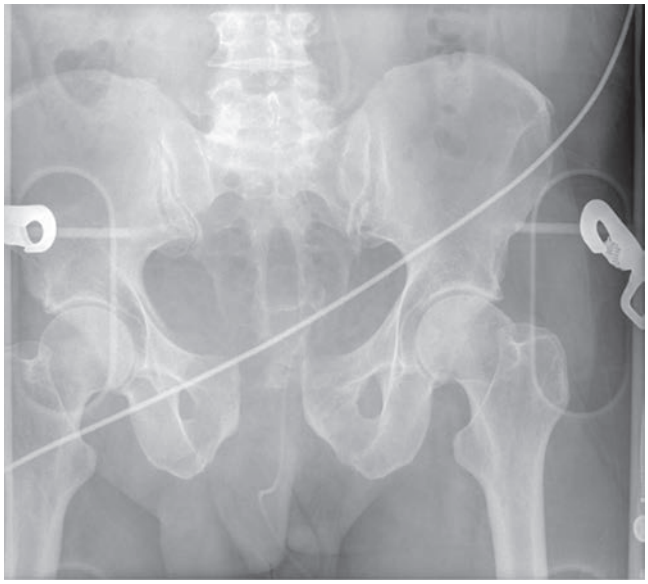
Pelvic Binders

Pelvic binders have been traditionally used as the primary temporizing measure in bleeding control of PRF both in the prehospital setting and in the trauma bay.[14-17] A binder is primarily indicated to stabilize the pelvis and reduce the volume after a pelvic x-ray confirms an open-book fracture. The thought behind the wrap is to decrease the space of the unstable disrupted pelvis, which can contain several liters of blood. It is our practice to follow the pelvic binder with a second pelvic x-ray to confirm reduction of an open-book fracture. Pelvic binders also act by stabilizing bony fragments and helping to slow bleeding (Fig. 39-6). In contrast, binding a significant LC mechanism pelvic fracture can have the opposite effect and can increase bleeding (Fig. 39-7). Under these principles, simple stabilization by a pelvic device is desirable in all unstable fractures, but significant compression should only be used in the open-book variety.

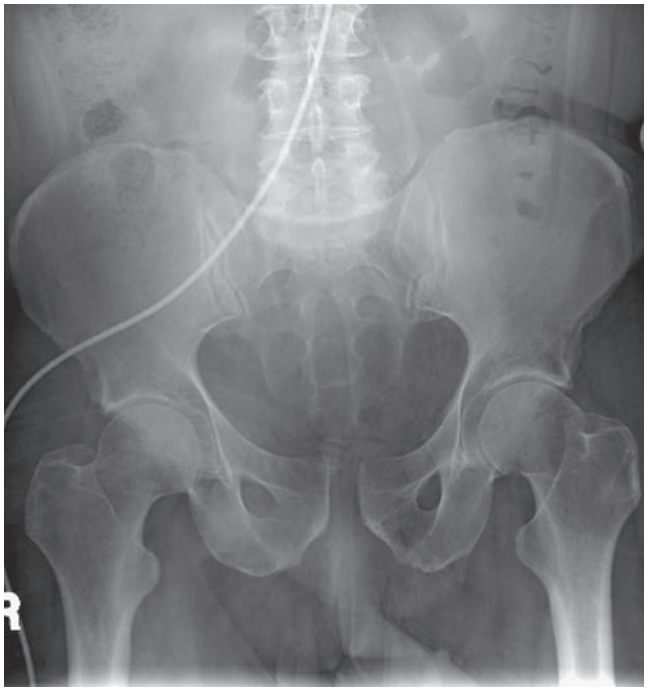
FIGURE 39-7 A fracture that would be inappropriate for a tight pelvic binder. Displacement with forceful lateral compression by the binder could be exacerbated and result in vascular injury.

A bed sheet is frequently used as an immediately available and inexpensive way to wrap the pelvis.[17] The edges of the sheet are tied together around a rod, which can be turned to tighten the sheet and apply the desired degree of compression (Fig. 39-8).

Pelvic binders have been commercialized by different companies along the same principles with only a few differences



A



B

FIGURE 39-8 A simple sheet wrapped around the pelvis produces inexpensive and adequate reduction of a pelvic fracture. A significant pubic diastasis, as shown in the first image (**A**), is reduced by the sheet, as shown in the following image (**B**).

among them. Typically, a binder consists of a wide belt with a Velcro that attaches the two ends of the binder (which can be cut to customize its length according to the patient's body habitus). On the belt, there is a "buckle pulley" mechanism. By pulling the strings, the binder tightens and compression increases. The device is radiolucent, which allows radiographic imaging with no artifacts. The evidence on the effectiveness of pelvic binders is poor.[14,15] There are three major pitfalls related to its use after x-ray confirmation of an open-book pelvic fracture. First, an inappropriately high placement of the binder can lead to excessive abdominal pressure and minimal pelvic stabilization. It is not uncommon to place the binder too high. Correctly, the binder must be centered around the greater trochanters and not over the iliac crests. Usually, it needs to be gently passed under the patient's back and then pulled slightly lower and over the buttocks for proper placement. Second, indiscriminate pulling of the strings can lead to greater compression than necessary. The initial step should involve only moderate tightening if a pelvic x-ray has not yet been performed. The pulley mechanism attached on the binder makes tightening very easy, and with minimal force, an enthusiastic operator can squeeze the binder tight, producing on occasion more harm than good. Third, the binder may compromise the viability of skin, subcutaneous tissue, or even muscle if left in place for too long. A general guideline of a maximum 24-hour placement exists, but obviously even this may be too long after a tight application of the binder.[16] The health care providers should understand that the binder is only an imperfect and temporary tool for bleeding control. Definitive pelvic reduction and cessation of hemorrhage should be planned immediately in order to minimize the need for a binder.

The military antishock trousers (MAST) garment became popular in the 1980s after initial reports of improved survival in patients with multiple injuries. However, in 1989, a definitive prospective randomized study found it to be associated with increased mortality, mostly related to respiratory compromise and compartment syndrome due to its interference with blood supply.[18] MAST was for the most part abandoned, although some emergency medical systems still use it on patients with pelvic or lower extremity fractures. *Based on the data, use of MAST should be abandoned.*

External Fixation

External fixation has been popularized as a rapid means of controlling bleeding. In a few institutions, this can be accomplished in the emergency department, but in most centers, the patients are transferred in the operating room. A number of clamps and devices have been used to provide external fixation. The C-clamp was designed for easy placement in the emergency department in the presence of a posterior pelvic fracture.[19] As opposed to other fixators, it is easy to assemble and apply. Its crossbar rotates around the fixation pins, which are anchored in the cancellous bone in both acetabula. The rotation of the clamp allows other procedures in the abdomen or pelvis to be offered without difficulty. The pins can be placed more anteriorly or posteriorly according to the location of the pelvic fracture and the need to reduce them. It is clearly a temporary method, which needs to be replaced later with either a proper pelvic frame or internal fixation. The C-clamp has been used more frequently in European than American trauma centers, which typically prefer a frame placed in the operating room.

Early external fixation stabilizes the fractured elements, decreases the pelvic volume, and allows clot to form. A variety of external fixators exist. The early systems used small pins and heavy bars, whereas the newer systems are more compact, are easy to adjust, and have larger pins. The standard placement of pins is in the superior iliac crest above the superior anterior iliac spine. Lower placement of the pins is also acceptable and can improve the access to the abdominal cavity. In certain designs, more than one pin is placed on each side. Pins can be placed by an open or percutaneous technique. All single-bar systems require two pins in each hemipelvis, whereas the frames require three pins on each side, except the Pittsburgh system, which requires two clusters of two pins in each hemipelvis. In most cases of a true unstable pelvis, external fixators remain a temporary device, which bridges the period to definitive internal fixation. In the supine position, external fixation provides adequate stability. In the standing position, the vertical load is usually greater than the capacity of the external fixator to resist these forces. Dislocation of fractured elements can happen, particularly at the sacroiliac complex.[20]

After placement of the frame, reduction of the pelvic fracture is done by applying opposite forces to the ones that created the fracture. Open-book fractures are corrected by internal rotation of the pins, whereas LC fractures are reduced by external rotation. Vertical shear fractures require skeletal traction by placement of a femoral pin, and are the ones least likely to be adequately reduced and stabilized by external fixation.[21]

If not converted to internal fixation, external fixators usually stay for 6 to 12 weeks. The most common complication is infection at the pin sites, ranging from mild to severe. Appropriate sterile technique during pin placement and proper care of the pin sites are essential to avoid infection. If the pins become infected or loose, they must be removed and replaced. Other complications are typically associated with placement and include injury to the lateral femoral cutaneous nerve or other neurovascular structures.

In general, it seems that external fixation should be considered in two stages, an early resuscitative and a later definitive stage. In the early stage, the fixator is placed to stabilize the fracture and help control the bleeding. At a later stage, a decision must be made about the long-term effectiveness of the external frame versus the need to convert to internal fixation. LC fractures are likely to respond to external fixation as the only method, if reduction is satisfactory. Vertical shear fractures are unlikely to be managed without definitive internal fixation.[22] Each patient must be carefully assessed to balance the therapeutic choices of fixing the fracture while maintaining hemodynamic stability and inflicting the

minimum physiologic insult during the initial critical hours after trauma.

Angiographic Embolization

PRF producing hemodynamic instability is one of the most common indications for angiographic embolization. Historically, surgical ligation of the internal iliac arteries was performed to control bleeding associated with pelvic fractures. This technique has proven to be ineffective given the rich collateral blood supply to the pelvis.[23] The ability to control the bleeding by minimally invasive techniques and without the need for an operation, which is routinely unsatisfactory, is very appealing. The appeal is hampered, however, by the unavailability of interventional radiology teams around the clock, the presence of minimal contrast extravasation on some CT scans, the poor monitoring available in an angiography suite, and the long time spent on the angiography table. All these reasons have been mitigated in modern trauma centers.

Interventional radiology teams are now readily available on short notice in most Level I trauma centers. Monitoring and resuscitation in the angiography suite should be no different in a Level I trauma center than it is in the operating room. High-rate fluid infusion devices, noninvasive hemodynamic monitoring, mechanical ventilatory support, arterial blood gas assessments, blood transfusions, and aggressive resuscitation efforts should take place during angiography.

The first challenge for the trauma and interventional radiology teams is to decide if the patient would benefit from angiographic embolization. Active arterial contrast extravasation (blush) on angiography and the presence of pelvic hematoma in a hemodynamically abnormal patient with PRF are accepted indications for embolization. CT scan has a sensitivity of 60% to 90% and a specificity of 92% to 100% in predicting the need for angioembolization. Unfortunately, approximately one-fourth of the angiographies performed for PRF find no direct or indirect evidence of ongoing bleeding (blush) on angiography.[24] There are no controlled studies in the present literature, however, and the precise indications are unknown. In 97 patients with pelvic fractures retrospectively reviewed, no factors predicted a positive angiogram with sufficient likelihood.[22] Mechanism of trauma, injury severity, hemodynamic presentation, and associated injuries were similar between patients with and without radiographic evidence of pelvic bleeding. In a later prospective study by the same group, 65 patients with pelvic fractures were included in the study total of 100 consecutive patients evaluated by angiography for bleeding.[25] Three independent predictors of bleeding were identified: age older than 55 years, absence of long-bone fractures (indicating that the pelvis was the main source for bleeding), and emergent angiography (indicating that semi-acute interventions had a lower likelihood of identifying bleeding). The predictive effect of age was confirmed by another prospective observational study.[26] Approximately 94% of patients older than 60 years of age had a positive angiogram, as opposed to 52% of younger patients. The authors recommended that angiographic embolization be offered liberally to pelvic fracture patients over 60 years old.

Pelvic fracture pattern is considered a major predictor of bleeding. Traditionally, three types of PRF are considered to be associated with hemorrhage: pubic symphysis diastasis of more than 2.5 cm, bilateral superior/inferior pubic rami fractures (butterfly), and posterior fractures (especially of the vertical shear variety).[27] There is evidence, however, that even anterior fractures can produce bleeding,[24] particularly in older patients or those receiving anticoagulants. The presence of contrast extravasation on pelvic CT scan has also been widely used as a predictor of a positive angiogram.[28,29] It is suggested that the sensitivity and specificity of a "contrast blush" on CT to identify bleeding that requires embolization are 84% and 85%, respectively, with an overall accuracy of 90%.[29] Our experience has been that the new-generation CT scanners are highly sensitive and—in combination with precise intravenous (IV) contrast infusion protocols—may pick up small bleeds that are potentially self-limited without further intervention. Therefore, the mere presence of contrast extravasation on CT is not an immediate indication for angiography in our institution. We consider contrast extravasation a crucial element of the constellation of symptoms, signs, and findings of PRF and consider it in the context of the entire clinical picture. A patient who is hemodynamically labile and has a contrast blush is emergently transferred to the angiography suite. A patient with a contrast blush, who is hemodynamically stable and has a small pelvic hematoma, does not usually receive a preemptive angiogram but rather is placed under close observation. In a study of 296 patients with pelvic fractures, 40% were found to have extravasation on CT, but only half eventually required some form of pelvic hemorrhage control.[30] Similarly, the size of pelvic hematoma cannot be used as an isolated indication for angiography.[31]

Interventional radiologists typically seek to identify the precise site of bleeding and control it with selective embolization via coils. This requires subselective intubation of internal iliac artery branches, time, and larger doses of IV contrast. For true trauma emergencies, the interventional radiologist should be in a different mindset. In alignment with surgical damage control principles, damage control angiography should be offered. The procedure should be rapid, effective, and temporary. Bilateral internal iliac artery embolization embraces these principles. The interventional radiologist does not consume time maneuvering small catheters into small arterial branches. The bleeding is controlled by truncating all the branches of the internal iliac arteries using a temporary agent, such as gelatin sponge particles (Fig. 39-9). There are at least three reasons for performing bilateral internal iliac artery embolization: (1) At the time of embolization, the patient is often in shock and profoundly vasoconstricted. This prevents IV contrast extravasation during angiography and offers a misleading impression of bleeding control. Once the patient is resuscitated and vasoconstriction is reversed, bleeding may ensue. Blockage of all the branches of the internal iliac arteries prevents this problem. (2) The pelvic vascular network is so extensive that a bleeder may be fed from the contralateral

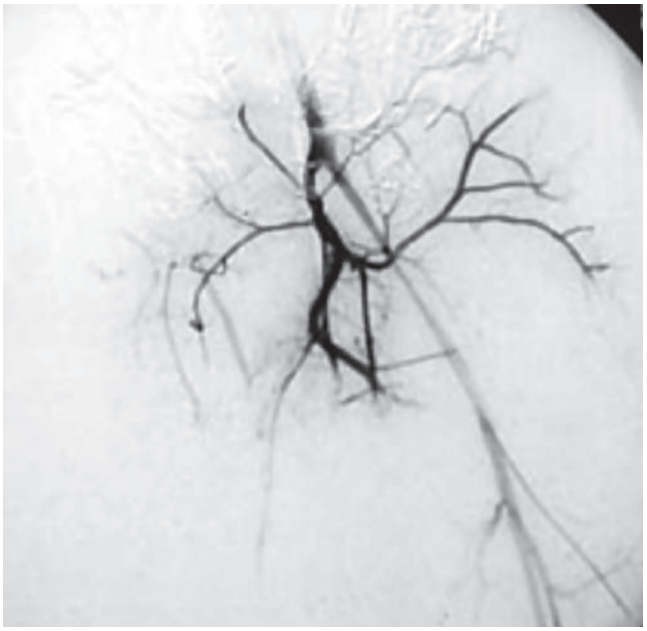


FIGURE 39-9 Truncation of all the branches of the internal iliac artery after injection of gelatin particles.

side. Embolizing only the unilateral internal iliac artery may not offer effective bleeding control (Fig. 39-10). (3) Some bleeders are right in the center, and it is difficult to discern if they are supplied by the right or the left arterial system.

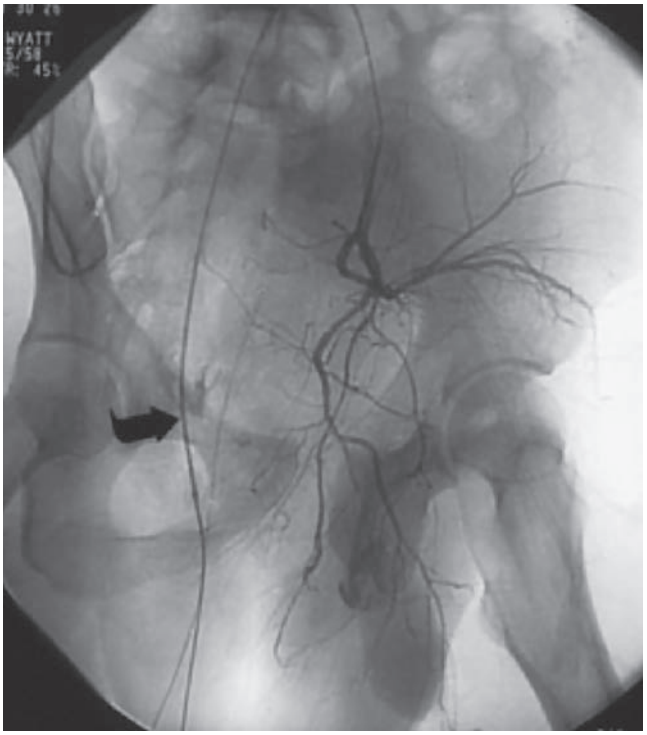

FIGURE 39-10 A right pelvic bleed is fed via the extensive pelvic network through the left arterial circulation. In such cases, bilateral embolization may be appropriate.

FIGURE 39-11 Midline bleeds can be hard to attribute to the left or the right circulation. Bilateral embolization may be appropriate.

Embolizing both sides is the more effective way to control the bleeding (Fig. 39-11).

The safety of bilateral internal iliac artery embolization has been shown in a study of 30 consecutive patients who received the procedure with no major complications.[32] It seems that the extensive vascular supply of the pelvis ensures survival of pelvic tissues and organs during the few days of Gelfoam embolization and until the arteries recanalize (Fig. 39-12). Gelfoam pledgets are usually cut to a size not smaller than 2 mm to prevent migration to smaller vessels and allow baseline collateral circulation. Despite isolated reports of serious complications with bilateral embolization,[33,34] such as colon necrosis, perineal wound sepsis, or avascular necrosis of the femoral head, our experience over the past 15 years has been very encouraging and without any significant complications. In a case-matched study of similar male pelvic fracture patients with and without bilateral iliac artery embolization, the incidence of sexual dysfunction 1 to 2 years after the injury was high but not different between the two groups.[35] Although major pelvic fractures affected sexual function, the addition of temporary embolization of both internal iliac arteries did not worsen the outcome. The authors assumed that, if this delicate function was not affected by embolization,

FIGURE 39-12 Heavy bilateral internal iliac artery embolization with near complete (but temporary) interruption of the pelvic circulation. The patient did well.

it was unlikely that any other pelvic organ would suffer major long-term consequences.

Failure of embolization occurs in approximately 15% of patients and is typically associated with coagulopathy.[36,37] In such patients, the thrombogenic potential of the injected gelatin material may not be fully realized and vessels may not be effectively blocked, showing near-full recanalization within only hours of seemingly effective initial embolization. Superselective embolization is associated with a higher risk of rebleeding. Patients who continue to require blood transfusions within 72 hours after embolization should be taken back to the angiography suite, because repeat embolization is typically successful.[24,38]

Resuscitative Endovascular Balloon Occlusion of the Aorta (REBOA) (See Chapter 13)

Central temporary aortic occlusion has been described for temporary control of exsanguinating truncal/pelvic bleeding.[39-42] This is done either via extraluminal aortic thoracic compression by resuscitative thoracotomy and aortic clamping or through a minimally invasive approach using a percutaneous endovascular balloon inserted through the femoral artery. The balloon is inflated in one of two zones: zone 1: descending aorta above the celiac artery; or zone 3: abdominal aorta between the lowest renal artery and aortic bifurcation. Zone 2 (abdominal aorta between the celiac artery and lowest renal artery) inflation is not used. The zone 1 surface landmark is the xiphoid process. The zone 3 surface landmark is the umbilicus. For exsanguinating pelvic injuries, the balloon is usually inflated in zone 3. There is no strong prospective evidence to support its efficacy. Retrospective studies have shown it to be effective in managing severe hemorrhagic shock from an intra-abdominal or pelvic source with a low complication rate, with the main barrier being expertise. The main complications are vascular events, acute renal failure, and rhabdomyolysis.

Preperitoneal Pelvic Packing

Packing is an important part of damage control operations for severe abdominal injuries. Its utility in the setting of severe pelvic fractures became apparent when European trauma surgeons Ertel et al[43] from Switzerland showed excellent bleeding control after major pelvic fractures using a combination of packing and external fixation by C-clamp. It is not clear which of the two techniques was primarily responsible for the outcomes. Recently, pelvic packing was reintroduced in the United States by the Denver trauma group and has become a useful adjunct in the management of bleeding PRF patients.[44] Unlike intra-abdominal packing, the preperitoneal pelvic packing technique involves placing laparotomy sponges within the preperitoneal space, in order to effectively tamponade venous and bony sources of bleeding and reduce the available volume of the retroperitoneal space.[45]

A small suprapubic incision is made, the fascia opened, and recti muscles retracted laterally. If intra-abdominal hemorrhage is also suspected, care should be taken to keep the suprapubic incision separate from the midline laparotomy. A minimum of three packs are placed on either side of the bladder deep into the pelvis, while ensuring that the peritoneum is not violated. If the peritoneum is incised and the abdominal cavity entered, tamponade is released and packing is rendered ineffective. Furthermore, the open funnel that the pelvis presents does not allow for the packs to remain in place and exercise a hemostatic effect by compression; rather, they float free back toward the abdomen.

If a separate laparotomy is required, the incision should be limited to the upper margin of the pelvic hematoma (Fig. 39-13). The preperitoneal packing technique can be lifesaving in patients who are hemodynamically unstable and cannot tolerate transport to the angiography suite. In these patients, the pelvic hematoma is typically very large, and more than six packs may be needed to effectively compress all the bleeding sites. One needs to remember that the bleeding typically originates in the posterior pelvis, and therefore the packs should be placed deep into the pelvis and pressed against the sacrum. Given that the preperitoneal pelvis is not an open cavity, it is not an unusual pitfall to put the packs in a relatively superficial plane, failing to produce adequate compression against the bleeding vessels.

Furthermore, pelvic packing is effective in controlling hemorrhage from the vast venous plexus surrounding the pelvis, in situations where angiography may not be effective or

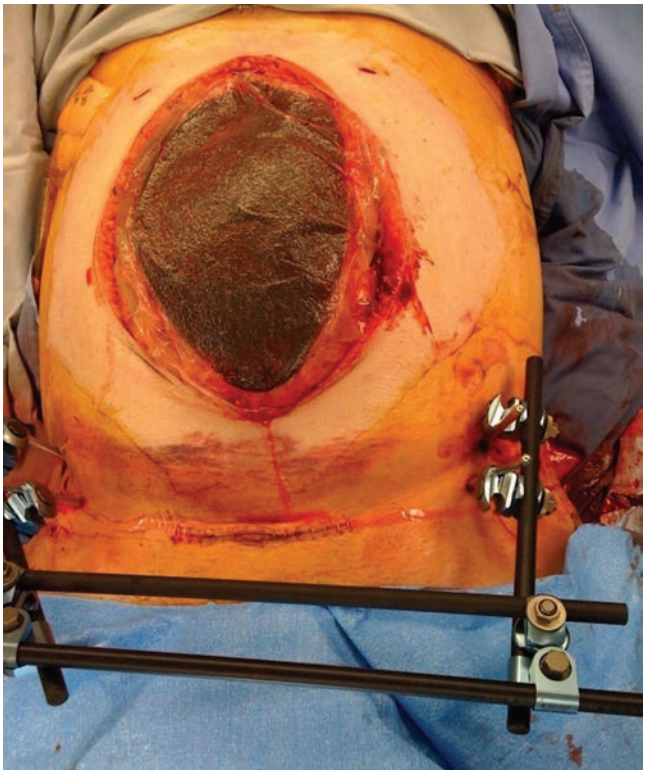

FIGURE 39-13 Note the Pfannenstiel incision, which is separate and distinct from the midline laparotomy, leading to the open abdomen. An external fixator is also placed to reduce the fracture. Very likely, such a patient will also receive angiographic embolization immediately following the operation.

may be unavailable. External fixation of the pelvis can also be performed at the time of pelvic packing.

In a study of 28 patients receiving preperitoneal pelvic packing by the Denver trauma group, 21 (75%) survived. Only 14% of the patients had postoperative angiographic embolization.[44] In a similar study by a Norwegian group, 13 (72%) of 18 patients with packing survived, but postoperative angiographic embolization was used in 80% of the patients.[46] In a follow-up study from Denver, 75 patients who received preperitoneal pelvic packing and external fixation were reviewed. Hemorrhage control was successful in most patients, and angiographic embolization was offered only in a minority who required additional interventions to control the bleeding.[47] One should consider these three procedures (preperitoneal pelvic packing, external fixation, and angiographic embolization) complementary rather than competing.[48] All of them can be offered on the same patient. While angiographic embolization is the preferred method of controlling pelvic bleeding for most patients, preperitoneal pelvic packing provides a useful management alternative in the following circumstances: (1) if there is no angiographic support, as may happen in non–Level I trauma centers; (2) if there is angiographic support but the team cannot assemble expeditiously; or (3) if there is profound hemodynamic instability, which makes even mild delays unacceptable and calls for rapid packing in a ready operating room. Following packing, angiographic embolization should still be strongly considered if the patient has ongoing transfusion requirements, and arrangements made accordingly for transfer to definitive care.

After resuscitation and correction of coagulopathy, packs should be ideally removed within 24 to 48 hours to minimize infection risk. Pelvic space infection can occur in up to 15% of patients. Risk factures include open pelvic fractures with associated bowel or bladder injuries, as well as multiple packing procedures.

DEFINITIVE FIXATION

Unstable and bleeding PRFs are usually managed by a staged repair, which includes a pelvic binder initially, external fixation shortly after that, and internal fixation as the final step to reconstruction. The timing and surgical approach for definitive internal fixation of the pelvis are patient specific and beyond the scope of this chapter. External frames via anterior external fixator or posterior pelvic C-clamps can be placed in the emergency department or operating room. Once placed, they do not interfere with intra-abdominal or preperitoneal packing access in the operating room and also allow operative access to the abdomen and pelvis and may serve as definitive therapy in certain clinical scenarios, particularly in anterior PRFs. They do not offer adequate stability in posterior fractures, particularly in the vertical axis. External fixation is appealing as a long-term solution because it avoids the risks of open operation, but the reduction needs to be precise. If a reduction to less than 1 cm of initial displacement is not maintained throughout the period of healing, then 80% of the patients require chronic analgesics compared with almost none with precise reduction.[49] The complications rise as time progresses, however, and pin infection develops in 50% of definitive fixators, as opposed to 13% of temporary fixators.[50] The most common reason for replacing an external fixator is aseptic pin loosening. Approximately 10% of patients require replacing external with internal fixation as definitive treatment. For APC-II injuries, a plate across the pubic symphysis may be enough, as the posterior pelvic stability is maintained by the unaffected strong posterior sacroiliac ligaments.

APC-III and most LC-II and vertical shear fractures typically require posterior stabilization by internal fixation. According to the specific type of fracture, sacroiliac screws (placed openly or percutaneously), special LC screws, or plates should be used. The complications of internal fixation are many and range from bleeding to injury of nerves, devascularization of muscle, infection, suboptimal reduction, and chronic pain.

ASSOCIATED INJURIES

Major pelvic fractures are high-energy injuries and are therefore commonly associated with intra- and extra-abdominal injuries. The mean Injury Severity Score (ISS) for patients

with pelvic fractures is 18.[51] Traumatic brain injuries, long-bone fractures, and thoracic injury are commonly associated with injuries to the pelvis. The incidences of associated solid and hollow intra-abdominal organ injuries have been reported as 11% and 4.5%, respectively, and diaphragmatic injuries occur in 2% of pelvic fractures.[52] All these associations point to the complexity of diagnosing all the injuries and choosing the correct therapy. A patient with a major pelvic fracture will usually have—at least lower—abdominal tenderness and hemodynamic fluctuations. The decision to explore or avoid the abdominal cavity is often hard as clinical examination, FAST, DPA, or even CT scan may give equivocal information. The presence of a central neurologic injury will only confuse the picture further. The suggested algorithm shown in Fig. 39-15 at the end of the chapter can serve as a guideline for the management of major pelvic fractures, although each patient is unique and requires individualized decisions.

The most commonly identified injuries directly associated with PRF include lower genitourinary tract injury, rectal injury, or iliac vessel injury. Bladder or urethral injury occurs in 6% to 10% of patients, which increases by nearly fivefold with male gender and severe fractures.[53] The majority of bladder ruptures (80%) are extraperitoneal and can be managed by simple Foley catheter drainage for 10 to 14 days. Intraperitoneal injuries require a laparotomy and direct repair. Straddle injuries, typically producing bilateral pubic rami fractures, are associated with urethral injuries. The presence of a perineal hematoma or blood at the urethral meatus should alert the clinician about a urethral injury. A retrograde urethrogram should be performed before inserting a Foley catheter. On selected occasions, in which time is of the essence, advancing a Foley catheter without first performing a retrograde urethrogram is an acceptable alternative. It should be done by a senior person and with extreme care to stop and withdraw in the presence of any resistance. If a Foley catheter cannot be inserted because of a urethral injury, a suprapubic catheter is appropriate. Urethral injuries are usually repaired at a later stage after the inflammation has subsided, but there are reports of successful aggressive early management. Obviously, these decisions will be made jointly by a urologist and the trauma surgeon.

The perineum should be examined for evidence of lacerations requiring repair. In females, a speculum-based vaginal exam should be performed to identify injury due to open fracture. Patients with a suspected rectal injury should undergo an exam under anesthesia in the operating room with sigmoidoscopy to exclude a rectal injury.

Finally, less common associated soft tissue injuries include closed internal degloving injuries termed Morel-Lavallee lesions. They represent a traumatic separation of the skin and subcutaneous tissue from the underlying fascia. Perforating lymphatics and blood vessels become disrupted, leading to seroma or hematoma formation in the subcutaneous tissues. The pressure of this fluid builds, and as the lesion matures, a fibrotic capsule forms and blood supply to the skin can become compromised, leading to skin necrosis. These lesions classically occur over the greater trochanter but may extend along the trunk and lower extremities. Treatment can include percutaneous aspiration if the hematoma is small, but recurrence rates are high. The Mayo Clinic published their recent series and developed practice management guidelines favoring operative incision and drainage. In some cases, formal debridement of skin and soft tissues is necessary, with vacuum-assisted closure and eventual skin grafting.[54]

OPEN PELVIC FRACTURES

A combination of open wounds with pelvic ring injuries produces an extremely challenging situation, as bleeding and ongoing contamination are typically profound and death rates are usually in excess of 20% and up to 50%. Lacerations of the perineum are much more difficult to manage than anterior lacerations. These two types of open pelvic fractures should not be described as the same entity because the management should be different according to the location and extent of the skin laceration.

The priorities in management of major open pelvic fractures are not much different than the management of any other devastating injury and include, in order of priority, control of bleeding, control of contamination, and definitive fixation. Control of bleeding in open pelvic fractures involves packing through the laceration, application of a pelvic binder, angiographic embolization, and external fixation. Preperitoneal pelvic packing, as noted earlier, may not be effective because the tamponade of the retroperitoneal pelvic space is already released to the external environment. There is a debate about the need for colostomy to control contamination. Many authors believe that a diverting colostomy should be routinely performed as an integral part of the surgical management of an open pelvic fracture (Fig. 39-14). In a study of 39 patients with open pelvic fractures, the mortality was 26% and predicted by fracture instability and rectal injury. The authors suggested that early colostomy is important to survival.[55] In another study of 44 patients, 23 were managed with a diverting colostomy and 21 without it. Even if the patients with colostomy were more severely injured, they had a lower 30-day mortality. Pelvic sepsis and anastomotic complications contributed to mortality in the no-colostomy group, and the authors recommended the liberal use of colostomy.[56] A systematic analysis of the literature, however, showed that there were no differences in outcome between patients with and those without a colostomy.[51] Nevertheless, the authors recognized that the evidence was of poor quality and that solid conclusions could not be made, and called for prospective randomized studies, a rather unlikely goal given the low incidence of these injuries. A midway solution was described on 18 patients, of whom 5 had a colostomy because of perineal wounds, whereas 13 with anterior wounds were not subjected to this procedure.[57] No patient without a colostomy developed pelvic sepsis, and the authors

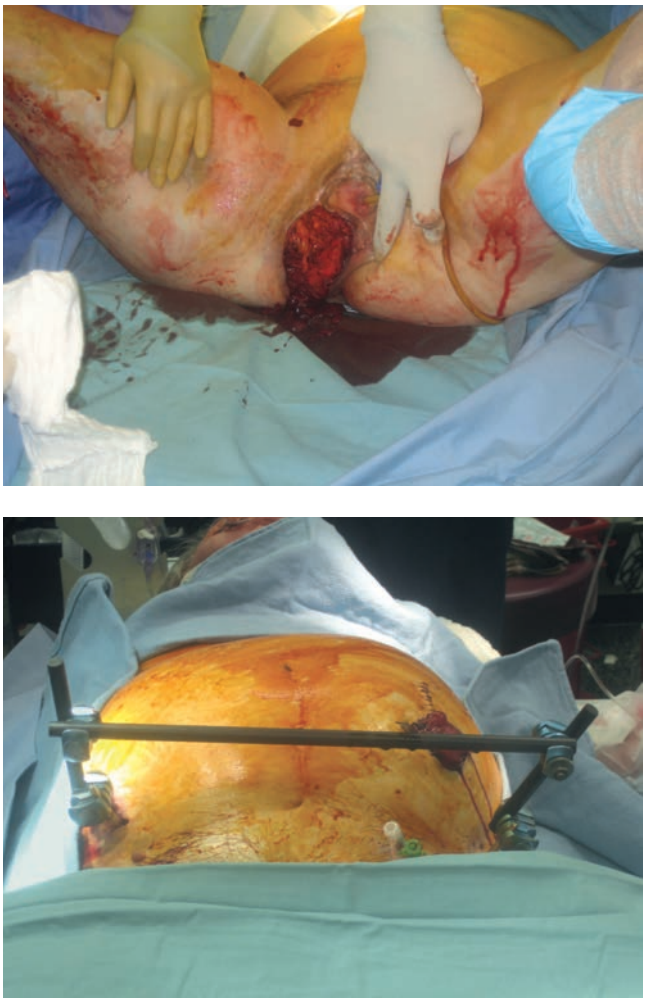

FIGURE 39-14 Colostomy is advisable for lacerations that are in immediate proximity or involve the perineum and perianal region. This patient received debridement and packing of the perineal wound, external fixation of the pelvic fracture, and a diverting colostomy.

recommended a selective approach. This is exactly our approach too. Patients with rectal wounds or with wounds in immediate proximity to the anus usually receive a diverting colostomy. Patients with more distal wounds are usually managed without fecal diversion. Debridement of ischemic tissue is an important part of the management. Despite all strategies, the mortality of open pelvic fractures remains very high, even in the modern era and even in expert hands. The Grady Memorial Hospital group described 44 such patients with a mortality of 45%.[58] The presence of bleeding and need for angiographic embolization were associated with a grim prognosis. Late pelvic sepsis developed in five patients, and three of them died. Therefore, it seems that primarily bleeding and secondarily sepsis continue to claim a heavy toll on the lives of patients with this devastating injury.

LONG-TERM OUTCOMES

Pelvic fractures, if severe, can be associated with significant morbidity and mortality. Mortality associated with severe pelvic fractures can reach up to 40%, depending on the degree of shock at presentation and identification of associated injuries.[59,60] In the early postinjury phase, patients with severe pelvic fractures requiring surgical fixation are at high risk for deep venous thromboembolism and pulmonary embolism.[61] Patients should receive prophylaxis (mechanical and pharmacologic) for deep vein thrombosis, or if contraindicated due to other injuries, a removable inferior vena cava filter should be considered.

Neurologic injury is also a characteristic complication after pelvic trauma with serious long-term implications. In an electrodiagnostic study of 78 patients with pelvic trauma and lower extremity neurologic symptoms, the incidence of gait instability and neuropathic pain was high.[62] As already discussed, sexual dysfunction remains a major problem in approximately two-thirds of male patients with major pelvic fractures.[35] Sensory impairments were noted in 91% of the patients with unstable sacral fractures 1 year after the injury.[58] Impaired gait was recorded in 63% and bladder, bowel, or sexual impairments in 59%. In a questionnaire study of 24 women with a Tile B or C pelvic fracture and a median age of 24 years, 16 reported de novo pelvic dysfunction.[63] Bladder symptoms were present in 12, bowel problems in 11, and sexual dysfunction in 7. Malunion of fractures can produce leg-length discrepancies, creating gait instability and pain. It is, therefore, obvious that even with optimal management, severe pelvic fractures are associated with long-term sequelae. Pain and neurologic impairments are the most common problems that can compromise the quality of life.

CONCLUSION

Major pelvic fractures are associated with significant bleeding, complications, and mortality. A multidisciplinary approach is important. The diagnosis of major pelvic bleed should be made in the trauma bay based on external clues of injury to the pelvis, physical examination indicating pelvic ring instability, pelvic x-ray, and focused abdominal sonography, as well as exclusion of other potential bleeding sources. CT scan is currently the most useful test to characterize fractures, detect hematomas and active contrast extravasation, and plan further treatment and operative approach. In the presence of bleeding, angiographic embolization is indicated and should be done in most cases along the principles of damage control angiography. Pelvic binding in the emergency department and external fixation are important interventions to reduce bleeding, pain, and ongoing injury. Internal fixation is best left for a later stage. Preperitoneal pelvic packing can be a life-saving maneuver for patients who are too unstable to travel to the angiography suite or in hospitals that do not have easy access to angiography. A general algorithm is provided (Fig. 39-15), but the exact sequence of interventions should be

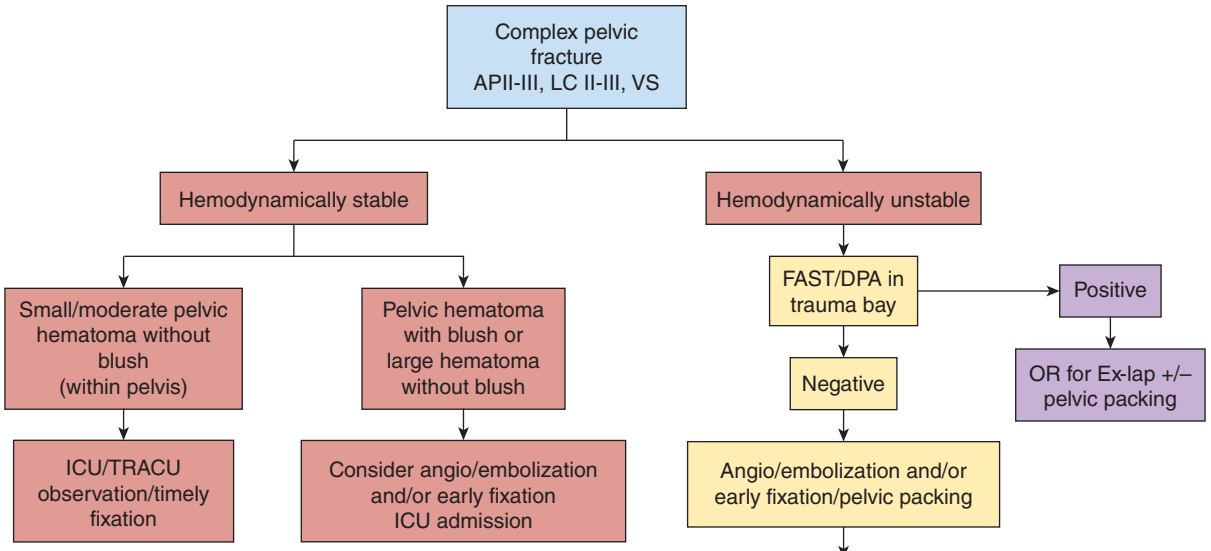

FIGURE 39-15 Algorithm for the management of major pelvic fractures. APC, anteroposterior compression; DPA, diagnostic peritoneal aspiration; FAST, focused abdominal sonography for trauma; ICU, intensive care unit; LC, lateral compression; OR, operating room; VS, vertical shear.

individualized to the particular complexities of these challenging patients.

Genitourinary Tract

Fernando J. Kim • Rodrigo Donalisio da Silva

KEY POINTS

- About 25% of kidneys receive accessory arterial branches directly from the aorta.
- Approximately 90% of significant renal injuries are due to blunt trauma in the United States.
- Injuries to the renal pedicle, including intimal disruption of the renal artery or renal devascularization, present with no hematuria in 20% to 33% of patients.
- Advantages of computed tomography (CT) over intravenous pyelogram (IVP) include identification of contusion and subcapsular hematoma, definition of the location and depth of parenchymal lacerations, more reliable demonstration of the extravasation of contrast, and identification of injuries to the pedicle and artery.
- Although hematuria is an important sign of ureteral injury, it may be absent 15% to 45% of the time.
- Indications for renal exploration include hemodynamic instability or ongoing hemorrhage presumably related to the kidney, pulsatile or expanding perirenal hematoma at laparotomy, and avulsion of the pedicle.
- Partial nephrectomy for polar lesions is performed using a "guillotine" technique with the transected vessels ligated and the collecting system closed.
- Ninety percent of grade V renal injuries require urgent nephrectomy.
- Delayed recognition of an injury to the ureter is managed with endoscopic or interventional radiology techniques due to local inflammation, edema, friability, and presence of a urinoma.
- Nonoperative management of an extraperitoneal injury to the bladder is with an indwelling catheter for 10 to 14 days followed by a cystogram.

INTRODUCTION

Genitourinary injury occurs in 2% to 5% of all trauma patients and in at least 10% of patients with abdominal trauma, emphasizing the need for a close collaboration between the general and urologic trauma surgeon. This unique relationship that the urologist and general trauma surgeon share in the management of urologic injuries requires common philosophies of management to be applied.

Controversies exist in the approach to urologic trauma, and recent efforts to achieve a broad consensus in the management of diverse urologic injuries have resulted in numerous publications. One such effort, sponsored by the World Health Organization and the Societe Internationale d'Urologie, involved a 25-year review of world literature focusing on levels of evidence and the development of evidence-based management recommendations.[1-4] Another effort through the European Association of Urology had a similar focus.[5] Both produced useful syntheses of a large body of literature. The current discussion will offer a broadly applicable approach to the management of urologic trauma based on current literature, local experience, and local perspective.

ANATOMY

The contemporary surgical approach to the injured kidney is through an anterior midline abdominal incision. Access to the kidneys and ureters is generally obtained by reflecting the colon medially on either side and exposing Gerota's fascial envelope. The exposure of an injured kidney may be achieved after obtaining vascular control of the renal vessels prior to entering the perirenal hematoma or by expeditious exploration of the retroperitoneum and manual renal control. Parenchymal compression is necessary in cases of active renal hemorrhage. The important step of either approach is to access the pedicle and apply atraumatic vascular clamping while damage is assessed and treated. Vascular control can be

accomplished through individual dissection and "looping" of the renal vessels through an incision in the posterior peritoneum over the aorta (which can allow access to either the left- or right-sided artery and the left-sided vein) or by first reflecting the colon on the side of the injury and then obtaining vascular control or access to the pedicle. This surgical step has been successful in experienced hands, but it may increase the exploration time. In cases of low suspicion of a renovascular injury and depending on the urologic trauma surgeons' comfort level, another successful approach to the kidney and renal hilum can be achieved by first reflecting the colon and then, by manual compression, the surgeon can achieve vascular control while the assistant can evaluate and apply an "en bloc" atraumatic vascular clamp if necessary.

The kidney is located high and posterior in the retroperitoneum. The midline incision may need to be extended to the xiphoid process, and additional upper abdominal retraction may need to be inserted for proper exposure. The kidney overlies the diaphragm, transversus abdominis aponeurosis, and quadratus lumborum muscle laterally and psoas major muscle medially. Significant bleeding from these muscles and the deep muscles of the back can occur following penetrating trauma and may be misinterpreted in the imaging as a kidney injury when it may be brisk bleeding occurring in the renal fossa. The kidney is enclosed in a thin but strong fibrous capsule, which should be left intact during renal dissection and mobilization. As the capsule is typically lifted off the parenchyma by an underlying hematoma, the entire capsule may inadvertently be stripped off the kidney by using a sweeping finger to quickly mobilize the kidney. Ideally, the kidney should be mobilized through sharp and blunt dissection working from a normal area toward the area of parenchymal injury to keep the capsule on the kidney. Stripping the capsule complicates the repair of the kidney and should be avoided.

Recognizing patterns of injury is important; the trauma surgeon should anticipate injuries to adjacent organs based on the relational anatomy of the kidney and ureter as well as the trajectory of a penetrating injury (Fig. 40-1).[6] The left kidney is crossed anteriorly in its upper portion by the tail of the pancreas and lies behind the lower portion of the spleen. On the right, the duodenum is immediately anterior to the hilar region. In the case of a renal injury on the right side, the right colon, liver, and duodenum are commonly injured in penetrating trauma. With blunt trauma, an associated hepatic laceration is most common. On the left side, injuries to the left colon, stomach, spleen, and pancreas are common in penetrating trauma, and lacerations of the spleen are particularly common with blunt trauma to the left upper quadrant. Injuries to the diaphragm are also common with penetrating renal injury and less common with blunt injury. The left adrenal gland is located medial to the upper pole of the left kidney, while the right adrenal gland is located in a more cephalad position relative to the right upper renal pole and may be in a retrocaval position.

At the level of the renal pedicle, there are commonly single renal arteries and veins present bilaterally. The renal vein, artery, and renal pelvis are organized in an anterior-to-posterior

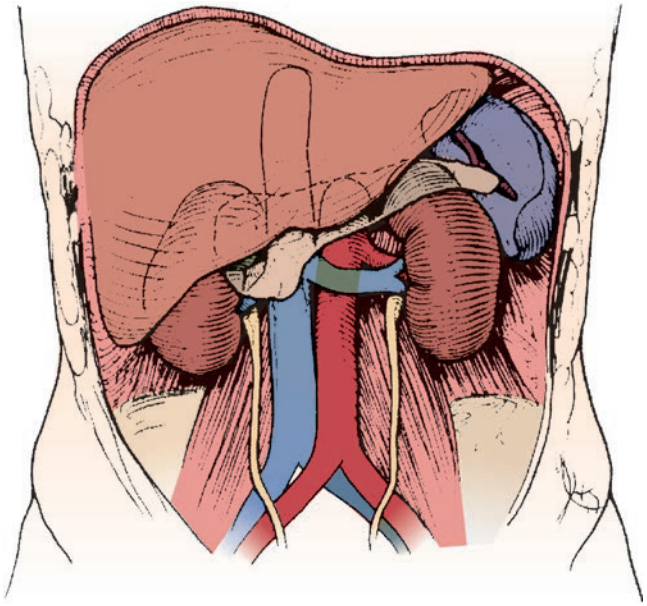

FIGURE 40-1 Renal anatomy: relational anatomy of the kidney. Note proximity of great vessels, duodenum, liver, spleen, pancreas, and colon, relevant to predicting patterns of injury and likely sites of concomitant organ injury in renal trauma.

orientation. On the right side, the gonadal vein arises from the vena cava at or slightly below the level of the renal pedicle. A lumbar vein, which may be quite large, often arises from the posterior aspect of the right renal vein near the connection with the inferior vena cava. The right adrenal vein enters directly into the vena cava, often on its posterolateral aspect. On the left, the main branches of the renal vein include the left gonadal, the adrenal, and one or more lumbar veins. This asymmetry of the collateral branches of the renal veins explains why the left renal vein can be safely ligated near the vena cava with an 85% chance of renal preservation. In contrast, the right kidney will most likely develop venous thrombosis and become nonviable if the right renal vein is ligated.

For the urologic trauma surgeon who engages in intrarenal surgery and renal reconstruction, knowledge of the intrarenal anatomy is important (Fig. 40-2). The renal arterial supply consists of the following five segments: apical, superior (anterosuperior), middle (anteroinferior), lower (inferior), and posterior. The posterior branch crosses cephalad to the renal pelvis to reach its segment. About 25% of kidneys receive accessory arterial branches directly from the aorta. These may enter through the renal sinus or at the upper or lower poles. Certain anomalies of the upper urinary tract, such as horseshoe kidney and congenital obstructive and duplicated systems, must be familiar to the trauma surgeon because they may impact management.

The blood supply to the ureter is particularly important in surgery for urologic trauma (Figs. 40-3 and 40-4). The main sources are the renal artery from above, the aorta or common iliac arteries, and the vesical arteries from below. Branches approach the upper and mid ureter primarily from the medial side, whereas in the lower pelvis, the blood supply

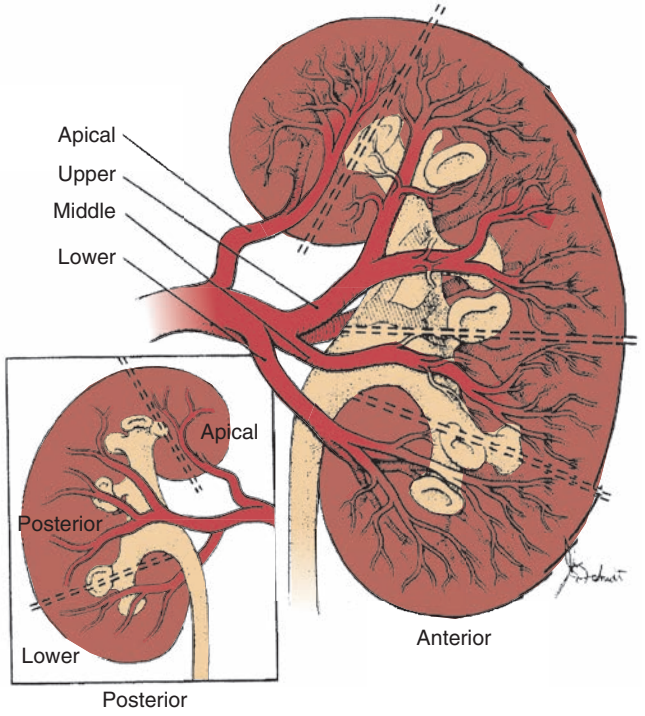

FIGURE 40-2 Intrarenal vascular anatomy: vascular branches supplying various arterial segments of the renal parenchyma. Knowledge of intrarenal anatomy is critical to successful reconstructive efforts.

to the ureter enters primarily from a lateral direction. These branches form a long, predictable anastomotic chain usually with a single longitudinal vessel that runs the length of the ureter in the plane between the ureteral adventitia and muscularis.

The anatomy of the urethra, perineum, and external genitalia may be less familiar to the general trauma surgeon. The gross anatomy and fascial layers of the genitalia and perineum are important in trauma because they largely determine the manner in which blood and urine extravasate following urethral or genital trauma (Fig. 40-5).

INJURY GRADING AND SCORING SYSTEMS FOR GENITOURINARY INJURIES

The American Association for the Surgery of Trauma (AAST) Injury Scaling Committee has devised a staging system for urologic injuries. The system, originally published in 1989 and since amended, addresses injuries to the kidney, ureter, bladder, urethra, testis, scrotum, and penis (Table 40-1).[7] For some organs, such as the kidney, the system has proven highly applicable and has come into common use. For other organs, such as bladder and ureter, the AAST system has been less commonly used for a variety of reasons, largely relating to lack of specificity of available imaging approaches to provide the necessary data for assignment of a grade. The grading systems for the urethra and external genitalia are becoming more

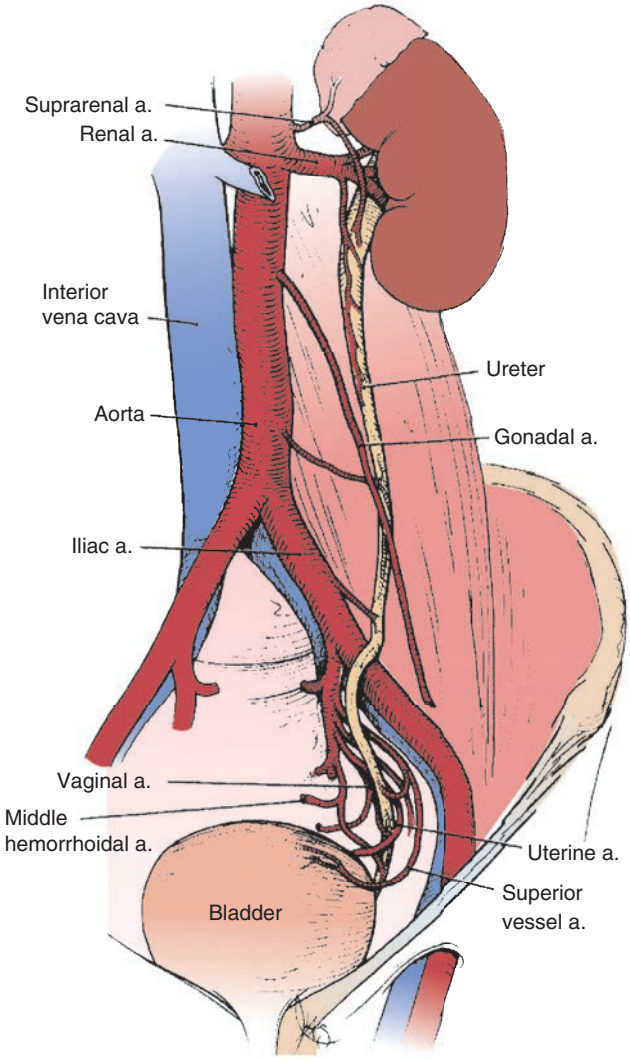

FIGURE 40-3 The ureteral blood supply originates from branches of the adrenal and renal arteries in the upper third, branches of the aorta and gonadal arteries in the middle third, and the pelvic vessels as shown in the lower third. Knowledge of the ureteral blood supply and derangements due to preexisting pathology or prior surgery is important in maintaining ureteral viability during surgical mobilization and reconstruction.

commonly used and are of value when addressing outcomes following such injuries. Several aspects of the staging system have received attention regarding their clinical significance and impact on decision making, complication rates, and patient outcomes.[8,9]

As noted in Table 40-1, the renal Organ Injury Scale uses five grades of injury, ranging from contusion or subcapsular hematoma (grade I) to shattered kidney or avulsion of the hilum (grade V) (Fig. 40-6). It is valuable to specifically distinguish the parenchymal lacerations from renovascular trauma in the group IV and V injuries when reporting experience because management and outcomes differ between these entities. The varying degrees of renal injury as described in the scaling system are depicted diagrammatically in Fig. 40-6.

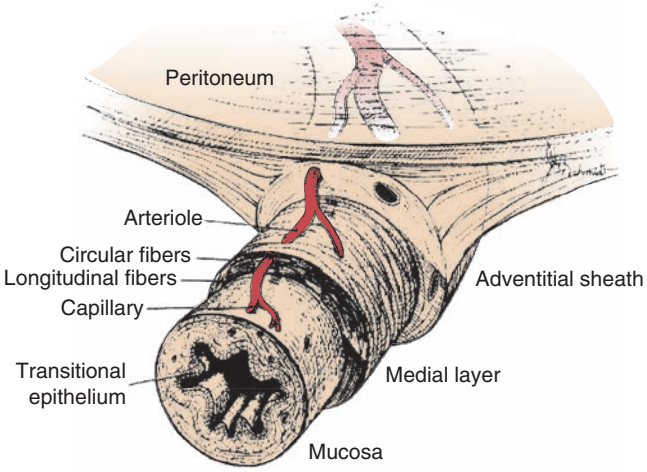

FIGURE 40-4 Ureteral anatomy: the longitudinal blood vessels run deep to the adventitial sheath; it is important to achieve a dissection plane superficial to this layer to avoid devascularization of the ureter during surgical mobilization.

Recent data have shown support for the clinical utility and validity of the renal injury scale, indicating that this system is predictive of morbidity in blunt and penetrating renal injury, of mortality in blunt injury,[9] and of the risk of nephrectomy with exploration for renal trauma.

The determination of ureteral injury type and classification can be challenging without surgical exploration, intraluminal endoscopic view, or use of radiopaque intraluminal contrast. Other indirect signs, such as the presence of ipsilateral hydronephrosis, can determine ureteral injury but will not determine the percentage of the ureteral circumference damaged. For the bladder, the distinction of intraperitoneal from extraperitoneal rupture is important and is addressed in the scaling system, but whether the length of the laceration in the bladder wall truly has clinical significance has not been demonstrated.

For urethral injuries, the scaling system addresses anatomic factors that can often be determined from retrograde urethrography (RUG) and provide advantages over the earlier system described by Colapinto and McCallum.[10] The current AAST system addresses urethral disruption based on whether the injury is complete or incomplete (eg, whether contrast enters the bladder), the length of the urethral defect, and the presence of extension into the prostate or vagina. Endoscopic assessment indicates cases where the RUG may suggest a complete disruption; however, partial circumference continuity may exist, which may allow for insertion of a catheter into the bladder. Despite some lack of specificity (anterior vs posterior injury), the AAST organ injury scaling system has substantial usefulness.

The scaling system for organ-specific injuries as applied to genitourinary trauma (Tables 19–22 and 29–31 from AAST website) has introduced a much-needed advance in the field.[7] The designations of the AAST system provide a universal language among clinicians to describe injuries and enact the right protocol and management of genitourinary trauma among different specialties.

CLINICAL PRESENTATION AND DIAGNOSIS OF RENAL TRAUMA

Incidence and Patterns of Injury

Renal injuries occur in approximately 1% to 3% of all trauma patients and up to 10% of patients with abdominal trauma. The percentage of blunt and penetrating trauma varies dramatically depending on the health care institution and the population served. In some urban trauma centers, penetrating

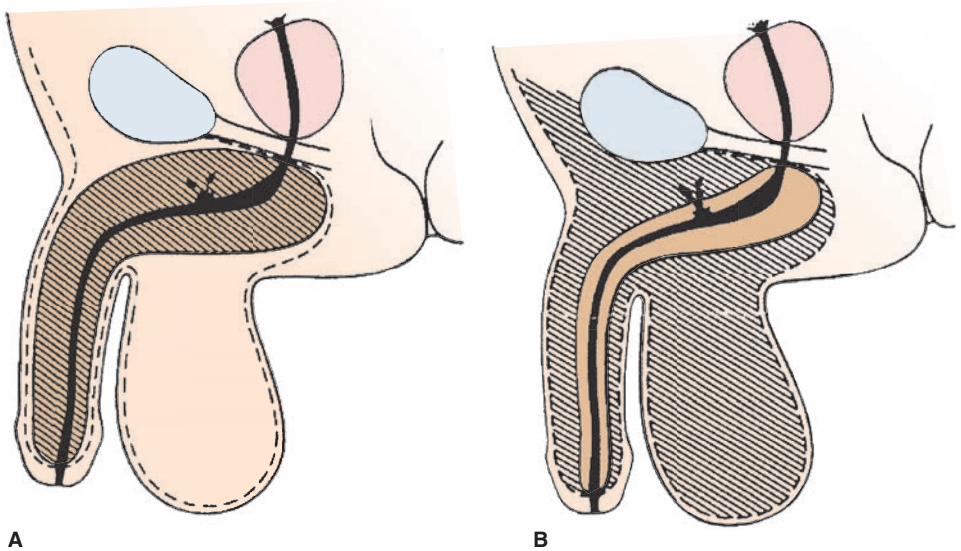

FIGURE 40-5 Diagram of sites of extravasation associated with urethral disruption. (**A**) With an intact Buck's fascia, extravasation of blood and/or urine is isolated to the penile shaft. (**B**) With Buck's facial defect, extravasation extends into the scrotal tissues and compartments.

TABLE 40-1: Urologic Injury Scale of the American Association for the Surgery of Trauma

Grade[a]		Injury description[b]
Renal injury scale		
I	Contusion	Microscopic or gross hematuria; urologic studies normal
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
II	Hematoma	Nonexpanding perirenal hematoma confined to the renal retroperitoneum
	Laceration	<1 cm parenchymal depth of renal cortex without urinary extravasation
III	Laceration	>1 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation
IV	Laceration	Parenchymal laceration extending through the renal cortex, medulla, and collecting system
	Vascular	Main renal artery or vein injury with contained hemorrhage
V	Laceration	Completely shattered kidney
	Vascular	Avulsion of renal hilum that devascularizes kidney
Ureter injury scale		
I	Hematoma	Contusion of hematoma without devascularization
II	Laceration	≤50% transection
III	Laceration	>50% transection
IV	Laceration	Complete transection with 2 cm devascularization
V	Laceration	Avulsion of renal hilum that devascularizes kidney
Bladder injury scale		
I	Hematoma	Contusion, intramural hematoma
	Laceration	Partial thickness
II	Laceration	Extraperitoneal bladder wall laceration ≤2 cm
III	Laceration	Extraperitoneal (>2 cm) or intraperitoneal (≤2 cm) bladder wall lacerations
IV	Laceration	Intraperitoneal bladder wall laceration >2 cm
V	Laceration	Intraperitoneal or extraperitoneal bladder wall laceration extending into the bladder neck or ureteral orifice (trigone)
Urethral injury scale		
I	Contusion	Blood at urethral meatus; urethrography normal
II	Stretch injury	Elongation of urethra without extravasation on urethrography
III	Partial disruption	Extravasation of urethrographic contrast medium at injury site, with contrast visualized in the bladder
IV	Complete disruption	Extravasation of urethrographic contrast medium at injury site without visualization in the bladder; <2 cm of urethral separation
V	Complete disruption	Complete transection with >2 cm urethral separation, or extension into the prostate or vagina

[a]Advance one grade for multiple injuries to the same organ.

injuries predominate.[6,11-13] Overall, approximately 90% of significant renal injuries in the United States are due to blunt trauma.[14]

For penetrating trauma, nearly all renal gunshot wounds are associated with injuries to other intra-abdominal organs; for renal stab wounds, approximately 60% of cases occur in combination with another intra-abdominal injury.

Interestingly, minor mechanisms of blunt abdominal trauma may cause significant renal injury and hematuria in kidneys with preexisting anatomic abnormalities (renal cysts, ureteral pelvic junction obstruction with hydronephrosis, renal neoplasm).[15,16]

Clinical Presentation and Evaluation

Any history of blunt and/or penetrating trauma to the chest, abdomen, or pelvis may increase the probability of a renal injury.

The physical examination of patients at risk for renal injury should include careful assessment of the abdomen, back, flank, and chest as well as a complete genitourinary examination. Findings suggestive of a renal injury include tenderness in the flank, costovertebral angle, or abdomen; palpable flank mass; or ecchymosis in the flank, back, or abdomen. Complete inspection of the torso for a penetrating injury is critical. Stab wounds posterior to the anterior axillary line carry a risk of renal injury, with only about 12% of such injuries being associated with an injury to another organ. Hematuria is the most common sign of renal trauma, although the magnitude of the hematuria correlates poorly with the magnitude of injury.[15,16]

Laboratory assessment should include urinalysis by dipstick, as well as a microscopic examination for blood or infection in the urine. The first specimen assessed in the emergency department should be analyzed for hematuria to optimize diagnostic accuracy. The determination of serum

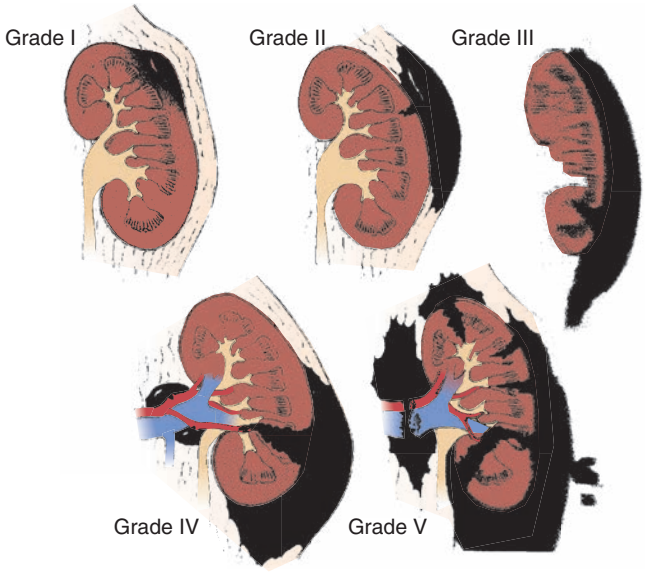

FIGURE 40-6 Organ injury scaling system for renal trauma.

electrolytes, blood urea nitrogen, serum creatinine, lactate level, and hemoglobin is important. A blood sample should be obtained to screen, determine blood type, and cross-match when clinically appropriate.

Radiographic Imaging for Renal Trauma

Traditionally, all patients with abdominal trauma and any degree of hematuria were imaged in the emergency department on presentation, yielding minor injuries in 90% of imaged patients without requiring intensive monitoring or intervention. Therefore, in order to be cost-effective and minimize potential morbidity of unnecessary imaging, more selective approaches to renal imaging in the trauma setting have been proposed without increasing the risk of missed injuries and delay in diagnosis.[17] In 1985, a group from San Francisco General Hospital analyzed their renal trauma experience and identified that the only findings that were predictive of significant renal injury were the presence of penetrating trauma, blunt trauma with gross hematuria, or blunt trauma with microhematuria and shock. Shock was defined as a systolic blood pressure less than 90 mm Hg at any time after injury, including during transport by emergency medical services. In a review of 812 patients with microhematuria without shock, no significant renal injuries were detected. All 44 injuries in this original series were found among the 195 patients with gross hematuria or microhematuria and shock. This series has been extended over the years, and in the expanded patient group of 2254 patients with renal trauma, it was found that approximately one-third were imaged and two-thirds were not. Within this group, no major renal injuries were missed when using the established criteria.[18-20]

Other investigators have modified imaging criteria according to their own experience and judgment. Some have suggested including standard imaging for patients with injury to the brain, loss of consciousness, or altered mental status, with the belief that the loss of information on a physical examination and the magnitude of trauma in such patients may create a higher risk of a missed injury. Some have suggested extending imaging indications to patients with mechanisms of injury consistent with deceleration trauma. This approach avoids missing injuries to the renal pedicle (eg, intimal disruption in the renal artery and renal devascularization), which may present with no hematuria in 20% to 33% of patients. The presence of fractures of long bones, lower ribs, or transverse spinous processes has also been suggested as an indication to modify the previous imaging restrictions, possibly predicting a higher risk of occult renal injury. In the pediatric population (addressed later in the section "Pediatric Renal Trauma"), imaging for patients with only microhematuria has been more liberally used.

Conversely, patients with penetrating trauma with any degree of hematuria, injury proximity, or suspicion are appropriate candidates for imaging of the urinary tract, regardless of the presence or magnitude of hematuria. Significant penetrating injuries can present without hematuria, particularly if trauma to the major collecting system causes all urine from the injured kidney to exit into the retroperitoneum, preventing ureteral peristalsis.

In penetrating trauma, imaging would generally be obtained while assessing a patient's candidacy for nonoperative management in the appropriate clinical setting. The concept of obtaining preoperative renal imaging solely to demonstrate the presence of two functioning renal units prior to surgical intervention has become less popular in recent years. Instead, careful intraoperative palpation of the kidneys and, on occasion, intraoperative intravenous pyelogram (IVP) may be used selectively during a trauma laparotomy to demonstrate renal presence or function.[21] The selection of imaging modalities has evolved greatly since the advent and availability of computed tomography (CT) scanning in emergency center evaluation.[17] Although bolus IVP with nephrotomography was previously the standard imaging approach, the CT scan has, over the years, become the gold standard for precise staging of renal injuries (Fig. 40-7) and has largely replaced IVP in most clinical settings.

Although the IVP was considered an accurate tool for clinical staging purposes in 60% to 85% of patients, CT scanning also offers a number of important advantages.[22] Nevertheless, trauma surgeons and urologists should maintain familiarity with the findings suggestive of renal injury on IVP because the use of CT for trauma assessment is not consistently available, especially when considering variations in international practice and infrastructure. These IVP findings that indicate renal trauma include the presence of a transverse process fracture on the scout film, presence of a mass effect in soft tissue, loss of the psoas margin on the involved side, and alteration of the longitudinal axis or vertical displacement of the kidney. Loss of a clear renal cortical outline, gross extravasation of contrast, ipsilateral decrease in renal excretory function, and loss of opacification in portions of the collecting

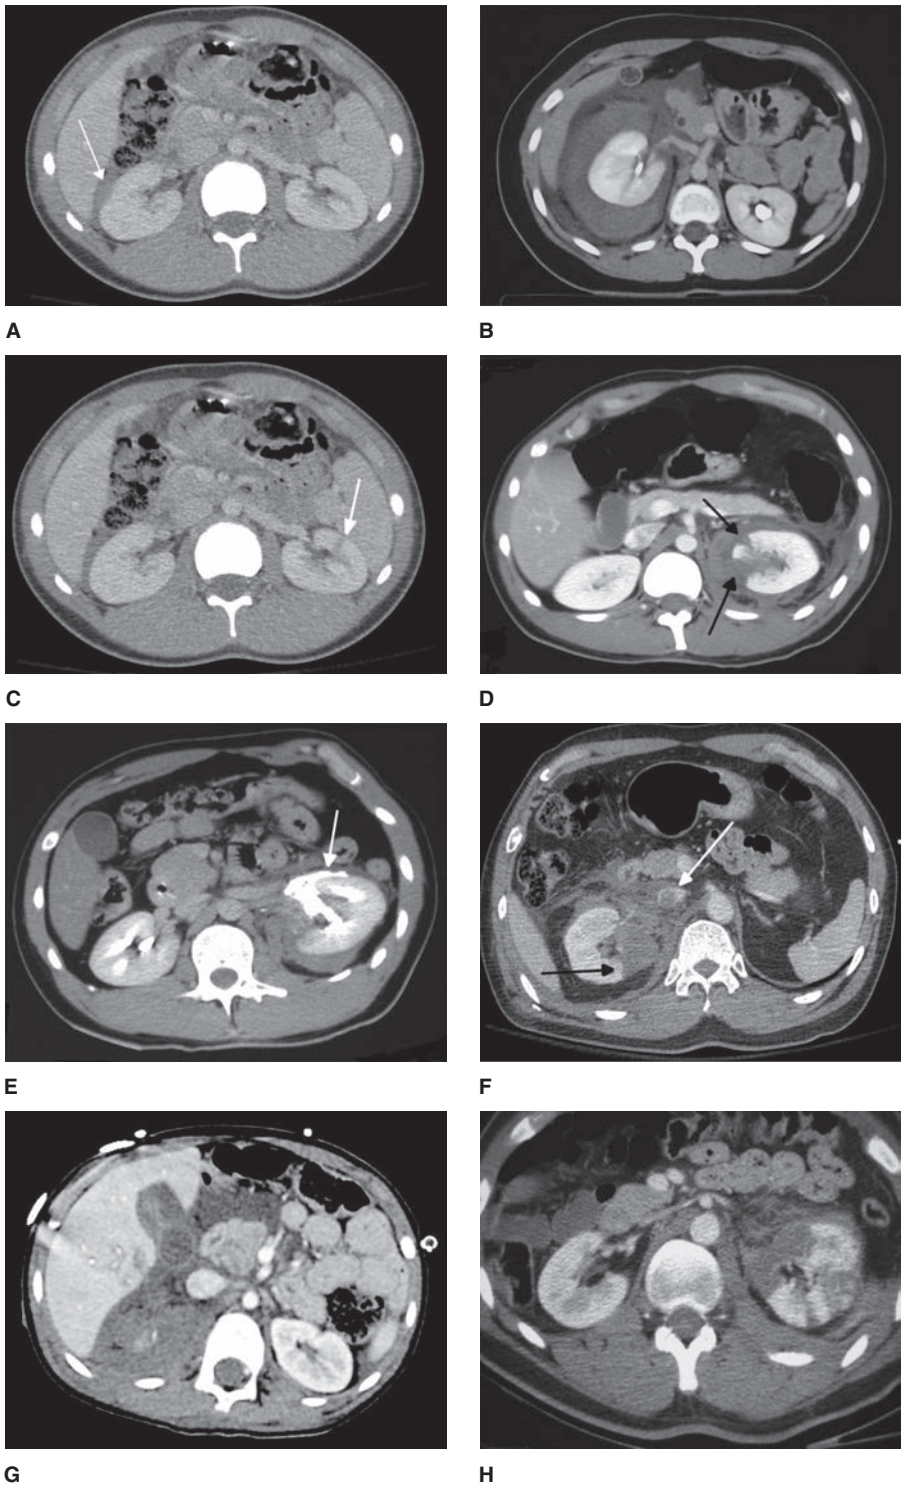

FIGURE 40-7 Staging computed tomography scans for renal injury. (**A**) Grade I hematoma (white arrow indicates right renal subcapsular hematoma); (**B**) grade II hematoma; (**C**) grade II laceration (white arrow indicates left renal parenchymal <1 cm laceration); (**D**) grade III laceration without urinary vascularization (black arrows indicate left renal parenchymal >1 cm laceration); (**E**) grade IV laceration with extravasation (white arrow indicates left renal parenchymal/collecting system laceration); (**F**) grade IV vascular with vena cava thrombus (white arrow indicates inferior vena cava thrombus and black arrow indicates right renal vascular compromise); (**G**) grade V shattered right kidney; (**H**) grade V vascular (left renal artery injury).

system should all be noted. The IVP allows confirmation of the presence of two renal units, gives general information of the extent of injury, and may show significant extravasation.

Estimates of the accuracy of IVP in detection of renal injury vary. In general, the IVP should be viewed as a crude means of detection rather than as a process to obtain precise staging. Some studies indicate that as many as 20% of patients with significant renal injuries may have a normal IVP. Renal arterial occlusion may not always be the cause of reduced function or nonfunction of a kidney on IVP. In up to 50% of patients, other factors, including contusion, hypotension, or hypoperfusion, may lead to a reduced function/nonfunctional kidney when viewed through IVP.

Advantages of CT over IVP include identification of contusion and subcapsular hematoma, definition of the location and depth of parenchymal lacerations, more reliable demonstration of extravasation of contrast, and identification of injuries to the pedicle and artery (eg, "rim sign," "cutoff sign") with or without three-dimensional reconstruction. There is also enhanced imaging of the perinephric space and other solid viscera (liver, spleen, pancreas), delineation of many cases of hollow viscus perforation, and identification of free intraperitoneal fluid. For these and other reasons, the contrast-enhanced CT scan has largely replaced IVP for trauma imaging. One should be extremely cautious to obtain correct CT scan sequences and obtain delayed, excretory images to avoid missing extravasation from the collecting system or ureter that may not be apparent from early nephrogenic and vascular phases.[23]

Often, interventional radiographic studies are obtained when vascular injury is diagnosed after CT scan and treatment is needed. Precise delineation of arterial anatomy, interventions to control hemorrhaging, or placement of a vascular Palmaz stent mandates the continued use of renal arteriography on a selective basis (Fig. 40-8). In several places, including the United States, the Focused Assessment for Sonography in Trauma (FAST) study is performed to assess for free intra-abdominal fluid rather than for the delineation

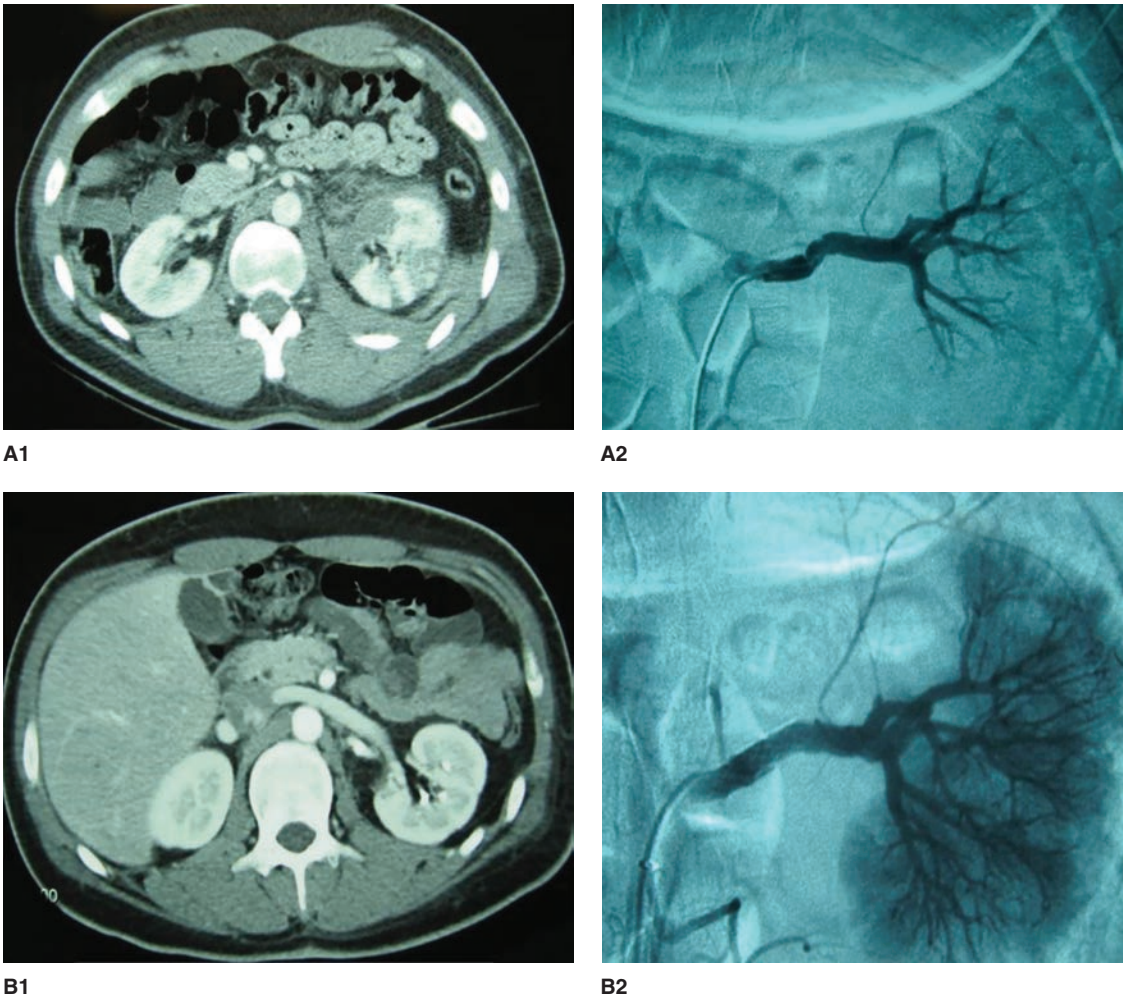

FIGURE 40-8 Left renal artery occlusion due to intimal disruption following injury (computed tomography [CT] and angiogram views of the same patient before and after vascular stent placement). (**B2**) Vascular stent placement angiogram.

of an injury to parenchyma of solid organs. The evolvement of high-resolution ultrasound and Doppler techniques for the assessment of renal perfusion and vascular anatomy can be used intra- and perioperatively in cases of renal trauma.[24]

Currently, retrograde ureteropyelogram plays a limited role in defining renal injury but can be performed to evaluate and treat concomitant ureteral injuries when ureteral stents may decrease urinary extravasation and/or assist the passage of blood clots from the upper collecting system.

PEDIATRIC RENAL TRAUMA

The pediatric kidney may be more vulnerable to trauma than the adult kidney due to the relatively larger size of the kidneys in relation to the body, the relative lack of perinephric fat in the child, and the association of renal injuries with congenital renal abnormalities in pediatric patients. One recent review found that 8.3% of pediatric renal injuries occurred in patients with preexisting renal abnormalities,[15] with other estimates of preexisting renal abnormality described in up to 23% of major pediatric renal injuries due to blunt trauma. Some data suggest that the kidney is the most commonly injured intra-abdominal organ in children.

It is commonly agreed that the presence of gross hematuria after trauma in the pediatric patient warrants further investigation with imaging of the urinary tract. As in the adult, the CT scan plays a major role in staging such injuries for the same reasons as described earlier. Several studies suggest that only about 5% of pediatric patients with major renal injuries will develop signs of shock, further emphasizing the importance of an aggressive diagnostic approach. Pediatric patients can maintain normal blood pressure despite significant blood loss, and persistent tachycardia is a particularly important parameter to note in the pediatric patient as a potential sign of significant blood loss.

Many authors suggest that all pediatric patients with any degree of hematuria after significant trauma should undergo renal imaging, whereas some have suggested modified criteria. One study has suggested that microscopic hematuria with greater than 50 red blood cells per high-power field in the pediatric setting should be considered an imaging criterion, regardless of hemodynamic parameters.[25]

Certain types of renal injuries are more common in the pediatric patient. These include laceration of the renal pelvis, avulsion of the ureteropelvic junction, and forniceal avulsion. When extensive medial extravasation is noted and/or the ureter does not opacify with contrast despite adequate excretion into the renal collecting system, a disruption of the major collecting system should be considered. In such cases, retrograde pyelography with ureteral stent placement may be necessary to define the anatomy, diagnosis, and treatment.

Much like in the adult, the use of the rapid spiral CT scanner can lead to a pitfall in diagnosis if a delayed sequence is not requested. Limiting the study to a nephrographic or early excretory phase may fail to demonstrate extravasation or asymmetrical opacification of the ureters that would be readily visible on later images.

Overall, approximately 85% of pediatric renal injuries from blunt trauma are minor (contusions, superficial parenchymal lacerations) and are managed with bed rest and observation. Pedicle injuries compose about 5% of renal injuries, whereas major parenchymal injuries occur in 10% to 15% of patients. As in the adult, it is these latter groups for which management is somewhat controversial; however, it is largely agreed among pediatric urologists that operative decisions are based mainly on hemodynamic status rather than imaging criteria. The potential for successful management of kidneys that appear severely injured in imaging studies is remarkable in the pediatric population, and a nonoperative approach is the norm. Surgical treatment is generally reserved for patients with ongoing bleeding or hemodynamic instability, for those who have clearly failed an attempt at nonoperative management, and for penetrating injuries.[26]

CLINICAL PRESENTATION AND DIAGNOSIS OF TRAUMA TO THE URETER, BLADDER, URETHRA, AND EXTERNAL GENITALIA

Ureter

Ureteral injuries are relatively uncommon, occurring in approximately 4% of patients with penetrating abdominal injuries and in less than 1% of those with blunt abdominal trauma. Concomitant visceral injury occurs in the majority of patients with ureteral injuries from penetrating trauma. Although hematuria is an important sign of ureteral injury, it may be absent 15% to 45% of the time. As such, a high index for suspicion of ureteral injury is critical.[27-29] In fact, the ureter is one of the most common sites of missed injury during laparotomy, with one recent report noting a missed injury rate of 11%.[13] Although direct visualization of the ureter is the mainstay of detection of ureteral injury at the time of laparotomy, imaging modalities useful for detection of ureteral trauma also include an IVP and contrast-enhanced CT scan with excretory phase.[16] Failure of the distal ureter to opacify or the presence of ipsilateral hydronephrosis on a CT scan should raise concern for a potential injury.[30,31] When noninvasive imaging fails to provide sufficient detail regarding ureteral anatomy or the specific nature of an injury, cystoscopy with retrograde pyelography and possible ureteral stent placement may be indicated.

Bladder

Sudden compression of the full bladder, shear forces, or a pelvic fracture may result in a blunt rupture, especially when the bladder is full. Rupture may be accompanied by lower abdominal pain, an inability to void, and suprapubic or perineal ecchymosis. The cardinal sign of injury to the bladder is gross hematuria, present in greater than 95% of cases, whereas only about 5% of patients will only have microscopic hematuria.[32] Over 80% of patients with a bladder rupture

have an associated pelvic fracture in health care centers with a high percentage of blunt trauma. An association of bladder rupture with disruption of the posterior urethra, along with the occurrence of a pelvic fracture, may occur in 10% to 20% of patients.[33,34] Overall, recent data indicate that genitourinary injury occurs in approximately 15% of pelvic fractures in the pediatric setting[15] and that the incidence of injury to a pelvic organ is fairly comparable between adult and pediatric patients.[35,36]

Voiding cystogram with postvoid film is the standard method for diagnosis of injury to the bladder (Fig. 40-9).[37] It is important that the bladder be adequately filled to avoid false-negative studies. For the adult bladder, the standard volume of filling is 300 to 400 mL of iodinated contrast (30% iodine commonly used), which is infused through the indwelling Foley catheter by gravity. Alternatively, the bladder can be filled by gravity to a point at which the patient describes a sense of bladder fullness. If the patient is unable to indicate that there is a sense of fullness, using a standard filling volume is a useful methodology. A vertically oriented abdominal filling film image, designed to show the entire abdomen, should be obtained. Postdrainage films are necessary to avoid false-negative cystograms in which extravasated contrast may be missed if located only anterior or posterior to the distended bladder on an anteroposterior film. Patterns of contrast extravasation have been described for intraperitoneal, extraperitoneal, and combined ruptures (Fig. 40-10). Hematuria of the bladder without contrast extravasation on

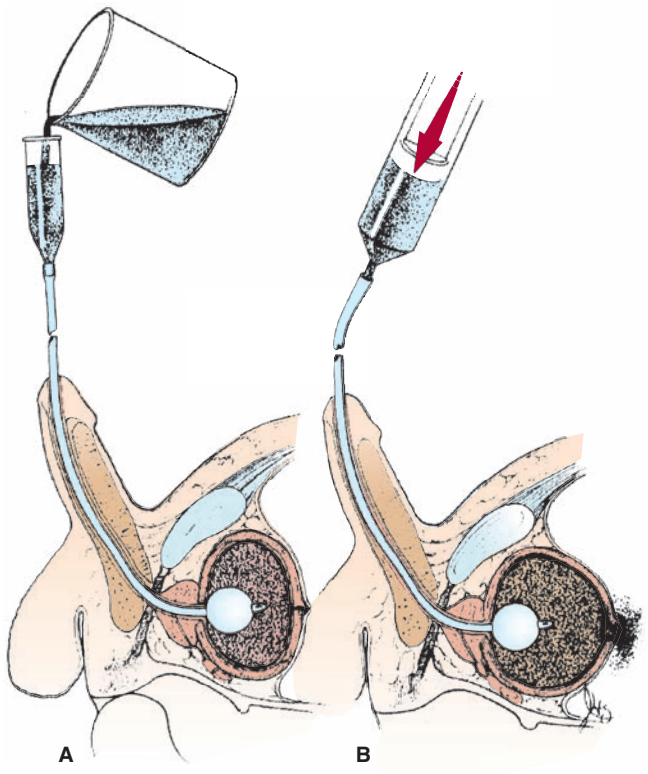

FIGURE 40-9 (**A** and **B**) Stress cystogram: through Foley catheter, the bladder is filled by gravity to a standard volume (300–400 mL typically in adult) or to the point of perceived fullness by patient. Plain radiograph is obtained to allow visualization of upper and lower abdomen, followed by washout film.

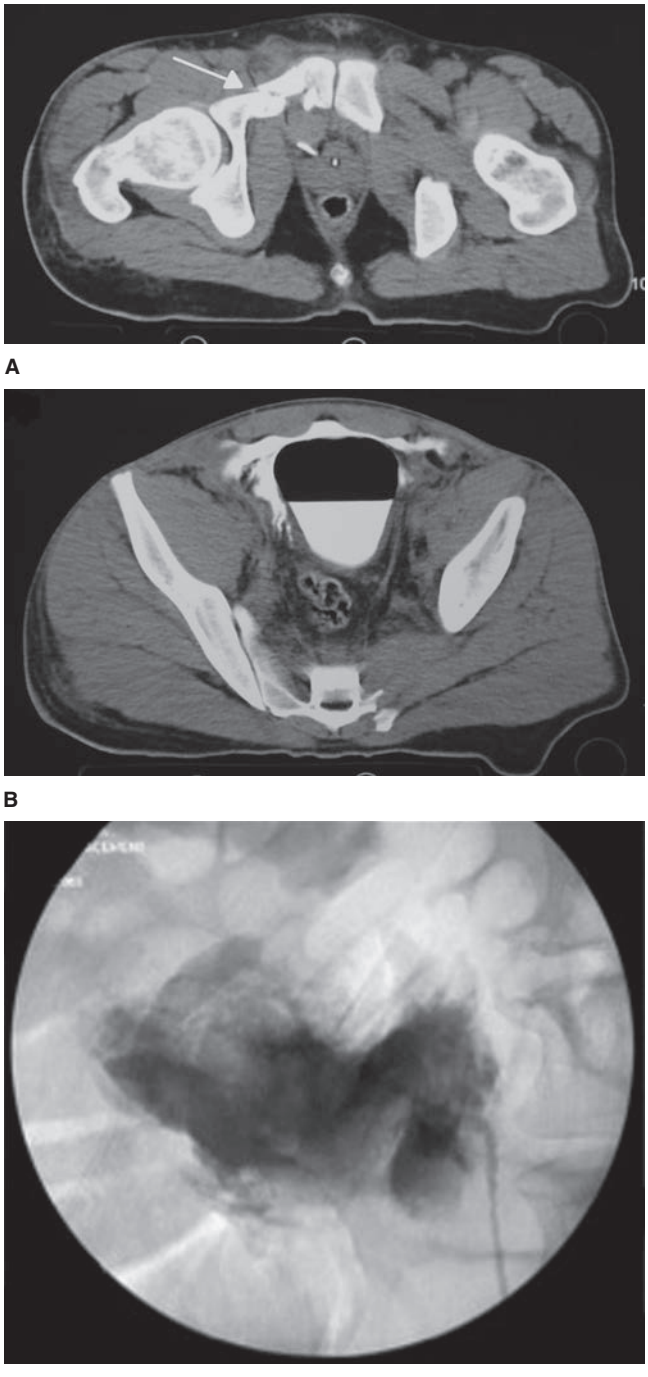

FIGURE 40-10 Bladder: stress cystograms for assessment of suspected bladder injury following blunt trauma to pelvis. (**A**) Pelvis computed tomography (CT) scan (white arrow indicates pelvic fracture). (**B**) CT cystogram reveals extraperitoneal bladder rupture with contrast extravasation confined to the retropubic space. (**C**) Voiding cystogram postdrainage film reveals extraperitoneal bladder rupture.

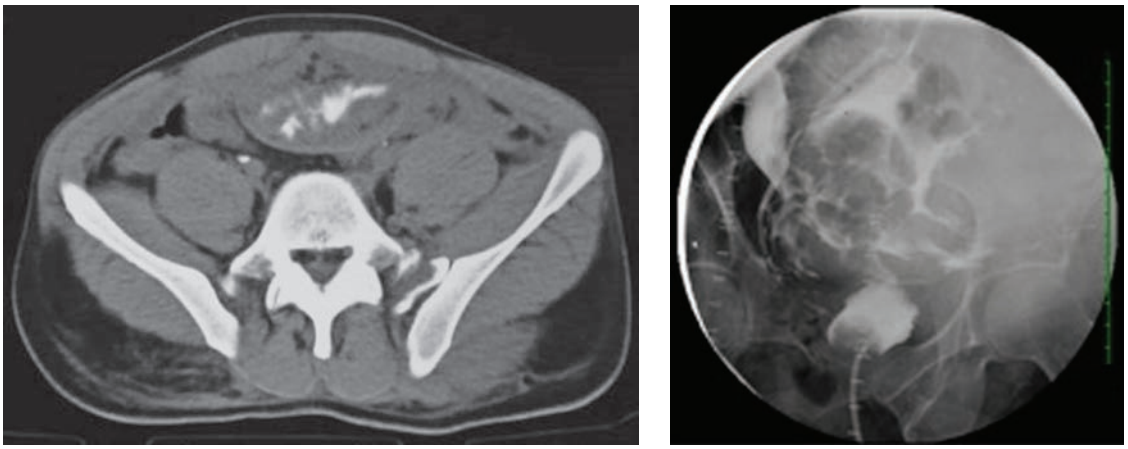

A B

FIGURE 40-11 (**A**) Computed tomography cystogram with intraperitoneal rupture (contrast delineating intraperitoneal small bowel). (**B**) Voiding cystourethrogram postdrainage film of intraperitoneal bladder rupture (contrast delineating intraperitoneal small bowel).

a properly performed voiding cystogram is consistent with a contusion or minimal mucosal injury, which is uniformly managed nonoperatively.

Currently, cystogram is most commonly obtained using a CT technique (Fig. 40-11A).[38] The advantages of CT cystograms are the speed to obtain the images, accuracy of extravasation detection, and the lack of need for voiding images (Fig. 40-11B). Studies comparing the accuracy of standard radiographic stress cystography versus CT cystography suggest equivalent capability in defining and staging bladder injuries. Simply clamping a bladder catheter following intravenous contrast administration, with the expectation that passive filling with contrast-opacified urine will suffice, is not adequate and will result in an unacceptably high percentage of false-negative examinations, with either the standard radiographic or the CT technique.[38] In selected cases, flexible cystoscopy may aid in the acute diagnosis of bladder injury and placement of a urinary Foley catheter.[39]

Urethra

Trauma to the anterior urethra may result from straddle injuries with sudden compression at the level of the mid urethra to deep bulbar urethra against the inferior pubic arch. Urethral distraction injuries or posterior urethral disruption may accompany pelvic fracture in 4% to 10% of patients. Bilateral fractures of the pubic rami, especially when accompanied by an open pelvic ring (abnormally distracted sacroiliac joint), may also be present in patients who have suffered posterior urethral disruption. The classification system used to further describe urethral trauma is discussed in the earlier section "Injury Grading and Scoring Systems for Genitourinary Injuries." It is important to determine from the urethrogram if an injury is partial (contrast passes proximal to the point of extravasation, filling the more proximal urethra or bladder) or complete (all contrast extravasates and none enters the urethra proximal to injury or bladder) because this factor has an impact on selection of management.[40]

Blood appearing at the urethral meatus, inability to void, presence of a perineal hematoma, and inability to clearly palpate the prostate on rectal examination should make one suspicious of urethral injury (Fig. 40-12). When urethral injury is suspected, a RUG should be performed (Fig. 40-13). Approximately 30 mL of iodinated contrast is instilled via a catheter inserted just within the urethral meatus, and then a plain radiograph is obtained. A normal RUG should demonstrate contrast filling an intact urethra and entering the bladder without extravasation. No attempt at insertion of a bladder catheter should be pursued until a negative RUG is obtained to avoid further complicating a urethral rupture (Fig. 40-14).

Following placement of either a urethral catheter (if the urethra proved normal or by a urologist using direct vision techniques in selected incomplete injuries) or a suprapubic catheter (if urethral disruption was revealed), a stress cystogram should still be performed if hematuria is present. This is because 10% to 15% of patients with urethral disruptions from a pelvic fracture will have a concomitant injury to the bladder.

External Genitalia

Genital injuries represent a diverse group of traumatic events.[41] These include the classic blunt penile fracture (which occurs from forceful bending of the erect penis, often during intercourse), crushing injuries with rupture of the testis, penetrating injuries, and industrial accidents. Amputation injuries of the penis or testicle can occur due to assaults, self-mutilation, or industrial trauma. After major blunt trauma to the scrotum, the risk of testicular rupture is approximately 50%. An ultrasound examination of the scrotum may be valuable to distinguish testicular rupture from a hematoma

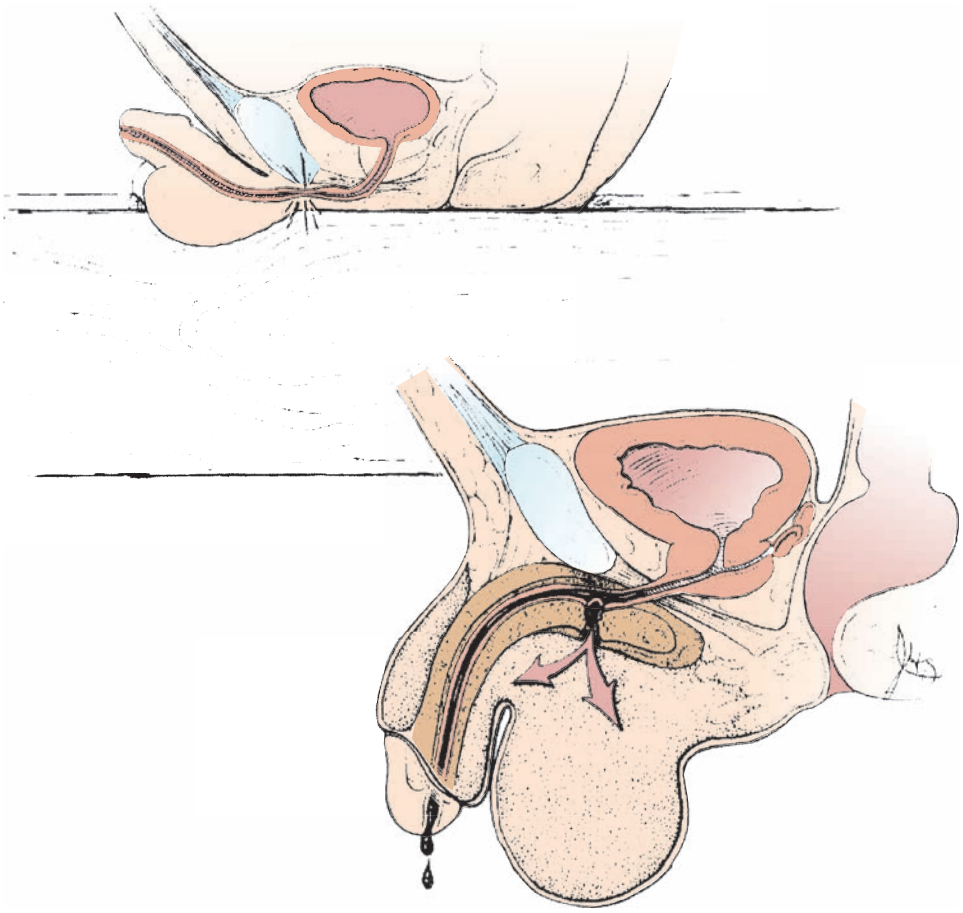

FIGURE 40-12 Mechanism of anterior urethral disruption due to straddle injury; extravasation pattern and hematoma limited in this case by Colles' fascia, due to rupture of Buck's fascia along with full thickness of urethral wall. Hematoma and urinoma may extend along shaft of penis and into scrotum and perineum.

of the scrotal wall or hematocele (blood within the tunica vaginalis compartment).

NONOPERATIVE MANAGEMENT OF GENITOURINARY INJURIES

Although nonoperative management for many urologic injuries has become well established, the selection of operative versus nonoperative management for certain genitourinary injuries remains controversial. Recent reviews of urologic management based on careful assessment of levels of evidence reveal a notable paucity of level 1 prospective management studies.[1-5] The relatively recent efforts to accurately and uniformly describe and stage the nature of injuries and the lack of long-term follow-up leave many questions regarding the best way to manage many forms of genitourinary trauma.

Kidney

It has long been accepted that low-grade renal injuries can be managed nonoperatively with a high success rate. Renal contusion and subcapsular hematomas are routinely managed expectantly and only rarely would require surgical or other interventions in such cases. These injuries heal spontaneously with few exceptions, as do low-grade parenchymal lacerations. Depending on the institutional bias and experience, some urologic trauma surgeons may limit operative management of renal injuries to those in which the patient is hemodynamically unstable, almost regardless of imaging findings. Alternatively, others would include high-grade injuries, presumably translating into a higher incidence of postinjury complications with nonoperative management. A number of indications for renal exploration following injury have been suggested by McAninch and Carroll.[42] These include hemodynamic instability, an ongoing hemorrhage requiring significant transfusion, pulsatile or expanding hematoma upon exploration, and avulsion of the pedicle. These strong indications for surgical or other procedural intervention remain widely accepted. Relative indications for surgical intervention have included high-grade injuries, large perirenal hematoma, presence of urinary extravasation on contrast studies, significant devitalized fragments of parenchyma, and findings in the operating room during laparotomy with an incompletely

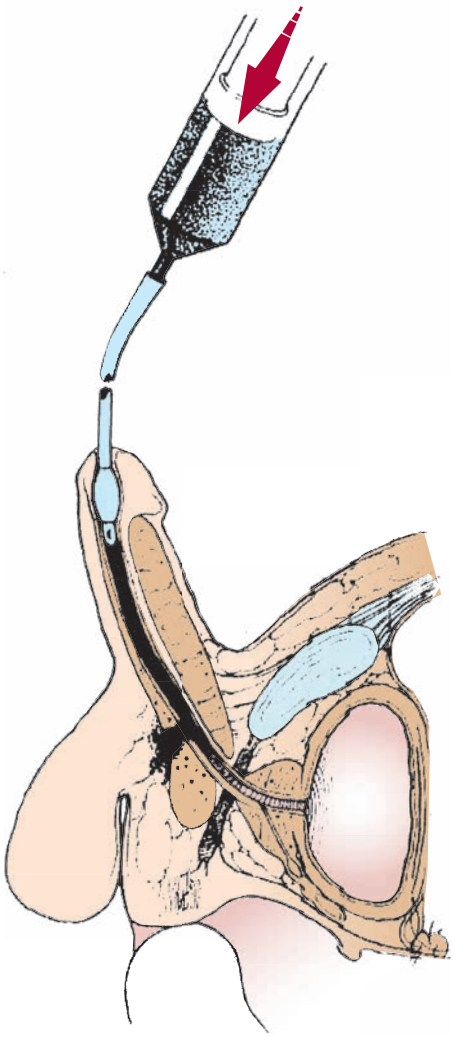

FIGURE 40-13 Technique of retrograde urethrogram. Retrograde urethrogram: catheter is inserted into urethral meatus, with minimal balloon inflation to maintain position and allow hands to be out of x-ray field. Contrast is instilled to distend urethra.

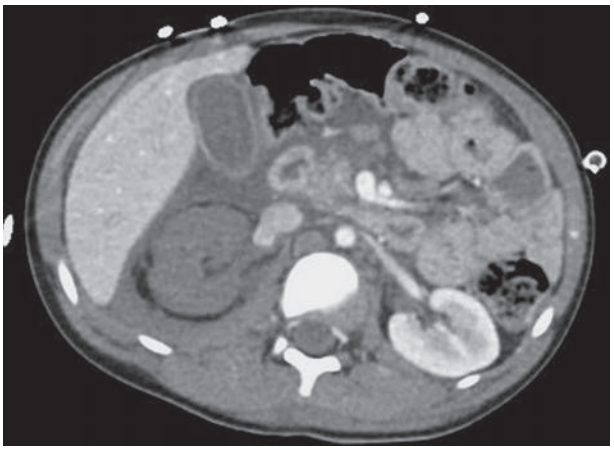
(**B**) Retrograde urethrogram with complete posterior urethral injury. Note the disconnected bladder, also known as "pie in the sky."

staged injury. Although there is lack of consensus regarding these relative surgical indications, there is a general trend toward nonoperative management in many of these situations as long as hemodynamic stability is maintained.[26]

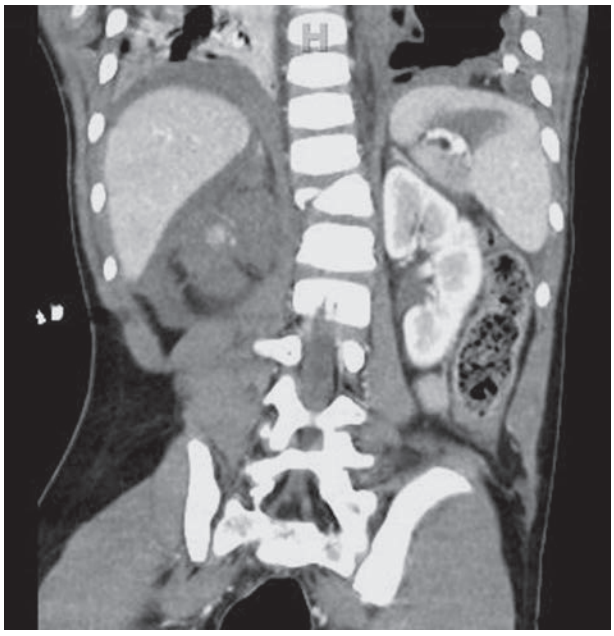
Proponents of the nonoperative management approach suggest that many high-grade injuries will heal without surgery, complications can frequently be managed with nonsurgical techniques (percutaneous drainage, stenting, angiographic embolization), and renal salvage rates are better overall when renal exploration is avoided. This school of thought would maintain that, with few exceptions, it is only hemodynamic instability that should prompt surgical intervention for the injured kidney, not injury stage or other predetermined imaging criteria.

In contrast, proponents of a more aggressive surgical approach would suggest that higher grades of renal injury carry an unacceptably high complication rate and that such complications, when they occur, have a high likelihood of resulting in otherwise avoidable morbidity or nephrectomy (Fig. 40-15). Proponents would suggest that early exploration offers the advantages of early debridement of devitalized tissue, definitive hemostasis, repair of injuries to the collecting system, and early utilization of appropriate drainage. As such, postinjury infection, urinoma, and hemorrhage risk are minimized. The descriptions of "absolute" and "relative" indications for renal exploration of trauma have been suggested to attempt to provide assistance in this decision-making process.[42-44]

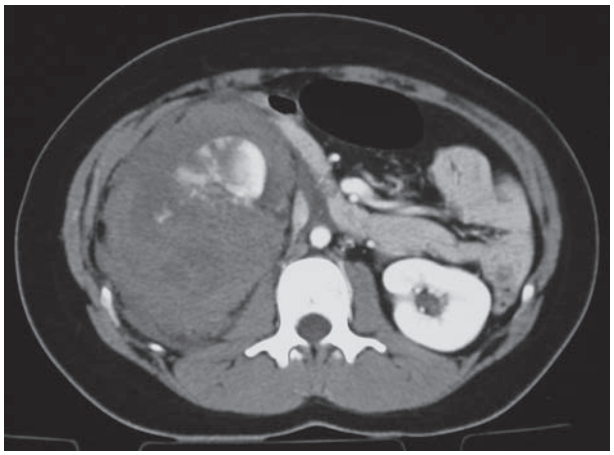
For certain injuries, operative management is commonly accepted. These include blunt avulsion or penetrating lesions of the renovascular pedicle, AAST grade V parenchymal injuries, and ureteropelvic avulsion or complete avulsion of the



A



B



C

FIGURE 40-15 Grade IV and V parenchymal injuries: (**A**) grade IV vascular; (**B**) grade IV right renal laceration and spinal fracture; and (**C**) grade V parenchymal laceration.

fornices. Although occasional case reports have suggested that grade V renal injuries can be managed nonoperatively, most studies demonstrate that 90% to 100% of such injuries require urgent nephrectomy.[45] In reviewing the literature on nonoperative management of grade V renal injuries, the accuracy of classification is questionable, and some reports of successful management of grade V injuries are likely describing grade IV parenchymal lacerations. In general, attempts at nonoperative management of true grade V renal injuries are not advised and may expose the patient to substantial risk, although some controversy remains in this area.[46]

Patients with significant ongoing bleeding from an injured kidney where angiographic control is not likely to correct the problem, is not available, or has failed will also require prompt operative attention. For penetrating renal injuries in cases where laparotomy will occur regardless, especially when preoperative radiologic staging has not been performed or is incomplete, operative management is widely recommended.

When moderate or high-grade renal injuries are selected for nonoperative management, certain general principles apply. Such patients are at risk for continued bleeding or significant delayed bleeding, and it is important that they be observed in the surgical intensive care unit. Serial abdominal examinations are essential, as are serial laboratory studies including hemoglobin level and electrolyte status. Typed and cross-matched blood should be available for the first 24 to 48 hours. The patient's hemoglobin should be maintained in such a range that a sudden drop from renewed bleeding would not be catastrophic. Particular attention should be paid to the size of the perirenal hematoma on initial imaging. Large hematomas suggest bleeding from larger intrarenal vessels and, presumably, indicate cases in which the risk of continued bleeding is greater. Elderly patients or patients with cardiovascular disease should be transfused more liberally, with a low threshold for intervention, as any sudden substantial blood loss may not be tolerated. When managing high-risk renal injuries nonoperatively, it is advisable to reimage such injuries at 48 to 96 hours to allow early diagnosis of complications such as enlargement of the perirenal hematoma, formation of a urinoma, or evolution of ischemic parenchyma. Early knowledge of such untoward events allows for treatment before the patient demonstrates complications such as sepsis, azotemia, or severe anemia.[47]

It is routine to impose a period of strict bed rest with nonoperative management of a major renal injury, although specific data to support this policy are lacking. Nevertheless, it seems reasonable to have the patient remain on bed rest for the first 24 to 72 hours or until significant gross hematuria resolves and then reinstitute ambulation cautiously in a monitored environment. If nonoperative management has been successful, patients should be instructed to avoid significant physical exertion until follow-up imaging reveals adequate healing.

In cases of emergent exploratory laparotomy and retroperitoneal bleeding, an intraoperative IVP with intravenous bolus injection of iodinated contrast (2 mL/kg body weight) and a 10-minute excretion film can offer better staging of

renal/ureteral injuries and presence of both kidneys. If significant anatomic distortion is observed, this is considered suggestive of major parenchymal disruption and/or injury to the collecting system for which exploration may be of benefit. If the kidney appears grossly intact, observation would be selected, often with postoperative CT scanning for more precise imaging. In general, current trends in the urologic literature favor nonoperative management of most blunt renal injuries in the absence of staged grade V lesions, active bleeding noted intraoperatively, or hemodynamic instability.

Injuries to branch renal arteries from blunt trauma, resulting in segmental devascularization without laceration, can be managed nonoperatively with a low complication rate and angiographic studies and vascular stent placement.

Penetrating injuries to the kidney are accompanied by injury to nonurologic organs in a large proportion of cases, and the majority of these patients will undergo laparotomy. These patients may or may not be imaged preoperatively. The issue of whether to explore the (suspected) renal injury in such cases is addressed in the later section "Operative Management of Specific Genitourinary Injuries." When the general trauma surgeon sees no clear operative indication and penetrating renal injury is possibly present, the urologist will have to decide on operative versus nonoperative management based on the clinical status of the patient and on the findings of a contrast-enhanced CT scan. In general, patients may be safely managed nonoperatively if they present with penetrating injuries (stab wound) to the kidney that involve the lateral and peripheral parenchyma with small perirenal hematomas, minimal if any extravasation of contrast, and in which the pedicle and renal sinus structures are not at risk (Fig. 40-16). Conversely, penetrating renal lesions that result in large perirenal hematomas; traverse the deep medial renal parenchyma, renal sinus, or hilar region; or cause major urinary or vascular extravasation carry higher risks for nonoperative management (Fig. 40-17). The risk of delayed bleeding from such injuries is significant, and some authors have suggested prophylactic arteriography with embolization of violated arterial branches prior to nonoperative management. In addition, the risk of a missed associated visceral injury must be considered with nonoperative management of penetrating renal trauma. In one retrospective review of the nonoperative management of penetrating renal trauma, 55% of renal stab wounds and 24% of renal gunshot wounds were managed nonoperatively with low complication rates.[48]

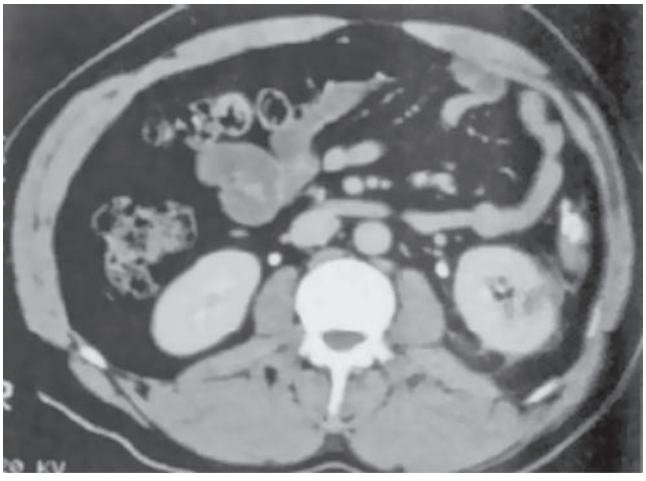


FIGURE 40-16 Penetrating renal injury, successful nonoperative management. Staging computed tomography scan demonstrating laceration to lateral left kidney. There is minimal perinephric hematoma, no urinary extravasation, and no devitalized parenchyma. Injury is lateral, and laceration does not extend into hilar region or renal sinus structures. Posterior descending colon is in proximity to injury, but general surgeons are prepared to manage nonoperatively. Ideal candidate for nonoperative management of a penetrating renal injury.

Although uncommon, blunt or penetrating trauma to the adrenal gland warrants brief mention. If an adrenal hematoma is not expansile, it is managed nonoperatively as with parenchymal injuries to other solid organs. If the adrenal gland is explored due to the path of a stab or bullet wound, suturing to achieve hemostasis and/or placement of biologic fibrin glue may prevent total adrenalectomy. Because each adrenal gland has several sources of arterial blood supply, devascularization from trauma is rare.

Ureter

Nonoperative management of ureteral trauma has limited applications. When a ureteral injury is recognized intraoperatively, surgical repair is favored.[49,50] Reviews of the outcomes of ureteral injuries indicate that most types of ureteral trauma fare better with early operative repair when compared to delayed repair or attempts at nonoperative management, with the exception of limited iatrogenic injuries from endoscopy. This is the case for stab and gunshot wounds, as well as avulsion injuries from blunt trauma (Fig. 40-18). Nonoperative management is performed in selected patients with missed ureteral injuries or other settings of delayed diagnosis or in patients in whom damage control strategies are being adopted. Traditional urologic teaching dictates that if ureteral trauma is recognized soon after injury, operative repair is performed. More significantly, delayed recognition is managed with utilization of endoscopic or interventional radiologic techniques (stenting or percutaneous nephrostomy diversion) followed by delayed operative reconstruction as indicated. This approach has developed due to the long-standing recognition of problems such as inflammation, edema, friability, presence of a urinoma, and increased risks and complications of reconstructive efforts encountered when operative intervention is pursued greater than 3 to 5 days after injury. Ureteral contusions recognized intraoperatively, due to either penetrating or blunt trauma, may be managed nonoperatively and observed; however, some reports suggest that the risk of late perforation and urinary extravasation may be reduced by intraoperative insertion of a ureteral stent.[51]

When nonoperative management is selected, retrograde ureteropyelography with attempted retrograde ureteral stent placement is often performed. Alternatively, percutaneous renal drainage may be the treatment of choice. The selection

FIGURE 40-17 Penetrating renal injury, complicated. (**A**) Staging computed tomography scan of abdomen following single stab wound to right posterior flank in patient presenting with gross hematuria. Deep laceration of right kidney with moderate-sized perinephric hematoma. Injury extends into renal sinus region, although no contrast extravasation is noted. After initial attempt at nonoperative management, patient develops major secondary hemorrhage manifested by profuse gross hematuria, resulting in hypotension, and requiring transfusion of 4 units of packed red blood cells. (**B**) Arteriogram reveals two areas of arteriocalyceal fistula, successfully managed with subselective embolization. (**C**) Delayed arteriogram image demonstrates wedge-shaped infarct defect due to embolization. Remainder of hospital course uneventful. Embolization is ideal means of managing this problem because the only indication for intervention is hemorrhage.

between these two approaches depends on the hemodynamic and metabolic stability of the patient as well as specific anatomic and logistical factors. These include the appropriateness of performing a procedure under general anesthesia, the ability of the patient to undergo a procedure in a prone position (generally necessary for obtaining percutaneous renal access), the skill and availability of interventional radiology, and the expected ease of percutaneous access. The latter depends largely on the anatomy and degree of distension of the collecting system and the presence of a perirenal hematoma. The finding of coagulopathy is often considered a relative contraindication to percutaneous renal drainage because renal bleeding is always a risk of such procedures. Achievement of percutaneous access can be followed by antegrade ureteral stenting if there is ureteral continuity and a guidewire can be placed across the injury into the bladder. Conversion from a nephrostomy tube to a percutaneous antegrade universal stent, which can be changed, manipulated, opened to external drainage, or

FIGURE 40-18 Ureter: gunshot wound to ureter with missed injury in a patient who had no hematuria on initial presentation. Patient developed abdominal fluid collection after laparotomy; intravenous pyelogram demonstrated missed ureteral injury 5 days postoperatively. Injury was initially managed with percutaneous nephrostomy and antegrade placement of universal stent. Long, densely fibrotic stricture of midureter developed, as shown here, ultimately requiring nephrectomy. A high index of suspicion is necessary to detect penetrating ureteral injuries at the time of initial laparotomy; outcomes are significantly improved with early recognition and prompt operative repair in such cases.

capped to allow internal drainage, may be attempted. Following an appropriate period, a pullback antegrade nephrostogram will determine if healing is complete and the patient is ready for stent removal with clamping of the nephrostomy tube.

When this type of management is used, ureteral strictures may be expected in approximately 50% of cases. A stricture may require an attempt at endourologic management, although delayed surgical reconstruction of the ureter is often necessary.

With blunt trauma, limited ureteral injuries with minimal urine extravasation may be treated with retrograde pyelography and retrograde ureteral stent placement. For penetrating injuries, small-gauge shotgun pellet wounds may create minute ureteral perforations that can be managed nonoperatively as well. Such injuries may be noted at laparotomy or may be seen on a contrast-enhanced CT or on intravenous or retrograde pyelography. Again, such cases represent the rare exception to the general principles that favor early operative exploration and repair when technically and medically feasible.

Bladder

Nonoperative management of extraperitoneal injury to the bladder has been the standard approach for over 10 years, largely as a result of the studies in which catheter drainage alone was consistently successful.[52,53] An 18F to 20F or larger bladder catheter should be used to allow free drainage for the adult. The catheter is left indwelling for 10 to 14 days followed by a cystogram to confirm cessation of extravasation prior to removal. After this period, more than 85% of bladder injuries will show absence of extravasation. If extravasation persists, another 7 to 10 days of catheter drainage followed by repeat cystography is appropriate. Rarely, persistent extravasation will occur after a prolonged period of catheter drainage. In such cases, CT scanning and/or cystoscopy is indicated to ensure that a foreign body such as a bony spicule from a pelvic fracture or some other anatomic cause is not resulting in failure of the laceration to properly heal. Indications for initial selection of operative management instead of catheter drainage alone include concomitant injury to the vagina or rectum, injury to the bladder neck in the female, avulsion of the bladder neck in any patient,[54] and the need for pelvic exploration for other surgical indications. If retropubic access is required for internal fixation of a pelvic fracture, surgical repair of the bladder is favored in order to prevent continued extravasation adjacent to orthopedic hardware. Open pelvic fractures may also require operative repair of the bladder. If catheter realignment is planned, the presence of combined extraperitoneal and intraperitoneal rupture or combined extraperitoneal bladder rupture and posterior urethral injury would be considered an appropriate situation to proceed with operative repair of the bladder as well. Finally, clot formation with troublesome occlusion of the drainage catheter may mandate operative repair.[55]

Intraperitoneal ruptures of the bladder are uniformly managed with operative repair. Such injuries typically result in large, stellate tears in the dome of the bladder due to the sudden rise in pressure within a full bladder as from a blow to the lower abdomen or compression by a seat belt. Rare exceptions to the routine application of operative repair for intraperitoneal bladder rupture include minimal intraperitoneal perforations. These usually occur during endoscopic procedures, mainly when a resectoscope is being used for resection of a bladder tumor or during biopsies of lesions of the dome and anterior wall, or other minimal iatrogenic injuries. Several reports have appeared in recent years describing laparoscopic techniques of repair for iatrogenic injuries.[56,57]

The application of laparoscopic repair techniques to manage intraperitoneal ruptures of the bladder from blunt trauma and other forms of bladder injury is being explored at several centers.

For penetrating injury to the bladder, nonoperative management is occasionally applicable in carefully selected extraperitoneal injuries.[58] Such patients may require proctoscopy and/or pelvic arteriography. Selectively, peritoneal lavage or laparoscopy may play a role in such cases to ensure that the peritoneal surface of the pelvis is intact. Cystoscopy and

upper tract imaging (IVP or retrograde pyelography) have been shown to be helpful in assuring that the magnitude of the defect in the bladder is minimal and is likely to heal with catheter drainage alone. The considerations for conversion to operative management, postinjury monitoring, postinjury imaging, and catheter management are comparable to those used with blunt extraperitoneal injuries.

Urethra

The nature (blunt or penetrating) and location of the injury (anterior vs posterior urethra), completeness (partial vs complete circumferential laceration), presence and severity of associated injuries, and the stability of the patient all impact the selection of management for urethral trauma.[59,60] When urethral trauma is suspected, RUG should be performed. If the RUG reveals minimal extravasation and flow of contrast past an anterior injury from blunt trauma into the proximal urethra and bladder, some authors have suggested that a single attempt at gentle passage of a bladder catheter should be performed. Other urologists believe that even minimal blind instrumentation of the injured urethra is ill advised, preferring an endoscopically guided approach. We believe that endoscopically guided instrumentation of the injured urethra is preferable to blind insertion of a catheter. The most conservative recommendation is to avoid any blind instrumentation of the injured urethra by the nonurologist. For incomplete anterior urethral injuries, urethral catheterization is a reasonable therapy. Early urethral realignment techniques for posterior urethral trauma fall within the realm of the experienced urologist and constitute operative procedure. Penetrating injuries to the anterior urethra are generally managed with operative exploration and repair.[61] Penetrating injuries to the posterior urethra may present complex challenges in management, may be complicated by adjacent rectal injuries or other intrapelvic or visceral injuries, and are also considered later.

Genital Injuries

Although penile fractures and testicular ruptures are best managed with early recognition as well as operative exploration and repair, certain genital injuries due to blunt trauma may be managed nonoperatively.[62] This would be the case when the injury is limited to the subcutaneous tissues, the tunica albuginea and urethra of the penis are intact, and the tunica albuginea of the testes is intact as well. For penile injuries, nonoperative management is appropriate for rupture of subcutaneous vessels, resulting in limited ecchymosis or a hematoma. Scrotal trauma may be managed nonoperatively when the testis is intact and there is a limited hematocele that is not bothersome to the patient. In most situations, however, significant genital trauma is best managed by operative exploration and repair. If physical findings are suspicious of a significant injury to deep tissue or the injury cannot be ruled out by imaging studies, operative exploration is prudent. This is because the outcomes of nonoperative management of such injuries like penile fracture or testicular rupture are poor as compared with the very high success rates of early operative repair.[63] Because the relative morbidity of surgical exploration of the external genitalia is minimal and the morbidity of missed injuries or delayed recognition is significant, one should err in the direction of operative management for such injuries.[41,64]

A scrotal ultrasound demonstrating heterogeneity of the testicular parenchyma is suggestive of testicular rupture, even if clear loss of continuity of the investing tunica albuginea cannot specifically be identified.[65] Certainly, if a clear defect in the continuity of the testicular tunic is noted on ultrasound, the diagnosis of testicular rupture should be suspected and operative repair undertaken. Patients with a significant hematocele (blood and/or clot within the tunica vaginalis compartment) with an intact testis may be observed, although they may often have a quicker recovery of activity and more rapid resolution of scrotal pain and swelling if this lesion is evacuated surgically. An intratesticular hematoma without testicular rupture is generally managed nonoperatively. At times, testicular ultrasound may demonstrate an abnormality in which a preexisting testicular lesion such as a germ cell neoplasm is suspected. Such may be the case when relatively minor trauma causes a significant intratesticular bleed or testicular rupture. When preexisting testicular pathology is suspected and nonoperative management is selected for the traumatic lesion, it is critical that the testis be reevaluated until the suspicious abnormality resolves or its continuing presence mandates further imaging and intervention.

For genital injuries involving significant loss of soft tissue or skin, nonoperative management may be appropriate as an initial approach, especially when more immediately life-threatening injuries demand priority. Wounds should be cleansed and a conservative approach should be adopted when determining whether to perform debridement of genital skin or soft tissues of marginal or questionable viability. Secondary operative management and delayed reconstruction with skin grafting or other tissue transfer techniques is often necessary when wounds are initially managed in this manner.[66]

OPERATIVE MANAGEMENT OF SPECIFIC GENITOURINARY INJURIES

Kidney

Renal exploration for trauma begins with prioritization of the injuries and determining that the initial operation is in fact the appropriate time to embark on the renal exploration (see the later section "Damage Control Principles in Genitourinary Trauma"). When contemplating exploration of an injured kidney in the absence of preoperative imaging, some assessment of the presence and normalcy of the contralateral kidney should be undertaken. Palpating the contralateral renal fossa for a grossly normal kidney is certainly appropriate and is often the only assessment necessary. In select cases, an intraoperative IVP may provide more precise information. This can be performed by administering 1 to 2 mL/kg of iodinated contrast intravenously and then obtaining a

10-minute excretion film. This can occur while other general surgical tasks are being accomplished to avoid wasting time. While an intraoperative IVP provides some additional reassurance that a functional contralateral kidney is present when exploring an injured kidney, it is generally advised to proceed with exploration of the injured kidney based on contralateral renal palpation alone.

If it is jointly determined by the urologist and the general surgeon that renal exploration should occur, exploration is carried out through an anterior vertical incision in Gerota's fascia. There has been some controversy regarding the importance of first obtaining vascular control of the renal pedicle prior to renal exploration, as previously described.[67,68] Some proponents claim a markedly reduced nephrectomy rate if the renal vessels are first dissected and controlled with vessel loops. Others claim that this maneuver is unnecessary for successful renal exploration and repair. This controversy is probably overstated, as even those who do not believe that individual dissection of the renal vessels is essential prior to renal mobilization tend to use some other approach to control the pedicle or limit renal bleeding during examination and repair of the kidney. The bulk of the literature would suggest that the rate of otherwise unnecessary nephrectomies is minimized by having exposure and control of the renal pedicle prior to renal exploration. This can be achieved by the traditional maneuver of incising the posterior peritoneum lateral to the aorta and individually dissecting and looping the renal vessels on the side of the injury (Fig. 40-19). This can also be achieved by reflecting the colon medially first and then clamping the pedicle if significant bleeding is encountered upon opening the Gerota's fascial envelope (Fig. 40-20). Alternatively, the pedicle or the renal parenchyma can be compressed digitally (most applicable to polar injuries) without having individual control over the renal vessels. Certainly, if there is an injury to the pedicle suggested by a large or expanding medial hematoma in the vicinity of the great vessels, there is broad agreement that central vascular control should be the initial maneuver.

Following pedicle control or access, the colon and mesocolon on the side of the injury are dissected medially following incision of the peritoneal reflection. When the anterior surface of Gerota's fascia is fully exposed, a generous vertical anterior incision is made through the fascia and the kidney is fully mobilized. As indicated earlier in the section "Anatomy," it is important to dissect in an extracapsular plane and avoid inadvertently dissecting the renal capsule away from the underlying cortex. Accomplishing this is facilitated by beginning the dissection in an area of intact parenchyma rather than directly within the laceration. Completely mobilizing the kidney is very helpful, as it allows the kidney to be lifted anteriorly into the wound for complete inspection. If significant bleeding results during this maneuver, a noncrushing vascular clamp is applied to the renal artery, renal vein, or entire renal pedicle. An initial decision must be made regarding renal salvageability and the magnitude of the reconstructive effort that would be required to repair the injury. This is based largely on the amount of devitalized parenchyma, the degree of injury to the central vasculature and central collecting system, and the condition of the patient. If the kidney is determined to be reconstructible in an unstable patient, any significant intrarenal vascular injury can be rapidly sutured and the kidney can be packed off with laparotomy pads as other surgical injuries are treated. After repair of other injuries or at the time of a secondary surgical procedure, a formal exploration and reconstruction of the kidney are performed.

If, based on the anatomy of the injury, the kidney is not considered reconstructible, a nephrectomy is performed. It is preferable to separately ligate the renal artery and vein to avoid the potential for arteriovenous fistula. A rapid search is made for accessory or polar vessels that must be ligated as well. Although urologists frequently suture or simply ligate the renal artery and a long stump of vein, vascular surgeons and some urologists prefer to oversew the short right renal vein with a continuous 3-0 or 4-0 Prolene suture. For trauma nephrectomies, the ureter and adjoining vessels are ligated near the kidney, whereas the gonadal vein is ligated and divided when necessary with no need for concern for adverse impact on the gonadal structures.

If renal reconstruction is planned, several steps are generally followed (Fig. 40-21). Following evacuation of the hematoma, the kidney is carefully examined to identify lacerated vessels, the open collecting system, and devitalized parenchyma. Large areas of lacerated, devitalized parenchyma are excised sharply, whereas smaller vessels are controlled with an absorbable 3-0 or 4-0 suture. In general, an absorbable suture is used for intrarenal suturing, as a permanent suture may create a nidus for stone formation if in contact with the collecting system. If adequate closure of the collecting system is achieved, there is no need for stenting or a nephrostomy. If repair of the collecting system is tenuous or incomplete, placement of an internal stent (complemented by a bladder catheter) or a nephrostomy tube may decrease the risk of postoperative urinary extravasation and the formation of a urinoma.

Partial nephrectomy for polar lesions is performed using a "guillotine" technique with the transected vessels and collecting system closed as noted earlier (Figs. 40-22 and 40-23). Topical hemostatic agents may be placed within a parenchymal defect to aid in hemostasis, with the capsule closed over the defect and the hemostatic material. If the capsule can be closed with mattress sutures or absorbable bolsters following debridement or partial nephrectomy, parenchymal hemostasis is aided considerably. If capsular closure is not feasible, either due to the shape and location of the parenchymal defect or due to loss of the capsule from the injury or dissection, using absorbable materials or native tissue as a patch may be helpful if hemostasis is still problematic. The argon beam coagulator has also been used successfully in the kidney to achieve hemostasis in the parenchyma after suturing larger vessels and closing the collecting system. Topical hemostatic agents and tissue adhesives may be used on the kidney, collecting system, ureter, and other urologic repairs to aid in hemostasis and minimize the risk of postoperative urinary

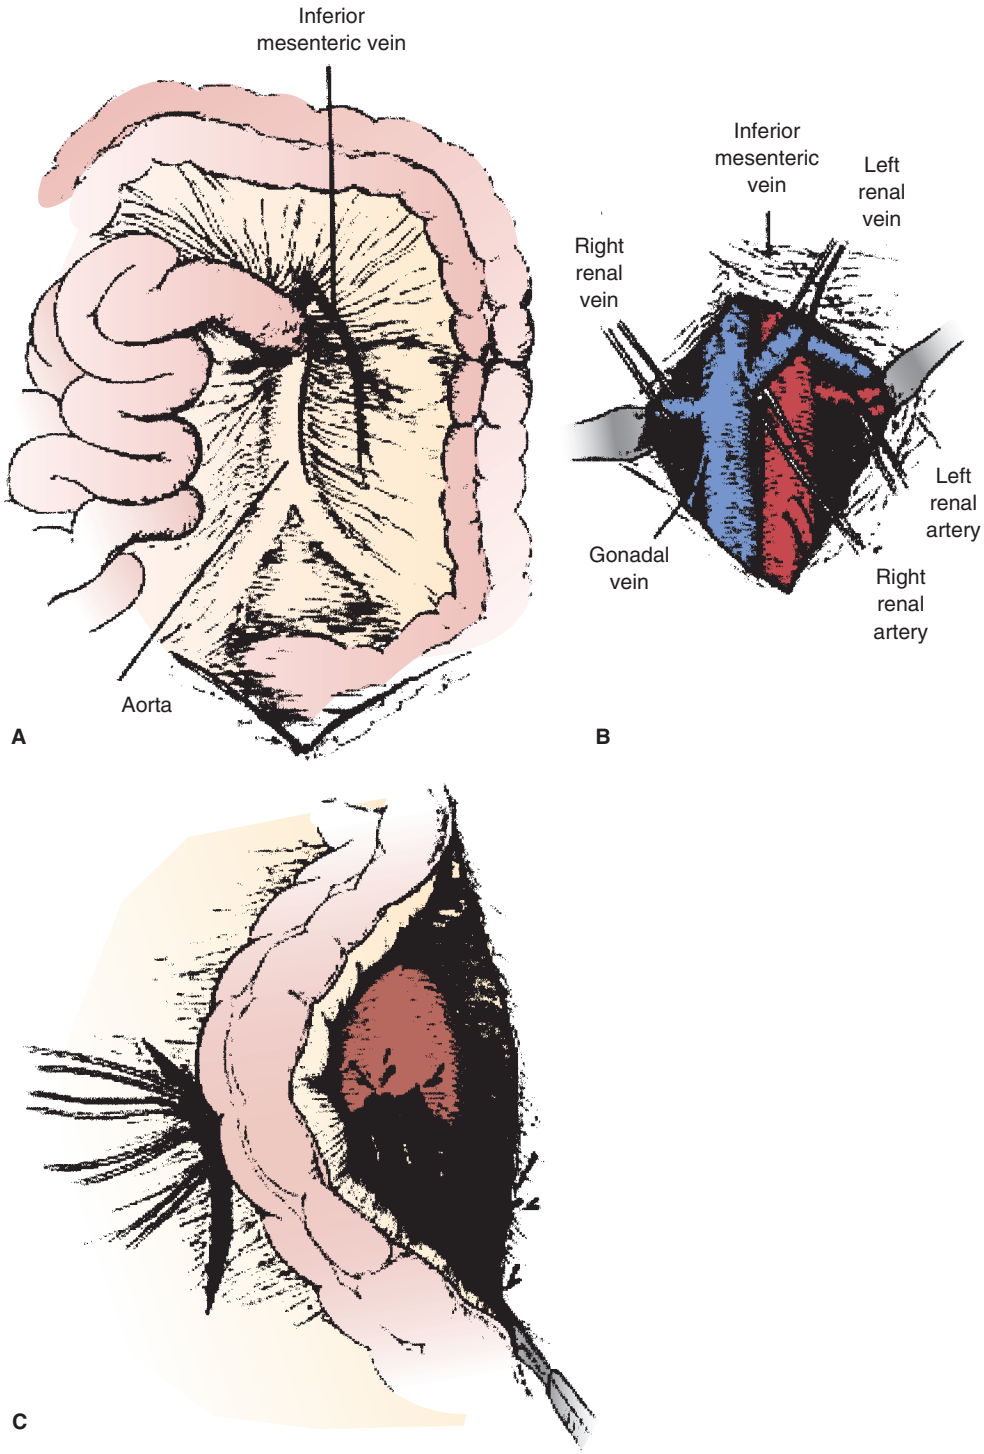

FIGURE 40-19 Surgical management of renal trauma: vascular control. Diagram demonstrating early vascular control prior to renal exploration. (**A**) The posterior peritoneum is opened over the aorta medial to the inferior mesenteric vein. (**B**) The renal vessels are individually dissected and surrounded with vessel loops. (**C**) The colon is reflected medially exposing the perinephric hematoma. Some clinicians believe preliminary control of the renal vessels is not necessary when performing renal exploration for trauma, although best renal salvage rates are reported when vascular access or control is obtained.

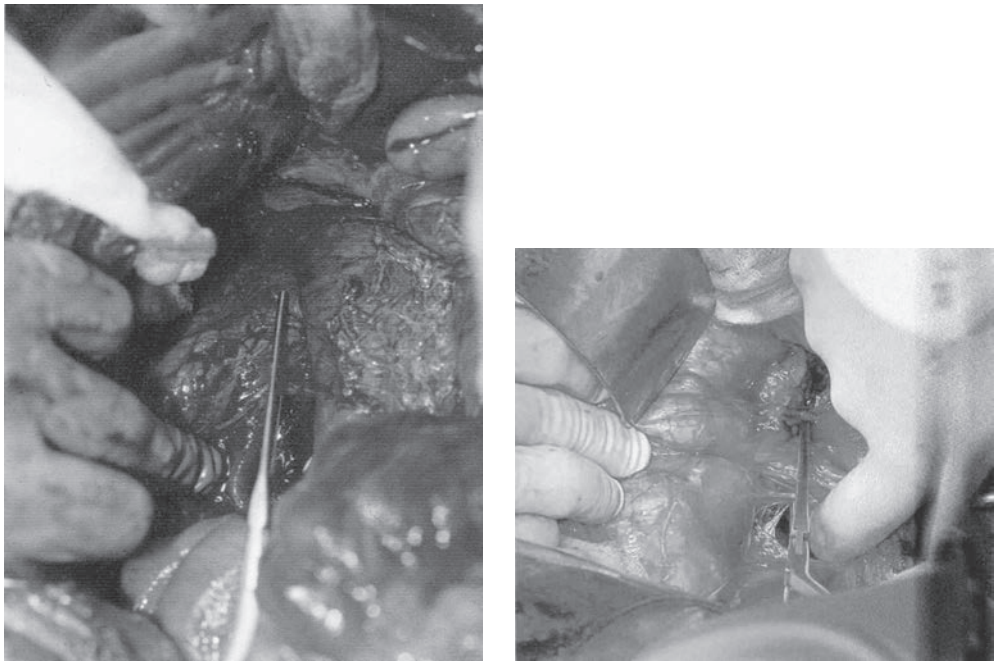

FIGURE 40-20 (**A**) Alternate means of obtaining vascular pedicle access prior to renal exploration. Colon is reflected medially initially. Blunt dissection lateral to vena cava allows creation of space anterior to psoas muscle for placement of pedicle clamp if necessary on renal exposure. (**B**) Comparable technique on the left side, creating space for pedicle clamp lateral to aorta. This approach has been used successfully in the author's center.

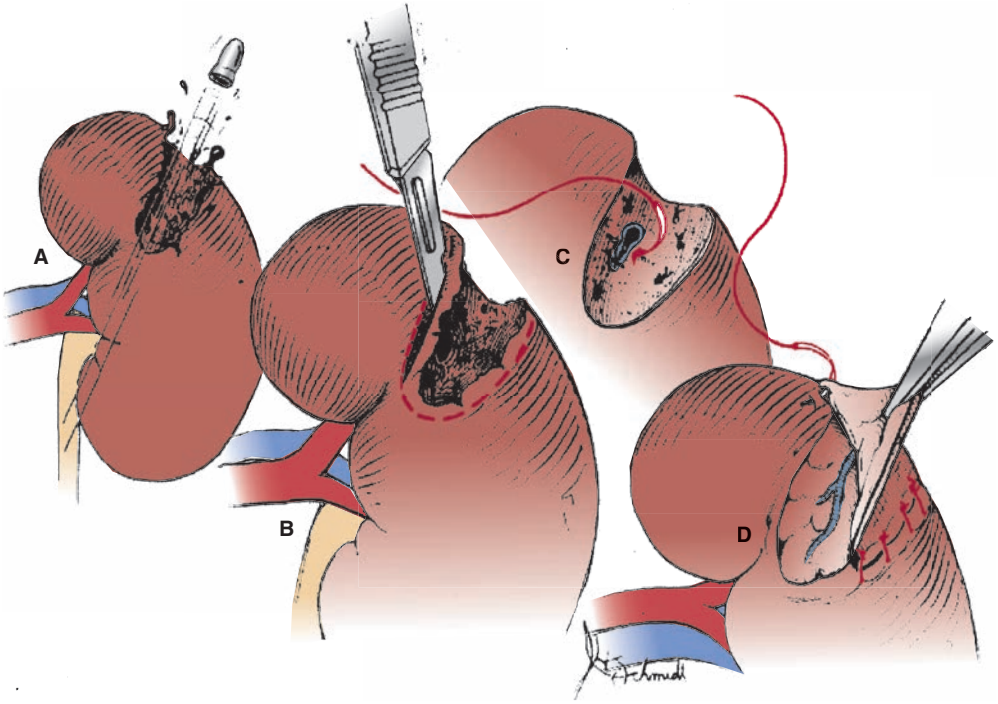

FIGURE 40-21 (**A** and **B**) Wedge resection of injured parenchyma. (**C**) Suturing of open collecting system and significant vessels with absorbable suture. (**D**) Capsule, if present, may be closed or reconstructed using peritoneal patch, with absorbable gelatin sponge or local fat pedicle to aid in hemostasis.

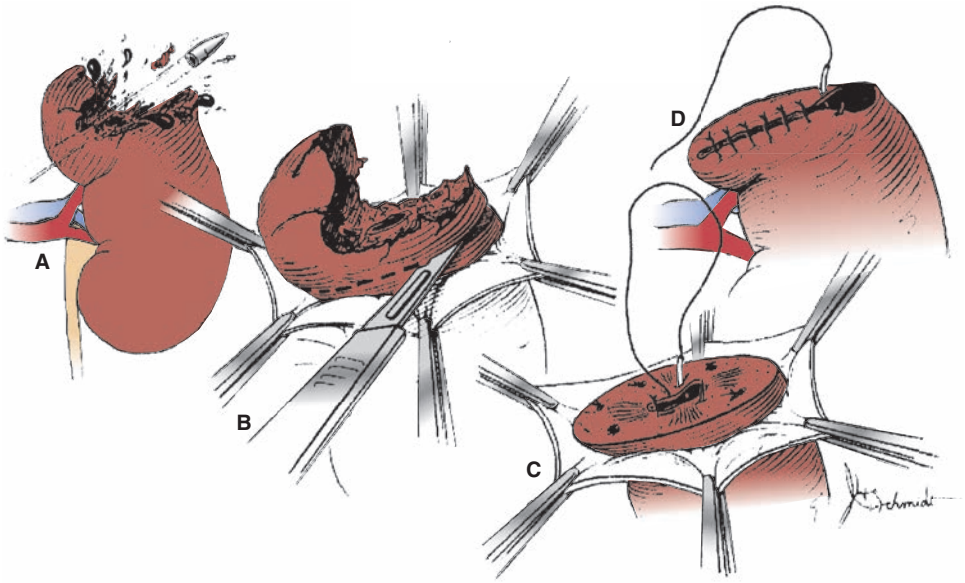

FIGURE 40-22 (**A** and **B**) Partial nephrectomy for major injury to upper pole. (**C**) Repair of collecting system and suturing of bleeding vascular branches. (**D**) Mattress sutures of 2-0 chromic gut to reconstruct parenchyma and aid in hemostasis.

extravasation.[69] Some data exist to suggest that the application of fibrin sealant over a urinary tract suture line may decrease the likelihood of postoperative urinary leakage.[70] At times, wrapping the decapsulated kidney in absorbable mesh material has been used to provide mild temporary parenchymal compression for continued venous bleeding from lacerated parenchyma (Fig. 40-24).

Injuries to adjacent organs such as the liver, pancreas, duodenum, and colon generally do not change the indications for renal salvage versus nephrectomy,[71,72] because good results have been described for renal repairs in the presence of injuries to these adjacent organs. It is desirable, however, to separate the renal injury from the adjacent visceral injury using available viable tissue. This can be accomplished by replacing the kidney within Gerota's fascia and closing the fascial layer over the kidney or by using omentum in the form of a pedicle flap. Drains for renal injury are used when the injury is complex, incompletely repaired injuries to the collecting system are present, or there is concern for the need to evacuate blood postoperatively. Closed suction drains are used because there is a lower risk of contributing to postoperative infection. When an injury to an adjacent organ exists, the organ sites should be drained separately.

Certain injuries are more common in the pediatric population and deserve specific mention. Avulsions of the fornices, ureteropelvic junction, and renal pedicle are more commonly seen in the pediatric population than in the adult.[73] Complete forniceal avulsion injuries are managed with nephrectomy because repair is nearly impossible. Avulsions of the ureteropelvic junction are amenable to repair through a direct anastomosis. Lacerations of the renal pelvis should also alert the trauma surgeon to the possibility of a preexisting obstruction of the ureteropelvic junction. Repair of the obstructing lesion may need to be performed with closure of the pelvis, or nephrectomy may be preferable if the kidney appears to have minimal parenchyma due to long-standing obstruction.

Renovascular injury from blunt or penetrating trauma presents certain challenges. As noted earlier, select patients are taken to laparotomy for revascularization surgery based solely on a CT scan demonstrating the classic findings of renal nonperfusion following deceleration trauma. If exploration is undertaken based on the CT findings or if arteriographic imaging has been performed, the approach is similar. The artery is dissected from its origin at the aorta toward the kidney and the arterial pulse is palpated or assessed with a Doppler instrument. The artery is clamped near the aorta and opened at the circular ring of hematoma, resected to the point of normal anatomy, and a direct end-to-end anastomosis is performed. When necessary, an autogenous vein graft or prosthetic graft is interposed. As in the pediatric population (in which the injury is more common), avulsion injuries involving the renovascular pedicle require urgent surgical intervention. Most of these patients are managed with nephrectomy, although isolated vascular repairs have been described depending on the level of the avulsion. Avulsion of multiple branches from within the renal sinus is virtually impossible to repair in the trauma setting and generally requires nephrectomy as well. Although current data suggest that the likelihood of achieving a favorable outcome with renal revascularization following renal injury is low,[74] patient selection is critical. In the appropriate clinical setting (brief warm ischemia time and a patient in suitable condition for surgery), the effort may be worthwhile in carefully selected patients. A collaborative approach involving the vascular surgeon and the urologist is highly applicable to cases in which renovascular reconstruction is planned. In selected

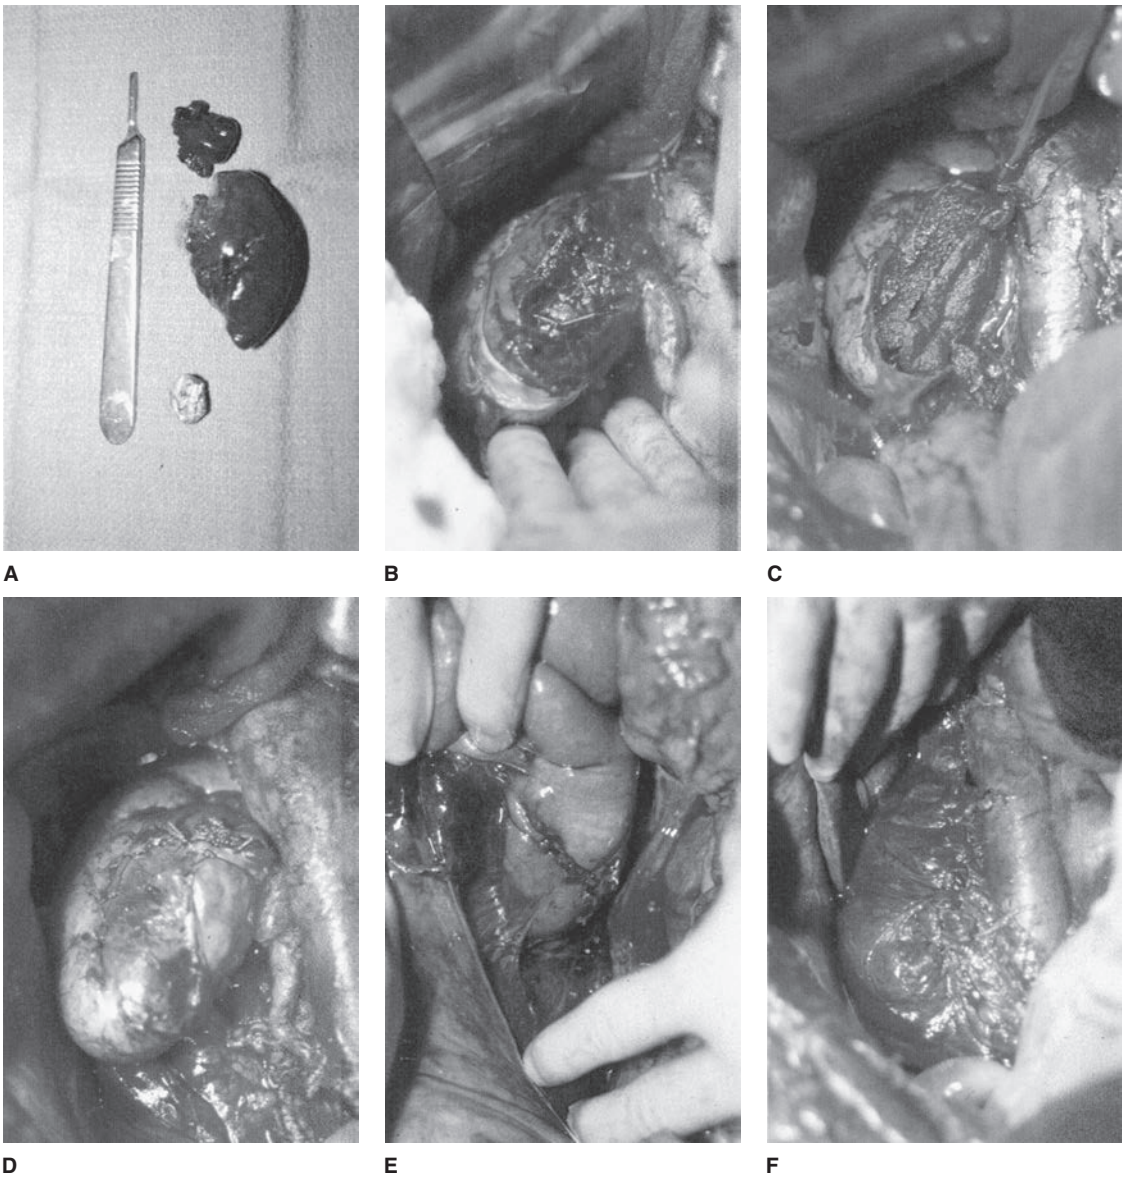

FIGURE 40-23 Surgical management of renal trauma. (**A**) Partial nephrectomy for lower pole laceration due to gunshot wound. Excised fragment of devascularized, lower pole parenchyma, debrided. Bullet removed, found immediately posterior to kidney. (**B**) Appearance of lower pole following suture repair of vessels and repair of collecting system. Capsule has been reflected back for completion of partial nephrectomy and will be used for coverage of defect. (**C**) Defect covered with absorbable gelatin sponge soaked in thrombin. Note vessel loops surrounding renal vessels. (**D**) Defect covered with adjacent capsule and peritoneal patch to aid in hemostasis. (**E**) Duodenal injury, repaired, immediately anterior to the renal injury. It is desirable to separate such injuries with viable tissue interposition, when possible, to minimize the risk of postoperative leak from either source affecting the other repair. (**F**) Gerota's fascia is closed over the kidney to separate the duodenal and renal injuries. Omental pedicle flaps are also very useful for this purpose. The renal repair was drained with an extraperitonealized closed suction drain.

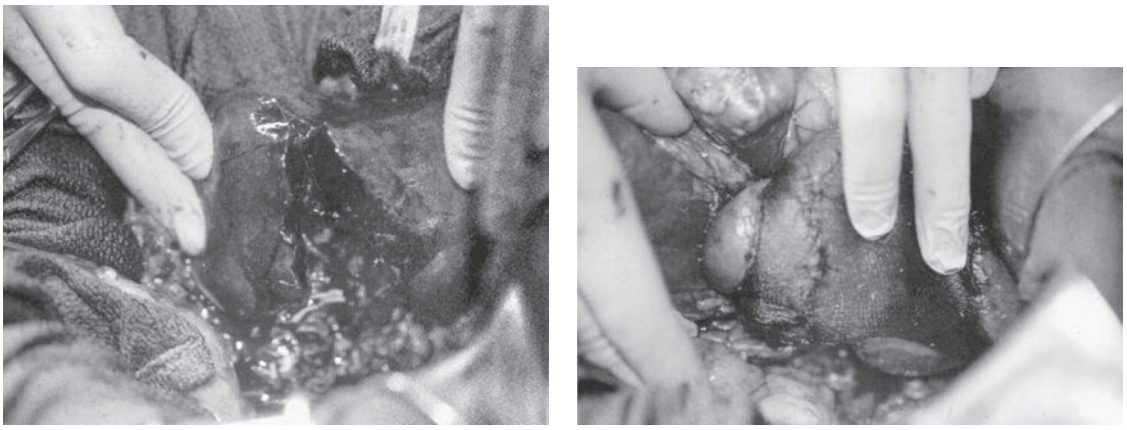
cases in which an intimal disruption of the renal artery is documented arteriographically but perfusion is maintained, radiologic placement of a vascular stent may be applicable. Many limited penetrating injuries to the renal vein can be repaired, whereas arterial injuries have a high rate of nephrectomy. Injuries to branch vessels in a parenchymal laceration are ligated. When diagnosed on imaging studies in stable patients with intact parenchyma, nonoperative management is appropriate.

Bilateral renal injuries are rare and present particular problems.[75] Assuming neither kidney is bleeding briskly, the kidney that seems to be less seriously injured (eg, based on hematoma size and location, apparent orientation and location of entrance and exit wounds) is assessed to ensure that renal salvage is feasible. One kidney can also be packed off temporarily after obtaining gross hemostasis while the opposite kidney is assessed in an effort to avoid nephrectomy in these cases whenever possible.



A B

FIGURE 40-24 Surgical management of renal trauma: renal parenchymal injury due to blunt trauma. (**A**) Large, deep laceration through posterior parenchyma, left kidney. Bleeding sites are sutured and collecting system closed with absorbable suture. Venous bleeding continues from lacerated cortex. (**B**) Due to absence of renal capsule (dissected away from parenchyma by hematoma), absorbable surgical mesh is used to wrap renal parenchyma, providing gentle compression to assist in achieving hemostasis.

Although rarely indicated, ex vivo renal reconstructive surgery may be used in the trauma setting. This would be the case when a solitary (functionally or anatomically) kidney is injured and a complex reconstruction is needed for salvage.

Ureter

The approach to ureteral repair depends largely on the level of the injury, the amount of ureteral loss (if any), and the condition of the local tissues. A ureteral laceration along with extensive destruction of the kidney from blunt or penetrating trauma is generally managed with nephrectomy. If the kidney is uninjured or the renal injury is limited and can be observed or repaired, ureteral repair is best performed at the time of recognition.[76,77]

Injuries to the ureter from blunt trauma require a high index of suspicion for diagnosis. Hematuria may be absent in such cases, and a delayed presentation is not uncommon. As noted earlier, the spiral CT scanners complete the initial renal imaging survey so rapidly that, unless a delayed excretory phase is requested, the study may be completed before the contrast has opacified the collecting system or injured ureter.

Blunt avulsion of the proximal ureter or ureteropelvic junction is best managed with limited debridement to viable tissue and a spatulated end-to-end anastomosis using fine absorbable suture (3-0, 4-0, or 5-0). In general, ureteral repairs performed after trauma are often stented (see Atlas Figure 64). This can be performed with an internal double-J-type stent or an externalized single-J stent. The single-J stent is usually exteriorized through a small stab incision in the anterior bladder wall and secured with a purse-string suture. Some surgeons also secure the stent to the bladder mucosa just outside the ureteral orifice with a fine absorbable suture (4-0 or 5-0). For tenuous repairs of the proximal ureter, diversion using a nephrostomy tube may be considered but is generally unnecessary.

A blunt injury to the mid ureter is uncommon, but when diagnosed, it is managed with a primary anastomosis. In the distal ureter (below the internal iliac artery), ureteral reimplantation into the bladder is preferred.

Injuries to the ureter from penetrating trauma also require a high index of suspicion for diagnosis. The presence of urine in the operative field may be difficult to appreciate, and the ureters, when at risk, must be thoroughly assessed by intraoperative inspection. The proximal and mid ureters down to the internal iliac arteries are easy to visualize and examine. For very distal injuries, a vertical cystotomy with observation of efflux from the ureteral orifices and intraoperative retrograde pyelography may be a less morbid means of assessing the area of concern rather than embarking on a difficult dissection of the ureter all the way to the bladder in the setting of a pelvic hematoma. Alternatively, intraoperative flexible cystoscopy with retrograde pyelography may be performed, avoiding the cystotomy. For proximal ureteral and mid-ureteral injuries, limited debridement of damaged tissue and a tension-free, spatulated end-to-end anastomosis is the procedure of choice (Fig. 40-25). For very distal injuries (generally below the internal iliac artery), reimplantation into the bladder is preferred, as noted earlier, because the blood supply to the distal ureteral stump may be compromised. A direct anastomosis to the bladder avoids the potential ischemic complications of a very distal ureter-to-ureter anastomosis. Stenting of such repairs is routine, as described previously.

For injuries to the lower third of the ureter, it is not always possible to perform a direct anastomosis to the bladder without tension. In such cases, the bladder can be brought cephalad and lateral toward the injured side to achieve a tension-free anastomosis with the ureter by several techniques. The most commonly employed is the "psoas hitch" (Fig. 40-26). The bladder is opened anteriorly, lateral peritoneal attachments are divided as needed, and then the bladder body is displaced toward the side of the injury and sutured

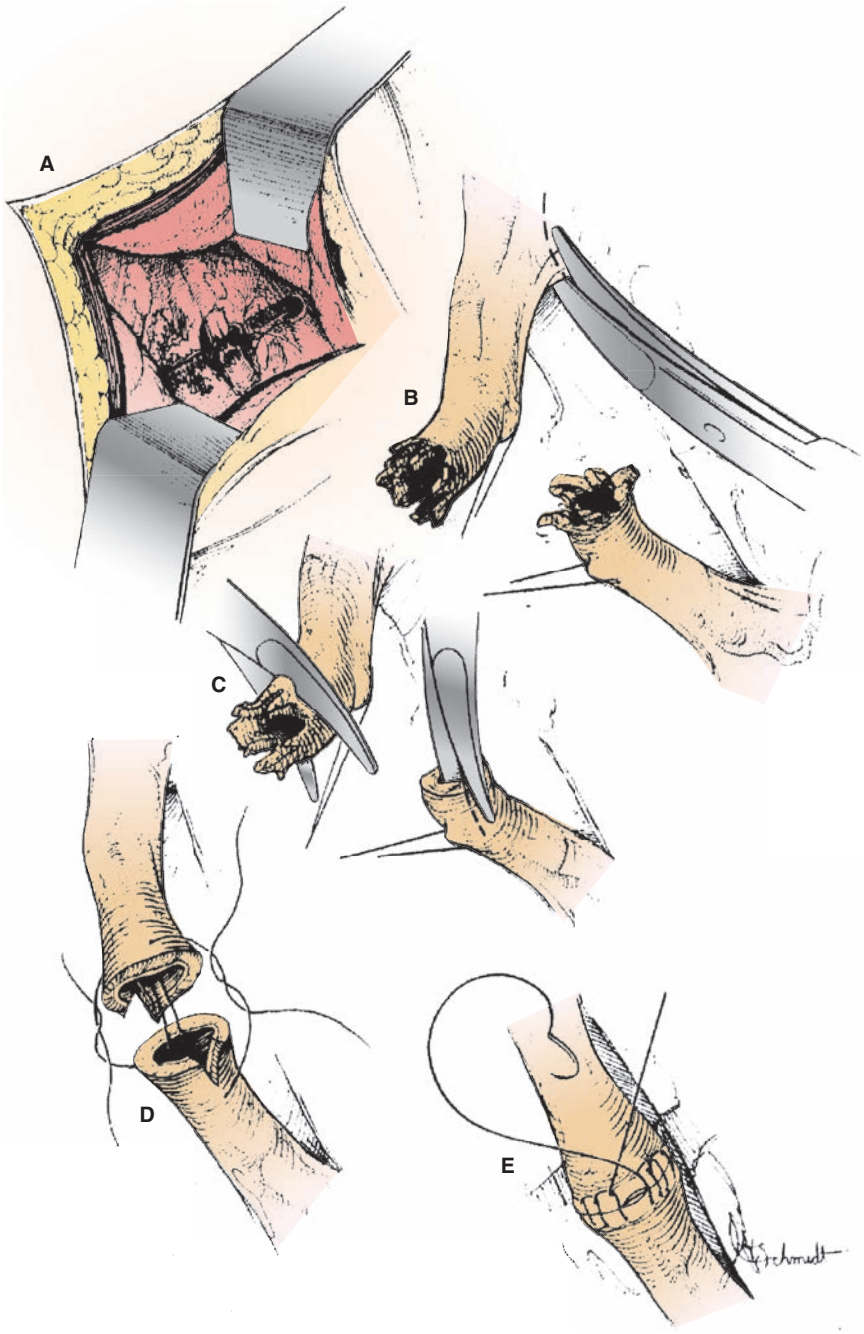


FIGURE 40-25 Techniques of ureteral reconstruction. Debridement and primary anastomosis for ureteral transection from gunshot wound. (**A** and **B**) Mobilization of ureter superficial to adventitial plane. (**C**) Limited debridement of lacerated ureter to viable tissue with spatulation for repair. (**D** and **E**) End-to-end anastomosis with fine absorbable suture over stent (not shown).

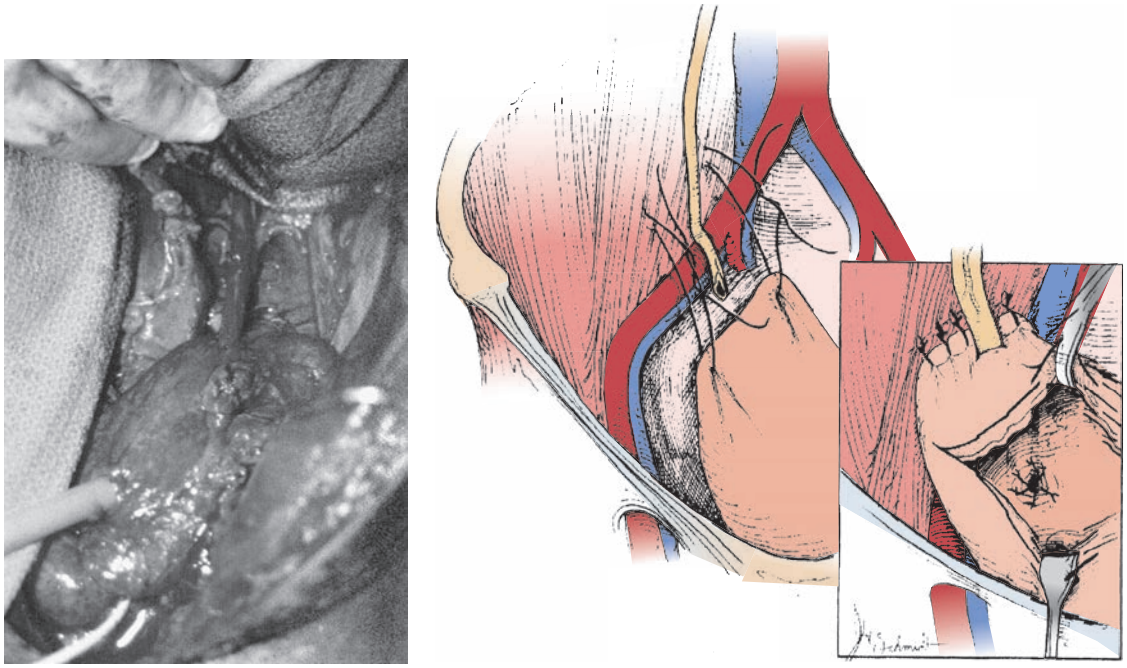
to the psoas muscle with 2-0 absorbable suture, taking care not to injure or entrap any major nerves. The ureter can then be reimplanted into the bladder using a tunneled antirefluxing anastomosis, or the tunnel can be omitted if length is still a problem. It is important to ensure that no obstruction or acute angulation exists at the vesical hiatus where the ureter enters. If a psoas hitch cannot achieve a tension-free connection to the ureter, a bladder flap (Boari flap) can be created. This procedure has a higher complication rate than a psoas hitch and is performed only if the psoas hitch does not accomplish the required objective. The bladder flap may be performed in conjunction with the psoas hitch to maintain the cephalad extension of the bladder wall posterior to the flap. Again, a nonrefluxing tunneled or a refluxing repair can then be performed. These procedures can also be performed laparoscopically.[78]



A B

FIGURE 40-26 (**A**) Ureteral reimplantation with psoas hitch for lower ureteral injury: the bladder is opened either transversely or vertically and obliquely toward the side of injury and then hitched to the ipsilateral psoas muscle with 2-0 or 3-0 Vicryl suture. A tunneled, antirefluxing anastomosis of the ureter to the posterior wall of the bladder is performed, being certain that an adequate width tunnel is created to prevent obstruction. If the available ureteral length is short, antirefluxing tunneling can be eliminated. Either an internal double-J–type stent or an externalized single-J stent can be used (not shown). (**B**) Psoas hitch ureteral reimplantation for penetrating injury to lower ureter, performed acutely during initial laparotomy in a hemodynamically stable patient. The bladder body can be seen sutured to the left psoas muscle, with the ureter entering cephalad. A single-J ureteral stent and suprapubic cystostomy exit from the bladder in the lower part of the photograph.

More complex techniques of ureteral reconstruction include transureteroureterostomy (TUU) (Fig. 40-27), ileal-ureteral replacement, and renal autotransplantation (Fig. 40-28). TUU is relevant when anastomosis to the bladder is not feasible due to inadequate length of the ureter, the condition of the bladder, or when it is desirable to move the repair away from the ipsilateral hemipelvis due to local conditions such as infection or prior pelvic radiation. Ureteral replacement with the ileum is seldom performed in the acute trauma setting because it is preferable to have a fully prepped bowel when performing this procedure. Renal autotransplantation may be appropriate in the acute trauma setting if appropriate vascular surgical expertise is available and less complex options for ureteral replacement are not feasible. The proximal ureter can be anastomosed directly into the bladder in the case of loss of the majority of the lower ureter, or an anastomosis can be performed to the lower ureter if it is clearly viable and not excessively distal.

When ureteral repairs are performed in direct apposition to adjacent vascular or visceral repairs, separation of the repairs by an omental pedicle or other viable tissue is desirable to prevent a fistula or contact with urine at the site of the adjacent organ injury. External drainage of ureteral injuries, in addition to stenting or diversion, may be desirable, particularly if the repair is tenuous or the vascularity of the repaired tissues is questionable. Some urologists prefer Penrose drains to closed-suction drains. In the postoperative period, antibiotic administration may be desirable, especially if urinary extravasation persists.

As noted later, ureteral injuries are also highly amenable to damage control strategies when the patient is not in suitable condition for repair at the time of the initial laparotomy. An external stent placed through the transected proximal ureteral stump allows maintenance for control of the urinary output while the patient is undergoing resuscitation in preparation for definitive delayed reconstruction.

Bladder

Surgical repair of the bladder is performed for many iatrogenic injuries, for nearly all blunt intraperitoneal injuries, and for selected cases of blunt extraperitoneal rupture. Penetrating injuries to the bladder may also be managed with operative repair.

Intraperitoneal ruptures of the bladder are approached through a midline abdominal incision or laparoscopic repair. The large laceration is nearly always in the dome of the bladder as previously described (Fig. 40-29). The interior of the bladder is palpated and inspected through the laceration to verify that no other injuries are present and that there is clear efflux from both ureteral orifices. The laceration may be

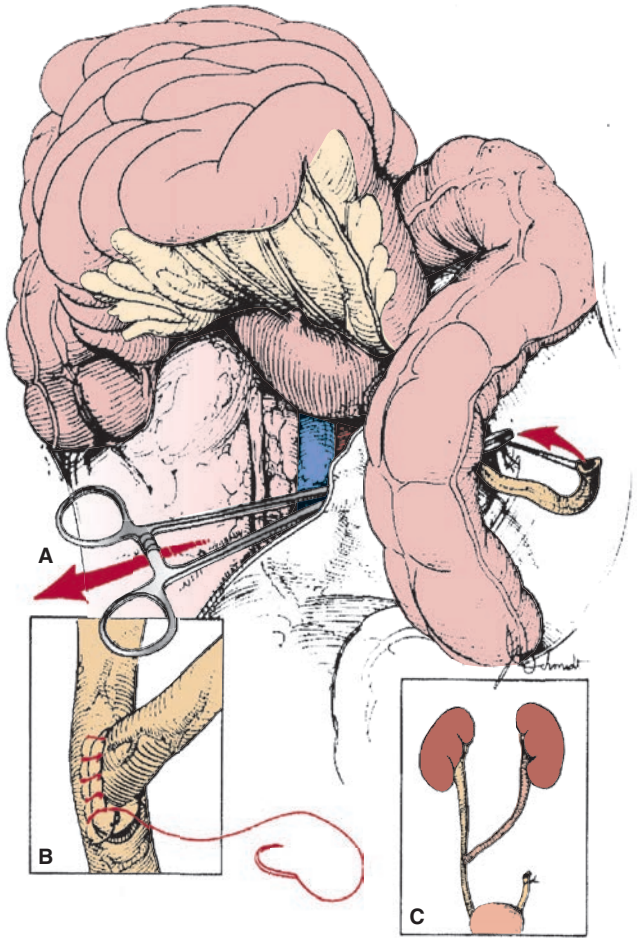


FIGURE 40-27 (**A**–**C**) Transureteroureterostomy (TUU) is performed when the loss of the distal part of the ureter is sizeable and ureteral reimplantation cannot be performed. (**A**) Use of right angle clamp to transpose carefully the left ureter to the right side through a peritoneal window (two fingerbreadth wide to prevent ureteral constriction) at the level of the promontory. (**B**) The injured left ureter is mobilized, spatulated, and reimplanted to the right ureter with mucosa–mucosa apposition, water-tight anastomosis and tension-free. (**C**) The left ureter is ligated at the site of injury prior to the TUU being performed. The left ureter should have a smooth transition at the transposition site to the right side to prevent obstruction as demonstrated in the figure.

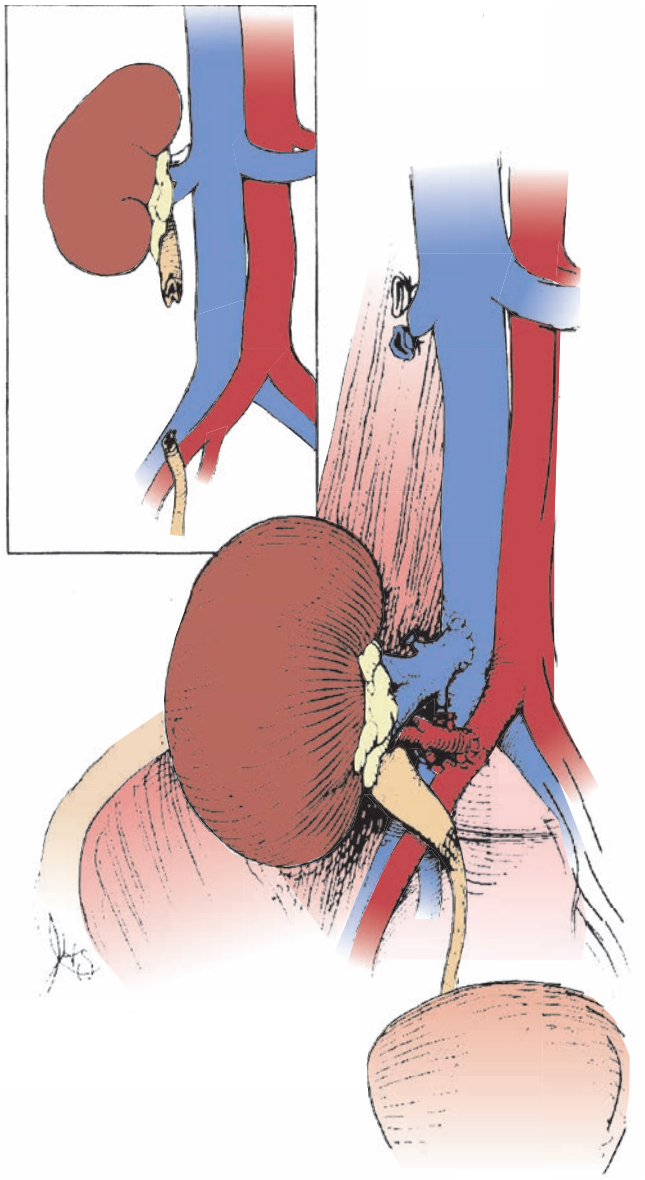

FIGURE 40-28 Renal autotransplantation for reconstruction following extensive loss of mid ureter, making direct union of upper ureter to bladder impossible. Alternative to ileal-ureteral replacement of most of the ureter. Nephrectomy must be tailored to include as much of the renal vessels as possible to aid in anastomosis to iliac vessels (in general, vein generally transected flush with vena cava on right, with artery transected more proximally, behind vena cava than shown here). Anastomosis of proximal ureter to viable lower ureter.

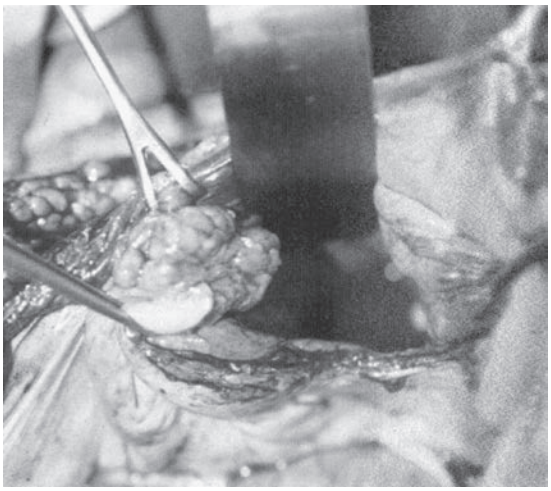
extended into an anterior midline cystotomy if further assessment is needed, but this is not usually necessary. The edges of the bladder laceration may require minimal debridement to remove devascularized tags of detrusor muscle or mucosa. The laceration is then closed using two layers of heavy absorbable suture. An adequate bore bladder catheter is used to allow free drainage of initially bloody efflux that clears in the first few days. The length of catheterization time is usually 5 to 10 days, but the period needed for urinary efflux to clear and the ability of the patient to be ambulatory and void comfortably should be considered. It is prudent to perform a cystogram prior to removal of the catheter following any operative repair and is mandatory with nonoperative management. Because a well-sutured repair carries an extremely low postoperative risk of extravasation, some practitioners remove the catheter without prior contrast imaging with excellent success. Suprapubic cystostomy catheters are not generally needed after repairs of intraperitoneal ruptures. They should be inserted only when there is a need for long-term bladder drainage, such as in a patient with a significant injury to the



A

B

brain, trauma to the pelvis or a lower extremity, or other factors that would be expected to substantially delay a return to ambulation.

For the selected cases in which extraperitoneal rupture of the bladder is managed with operative repair, there are several important differences when compared with intraperitoneal repairs. When operating on the injured bladder during a laparotomy following a pelvic fracture, an effort should be made to avoid entering the retropubic hematoma. This avoids potentially serious hemorrhage from a site that is often tamponaded. If repair of the bladder is necessary in this setting (see the previous section "Nonoperative Management of Genitourinary Injuries"), one should enter the bladder through an anterior cystotomy incision cephalad to the pelvic hematoma. The laceration, which is usually located in the lower anterior or anterolateral bladder, can be sutured transvesically by introducing Deaver or malleable retractors into the bladder and retracting them laterally. Often, only a single-layer, full-thickness closure is possible in this setting. It is useful to communicate with the orthopedic surgeons when operating on extraperitoneal bladder ruptures in the setting of a pelvic fracture to allow for coordinated care.

A penetrating injury to the bladder is most often managed operatively, although occasional patients (as previously described) may be candidates for nonoperative management.[62] If a patient is undergoing laparotomy and has gross hematuria following penetrating pelvic trauma, the peritoneal surface of the bladder is examined first. The retropubic space is then entered, and an anterior, midline cystotomy is created. This may be easier to accomplish if the bladder is partly filled with irrigant. For laparotomies in which bladder surgery is likely, including the genitalia in the sterile field can facilitate whatever manipulation may be necessary without abdominal contamination. Following cystotomy, the interior of the bladder, the ureteral orifices, and the bladder neck are thoroughly examined. The urinary efflux from both orifices should be observed; if bloody or absent, further investigation for trauma to the ureters or upper tract is recommended. Penetrating injuries to the bladder are closed with two layers of absorbable suture, as previously described.

In some patients, an iatrogenic or penetrating injury to the bladder may result in loss of a large portion of the detrusor of the bladder body. Closure over a bladder catheter is still recommended, as the bladder may expand to an acceptable volume with time. If minimal bladder capacity persists following a reasonable period of healing, augmentation cystoplasty can be performed electively.

As for renal and ureteral injuries, injuries to the bladder in the unstable trauma patient are amenable to damage control strategies. These include externalized stenting of the ureters with pelvic packing and delayed repair of complex lacerations.

Certain associated injuries impact the management of bladder trauma. Contiguous injury to the vagina or rectum, for example, requires close collaboration between the clinical services involved in caring for these injuries. When such injuries are suspected, it is helpful to have the patient in a modified dorsal lithotomy position so simultaneous access to the perineum and abdomen can be obtained. During surgical repair, the bladder should be separated from the rectum or vagina by placing an interposition flap of viable tissue if the loss of tissue is significant and the injuries directly overlie each other. This effort of separating the pelvic organs can be difficult in the trauma setting, and if the injuries do not directly overlie each other and tissue loss is minimal, simple transvesical closure is generally adequate. In this setting, longer indwelling catheter times, perioperative antibiotics,

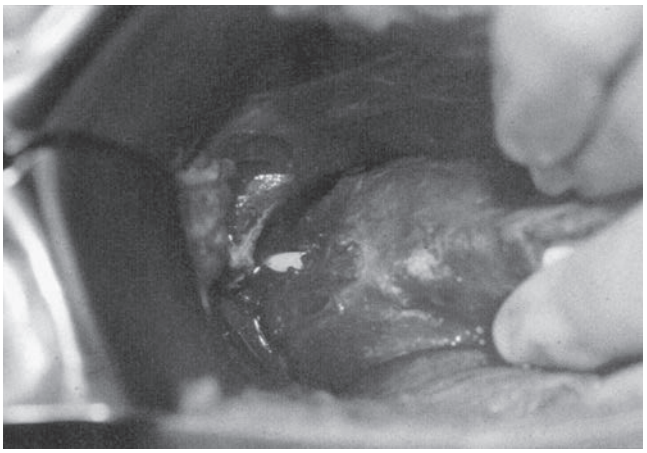

FIGURE 40-30 Bladder neck avulsion injury in an adult female with pelvic fracture. Operative appearance during surgical repair. An anterior midline cystotomy had been performed (to right in photo), with the tip of a Foley catheter protruding from the avulsed bladder neck for demonstration purposes. Anastomosis to urethral stump at level of pelvic floor performed over Foley catheter. The patient was initially managed with a percutaneous suprapubic cystostomy. This repair was performed 36 hours following injury, when the patient was hemodynamically stable and risk of excessive bleeding from the pelvic fracture would be lower.

and radiographic imaging prior to removal of the catheter are recommended. Open pelvic fractures are among the most devastating injuries in orthopedic trauma, and injury to the lower urinary tract may complicate such injuries. A close interaction between the urologist, orthopedist, trauma surgeon, and interventional radiologist is necessary for management of such patients. Chronic disability is common following these injuries.[79]

Avulsion injuries of the bladder neck, which are more common in the pediatric population, require operative repair (Fig. 40-30).[54] Repair for these complex injuries should be delayed until 24 to 72 hours after injury to support a damage control strategy and to minimize the risk of excessive hemorrhage from an associated pelvic fracture.

Urethra

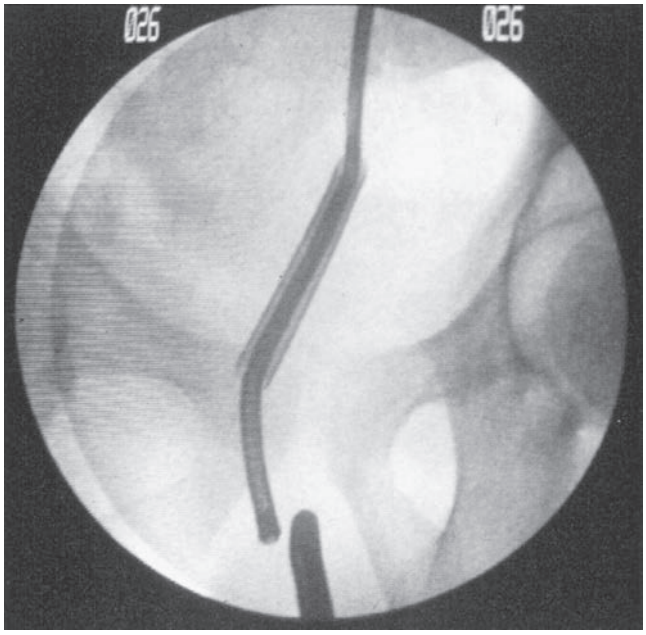
Operative management for urethral trauma includes the broad topic of elective urethral reconstruction following traumatic injuries and surgical repair of urethral strictures, and there are several in-depth reviews available regarding this topic.[80,81] This discussion will focus on immediate and subacute surgical intervention for urethral trauma, and clinical guidelines have recently been reported for these injuries.[82]

Incomplete anterior urethral injuries may be managed with the placement of a transurethral catheter or with suprapubic diversion. Endoscopic guidance for any attempt to catheterize the traumatized urethra is preferred. If a blind attempt at catheterization is performed and any resistance is encountered, an endoscopically guided procedure should follow. Complete ruptures of the anterior urethra from blunt trauma are best managed with suprapubic diversion for 3 months or longer, followed by elective end-to-end urethroplasty when the perineal hematoma and induration have fully resolved. Acute attempts at excision and repair are not recommended because it is unclear how much urethra should be resected due to the crush injury and result in tension-free healthy tissue anastomosis.

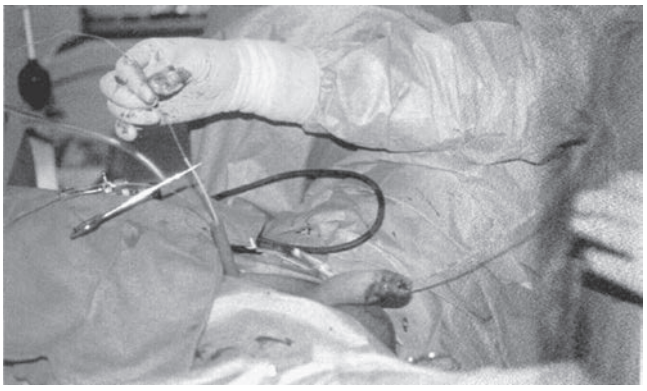
Penetrating injuries to the anterior urethra may be managed with local exploration and repair or with suprapubic diversion. With stab wounds or gunshot wounds from low-velocity missiles, performing limited debridement and repair with a spatulated anastomotic technique is usually simple. If the patient is not an appropriate candidate for immediate repair due to more serious injuries or other reasons, suprapubic diversion or endoscopically guided insertion of a transurethral catheter is performed. Extensive loss of the urethra from penetrating trauma or industrial trauma may require a staged repair.

The management of disruption or distraction injuries of the posterior urethra remains controversial. In recent years, there has been increasing interest in early catheter realignment for such injuries. Techniques used have included endoscopic guidance, open surgical approaches, and, historically, the use of interlocking magnetic sounds (Fig. 40-31).[83-85] A potential advantage of endoscopic realignment is the possibility that the injury will heal free of intractable stricture. This would obviate the need for late urethroplasty, shorten the period of urinary intubation, and may improve the anatomic result as compared with the nonintubated state by reducing malalignment. A potential disadvantage of this approach is the risk of infecting the retropubic hematoma because of the indwelling catheter, which can adversely impact late continence and sexual function; in addition, there is a high likelihood that a stricture will form regardless. When selected, catheter realignment should be performed by an experienced team in the operating room with endoscopic and fluoroscopic capability. Results are better for incomplete disruptions than they are for complete disruptions. Most patients managed in this manner develop a stricture that will require endoscopic intervention, often involving multiple procedures. Overall, patients managed with catheter realignment may avoid a subsequent urethroplasty about 50% of the time. Currently, a multi-institutional prospective cohort trial is underway to determine the utility of acute urethral realignment after pelvic fracture urethral injuries. The study is comparing the outcomes between primary endoscopic realignment and suprapubic tube placement.[86]

The traditional approach to a posterior urethral distraction injury is diversion with a suprapubic cystostomy, followed by a period of observation of 3 to 6 months while the pelvic hematoma resolves and the anatomy stabilizes. Repeat antegrade and retrograde urethrograms are then performed, and definitive reconstructive surgery is planned. The ultimate success rate of this approach is over 90%; however, the need for a long-term indwelling suprapubic tube while awaiting surgery may be frustrating for the patient. Nevertheless, endoscopic techniques such as catheter realignment can



A



B

FIGURE 40-31 (**A**) Urethral realignment with complete posterior urethral injury. (**B**) Endoscopic realignment under fluoroscopy using flexible and rigid cystoscopies as well as a super stiff guidewire.

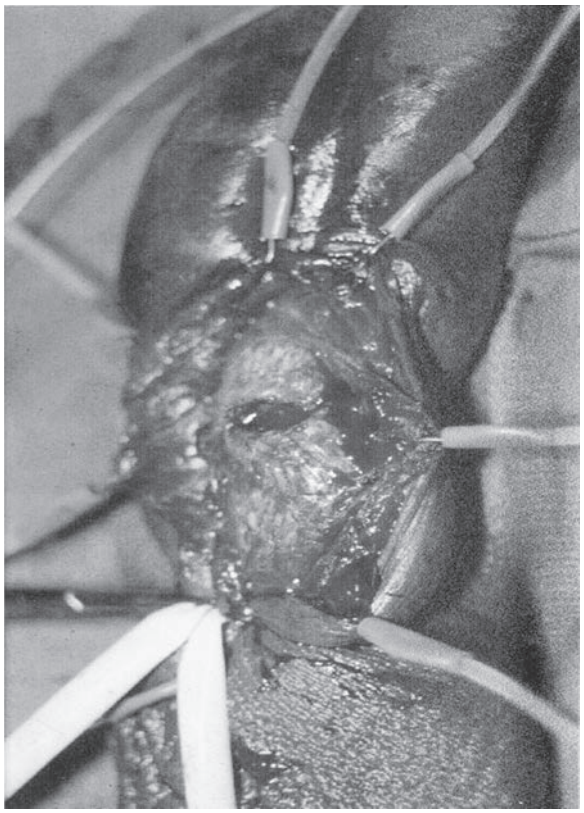


FIGURE 40-32 Penile fracture. Appearance of penis during surgical exploration for penile fracture sustained during sexual intercourse. Patient reported classic findings of pain, swelling, and detumescence following sudden marked bending of erect penis. Note marked swelling of distal phallus with subcutaneous hematoma. Penis is explored through a ventral, midline, penoscrotal incision. Dissection to area of palpable irregularity along penile shaft reveals transverse laceration of tunica albuginea of corpus cavernosum. A penile tourniquet, using a Penrose drain, is in place to reduce bleeding during repair. The hooks are part of a ring-retractor system commonly used in genital surgery. The tunica albuginea defect is closed with running 3-0 Vicryl suture. Early exploration and repair for penile fracture injuries produce the best results. Circumcising subglandular incision is preferred by some surgeons for this type of exploration and repair.

be performed successfully without the need for suprapubic catheters.[87]

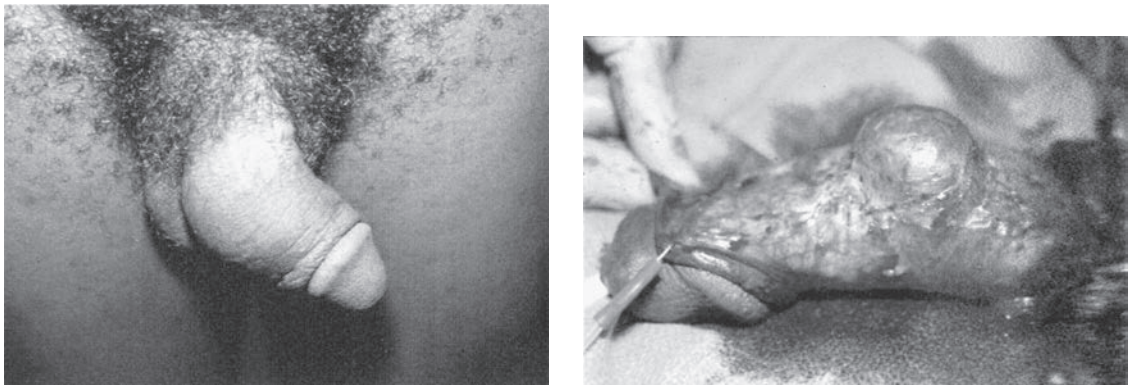
Penis, Testis, and Scrotum

Penile trauma is primarily managed through operative exploration and repair.[88] For blunt penile fractures, the penis is explored through either a ventral midline penoscrotal incision or a circumcising subcoronal incision. The defect in the tunica albuginea is exposed and closed with absorbable suture (Fig. 40-32). The outcomes following early operative repair of penile fractures are far superior to those resulting from nonoperative management. Deformity, painful erection, pseudoaneurysm, and loss of erectile function are common in nonoperative management of such injuries (Fig. 40-33).[63]

Similarly, penetrating penile injuries should be managed with operative exploration and repair (Figs. 40-34 and 40-35).[89] Because combined cavernosal and urethral injury occurs in roughly 10% of penile fractures, a preoperative urethrogram or flexible cystoscopy is useful in planning the repair.

In cases of penetrating penile injury, a similar surgical approach is used with conservative debridement, repair of cavernosal and urethral injury, and microsurgical repair of dorsal neurovascular structures when possible. For limited injuries, direct wound exploration may be a preferable approach. The possibility of an adjacent nonurologic injury (thigh, femoral vessels, pelvic organs) must always be considered in cases of penetrating genital injury.

Penile strangulation injuries due to constricting bands or other devices are managed with removal of the constricting



A B

FIGURE 40-33 Delayed presentation following penile fracture. (**A**) Note marked angulation to left with mass effect on right lateral side of penile shaft following untreated rupture. Patient presents 6 weeks after injury; the subcutaneous hematoma has resolved, while the defect in the corpus cavernosum remains, resulting in angulation and pain with erection. (**B**) Appearance of penis at surgical exploration through circumcising incision. Note large encapsulated hematoma under Buck's fascia, which, on incision, still communicates with cavernosal space. Defect repaired with correction of deformity.

object in the most atraumatic manner possible. Distal penile skin, glans, cavernosal, or urethral necrosis can occasionally occur in such cases. A conservative approach to debridement of tissues of questionable viability and diversion with a suprapubic cystostomy tube (if the urethra is compromised) are principles of management.

Patients with traumatic amputation of the penis require specialized management (Fig. 40-36). Often, patients who suffer traumatic amputation through self-mutilation are psychotic and/or are involved in substance abuse and require psychiatric as well as urologic intervention.[90] The severed organ should be cleansed, kept in cold saline-soaked gauze within a sealed bag, and then placed in ice. Replantation surgery is well described by Jordan and Gilbert.[91] In sequence, anastomosis of the corpora cavernosa, urethra, dorsal blood vessels, and nerves should be performed with appropriate

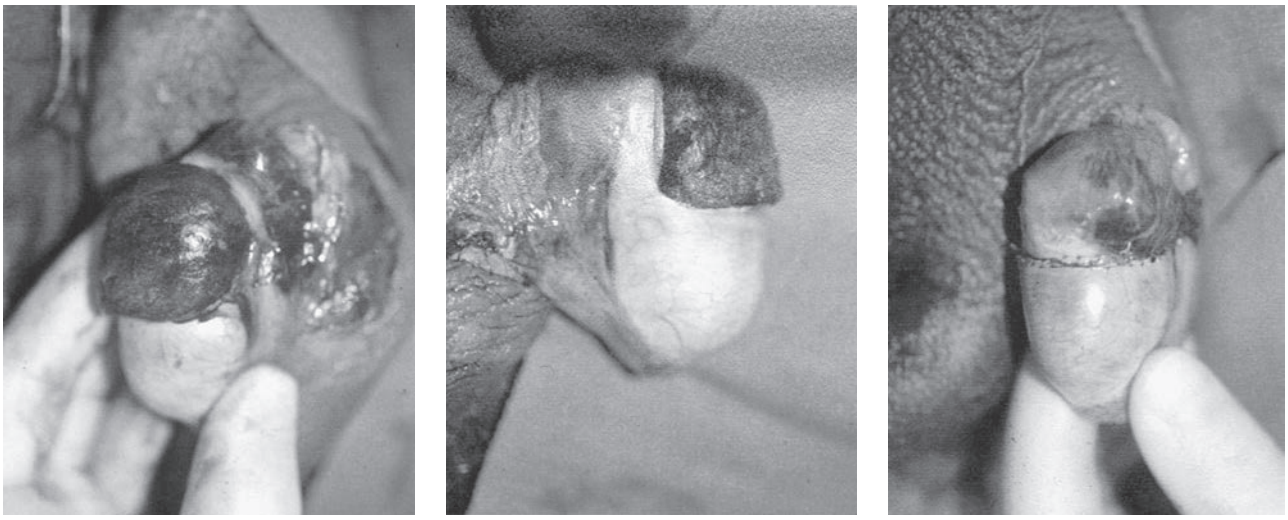
(**A**) Photograph demonstrates complete transection of body of penis with right-sided skin bridge attaching distal phallus to body. Left testis is exposed as well. (**B**) Preparing for surgical reconstruction—minimal debridement of corpora cavernosa and urethra, following extensive irrigation. (**C**) Corpora cavernosal anastomosis has been completed; urethral anastomosis about to be completed after spatulation and mobilization of distal ends to avoid tension on repair. Following completion of urethral repair over Foley catheter, microsurgical anastomosis of deep dorsal arteries, deep dorsal vein, and adjacent nerves was performed (not shown).



A B C

FIGURE 40-37 Testis: testicular rupture due to blunt trauma. (**A**) Scrotal hematoma after straddle injury. (**B**) Scrotal exploration: tunica albuginea rupture with extravasation of testicular tissue. (**C**) After testis repair with minimal tissue debridement.

microsurgical expertise. Functional outcomes are variable with such replantation efforts, largely reflecting the condition of the severed organ and the time that elapses prior to replantation.

Scrotal trauma should be explored if there is a concern about testicular rupture. In blunt trauma, a testicular ultrasound may be helpful in deciding if operation is indicated. In penetrating trauma, we often use an oblique upper scrotal incision that provides access to the groin, spermatic cord, penile base, and scrotal contents. Most scrotal injuries should be explored with the goal of evacuation of the hematoma, debridement of devitalized tissue, and repair and salvage of the testicle (Figs. 40-37 and 40-38). Reproductive outcomes are favorable following such management.[92]

Cases of scrotal and other soft tissue loss in the genital region should be managed with a conservative approach to debridement of marginally vascularized skin and soft tissues. Delayed primary closure or reconstruction of significant scrotal loss using meshed split-thickness skin grafting produces favorable results. Human bite wounds have a very high infection rate and should be left open if presenting in a delayed fashion (see Chapter 50).

COMPLICATIONS OF GENITOURINARY TRAUMA

The management of complications of urologic injury is an important issue facing the trauma surgeon. Extensive reviews of this topic are available.[93-95] Complications may be categorized as early and late occurrences and can occur in the setting of an early diagnosis of injury or a delayed diagnosis of injury. Early complications of injury to the upper urinary tract include bleeding, postinjury infections, problems related to urinary extravasation, and ischemic processes. Renal and ureteral injuries may also result in late complications including hypertension, hydronephrosis, and renal insufficiency. Functional abnormalities following trauma to the urinary tract may include a neurogenic bladder, urethral stricture, and sexual or reproductive dysfunction. Appropriate follow-up studies for high-risk injuries are critical in the early detection of complications of urologic trauma.

DAMAGE CONTROL PRINCIPLES IN GENITOURINARY TRAUMA

Damage control in genitourinary trauma is the process of managing immediately life-threatening conditions (ie, major active bleeding from the kidney or renal pedicle or the need for acute urinary diversion), intentionally delaying surgical interventions until the patient is more stable.[96,97] A majority of these delayed procedures are reconstructive surgery of the urinary tract.

The evolvement of diagnostic and interventional radiology, better-understood resuscitation protocols, and the concept of "packing" and "second look" can be applied to the upper and lower urinary tract when there is a need to control renal or pelvic bleeding.

Urinary diversion can be achieved by percutaneous nephrostomy tubes or externalized ureteral stents when major ureteral injuries occur, and suprapubic catheters may be expeditiously performed to drain the bladder when urethral catheters cannot be placed (Fig. 40-39).

Controlling urine leak is important to avoid creatinine elevation due to urine absorption and electrolyte imbalance and maintain potassium levels.

Certain bladder injuries may be difficult to repair at the initial operation as well. Visibility may be compromised because of packing from pelvic bleeding, the complexity of

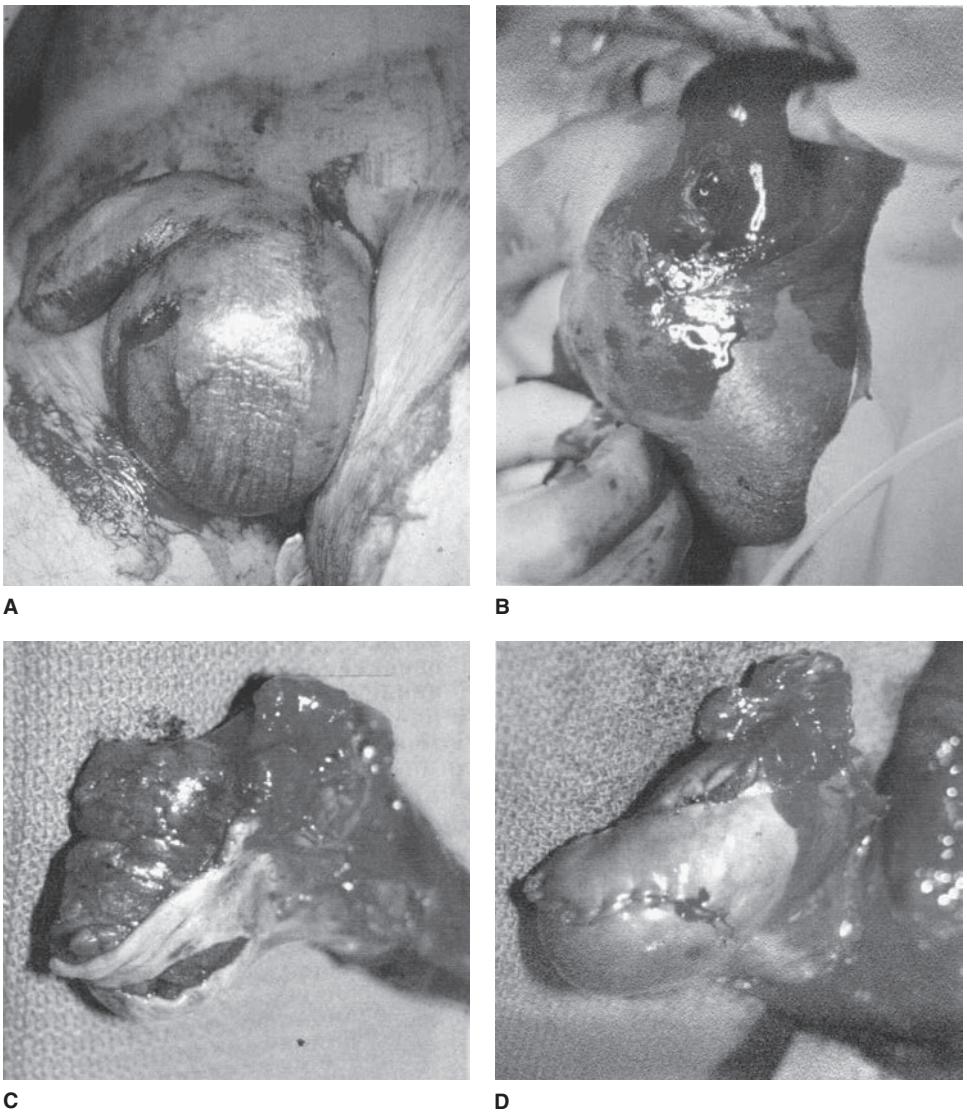


FIGURE 40-38 Scrotal exploration and testicular repair following gunshot wound to scrotum. (**A**) Entrance wound visible lateral to base of penis on left, exit just to the right of the median raphe; note marked left hemiscrotal swelling from hematoma. Surgical exploration is mandatory, and preoperative scrotal imaging is unnecessary. (**B**) Scrotal exploration performed through high oblique scrotal incision for optimal exposure of scrotal contents and possible extension to groin if further spermatic cord exposure proves necessary. Entrance into tunica vaginalis visible. Testis introduced out of scrotum on spermatic cord pedicle. (**C**) Appearance of left testis demonstrating complex laceration of tunica albuginea with extruded testicular parenchyma. (**D**) Appearance of testis following limited parenchymal debridement and reconstruction of tunica albuginea. Testis is then returned to scrotum following evacuation of hematoma and extensive irrigation; Penrose drain placed through inferior stab incision in left hemiscrotum (not shown).

the repair may require more time and blood loss than the patient can tolerate, or the degree of debridement needed may be unclear, as in cases with a high-velocity gunshot wound. Delaying definitive repair may be accomplished by inserting bilateral externalized ureteral stents. The pelvis can then be packed for bleeding by compressing the open bladder against the pubis. Placing an externalized suprapubic catheter (Malecot or Foley) within the injured bladder is also an option. If the catheter prevents tamponade of pelvic bleeding, it can be clamped temporarily and then reopened to drainage when the patient's coagulopathy is corrected. The use of damage control principles for complex penetrating pelvic trauma in the battlefield setting has been recently reported. In this series, 43% of patients had urologic injury, whereas 50% had major vascular injury. A 21% mortality rate in the first week after injury was reported, whereas 36% of patients with combined vascular and rectal injuries died.[98] A staged, multidisciplinary approach to management and reconstruction was shown to be valuable in this experience.

Injuries to the urethra and external genitalia can be temporarily managed with suprapubic catheterization or dressing

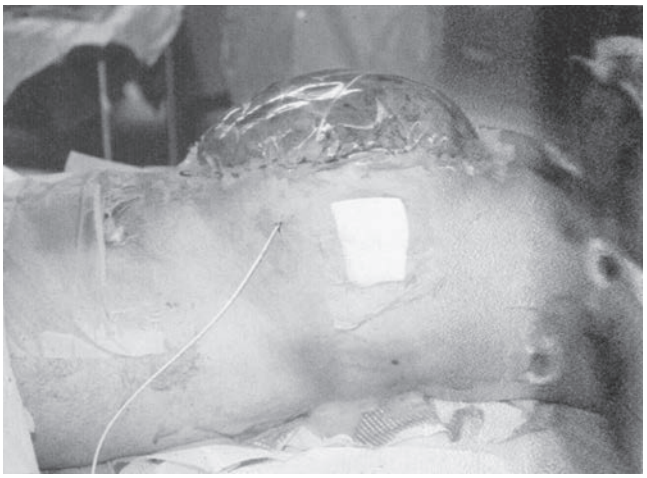

FIGURE 40-39 Patient managed with damage control laparotomy: gunshot wound to abdomen with injuries to small bowel, left iliac artery and vein, and left ureter. Patient was hemodynamically unstable following vascular repair, so ureteral injury was managed with damage control approach. Single-J stent was passed up proximal ureter at injury site and secured to end of ureter with silk tie; stent was externalized, exiting from left lower quadrant, as shown. Abdomen was closed with "Bogota bag" silo due to bowel and mesenteric edema. On return to operating room at 36 hours after injury, formal ureteral repair with psoas hitch and ureteroneocystostomy was performed.

applications pending the patient's return to surgery for definitive management.

The results of damage control management for urologic injuries in appropriately selected patients appear to be acceptable in terms of patient survival, renal salvage, and functional outcome.[99,100]

CONSULTATION AND INTERSERVICE INTERACTION

A specialty such as urology offers skills that are different from those of the general surgeon. These include endoscopic capability and familiarity with reconstruction of the urinary tract. The urology department should be informed of signs of urologic injury as early as possible, preferably from the emergency department. This allows the urologist to be involved in preoperative imaging and interpretation, later operative sequencing, and use of damage control strategies. The experience of large trauma centers in which an interested and capable urologic trauma team is involved often results in reduced rates of nephrectomy and improvements in other outcome measures.

TRANSGENDER PATIENTS

There are an estimated 1.4 million transgender adults in the United States, and this number is increasing.

The definition of *transgender* is as follows: of or relating to people who feel that their true nature does not match their sex at birth. Not everyone who is transgender prioritizes or desires procedures, such as hormone therapy and gender-affirming surgeries.

Eventually, these patients will need acute care in a trauma setting, requiring clinicians to obtain an inclusive history that takes into account possible gender-affirming surgery, managing hormone therapy, and other clinical issues.

Patients who underwent gender-affirming surgery have a unique anatomy that must be considered when they are under emergent and acute surgical care. The interpretation and understanding of laboratory values, surgical anatomy, and possible hormonal management may influence their clinical outcome.[101]

MEDICOLEGAL CONSIDERATIONS

Urologists frequently become involved in the management of injuries that were not diagnosed at the initial operation. These are often recognized later in a patient's clinical course, often after a complication (eg, urinary extravasation, bleeding, azotemia, sepsis) initiates further testing and imaging studies. In this case, it is important to communicate to the patient and family what is occurring and to document the events that have occurred in the medical record. It is important to educate patients and their families that traumatic injuries are complex and that certain complications are common and to be expected. Also, functional outcomes may be disappointing to patients, including urinary incontinence due to damage of urethral sphincter, neurogenic bladder that can occur after lumbosacral injuries and interventions, and erectile dysfunction and/or dyspareunia after pelvic or genital trauma.

Often, reconstructive procedures will occur after a long period of rehabilitation following trauma, and due to innumerous reasons, it is common for these patients to become lost to follow-up until complications arise due to retained ureteral stents (eg, urinary tract infection, stent calcification, obstruction, hematuria) or loss of urinary or renal function. With the advent of electronic medical records, special mobile phone apps, and patient safety culture implementation, ureteral stent track applications have been studied to decrease loss of follow-up and retained ureteral stent complications.[102]

Lastly, patients with major renal injuries may develop hypertension and/or proteinuria following certain injuries; this should be explained and documented.

CONCLUSION

There are very few prospective studies in the urologic literature, leaving levels of evidence at a suboptimal state for evidence-based medical practice. There is a broad international consensus, however, regarding the management of urologic injuries.[1-5] Evolvement in body imaging, endoscopic and laparoscopic approaches, endovascular stenting, and other radiologic and minimally invasive techniques has changed approaches to urologic trauma and selection of patients for operative versus nonoperative management. Over the past decade, the most significant change was the trend

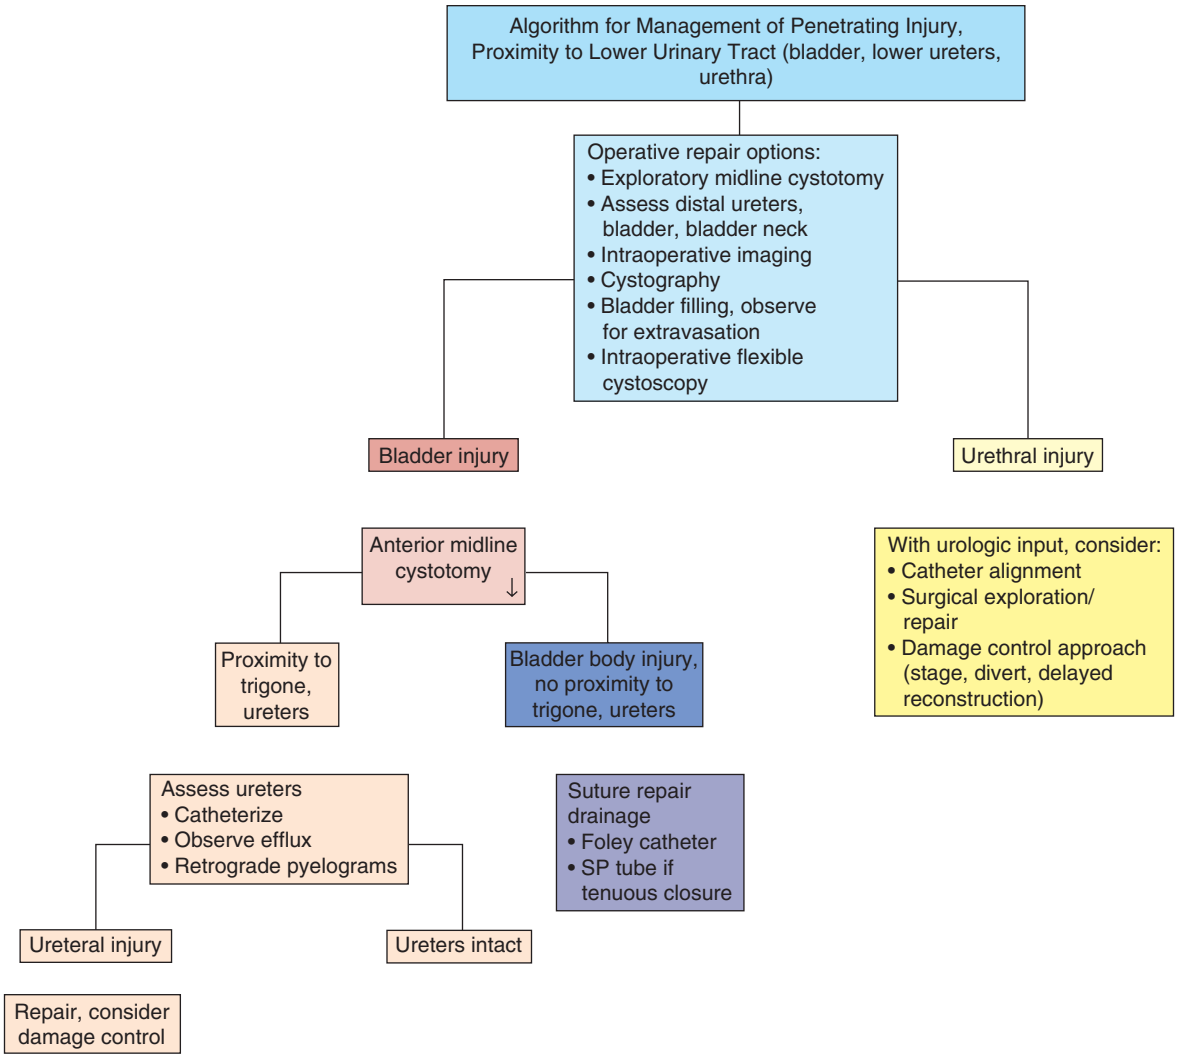

FIGURE 40-40 Algorithm for management of penetrating injury in proximity to lower urinary tract (bladder, lower ureters, urethra). SP, suprapubic.

toward conservative management whenever possible, especially when the kidney is involved; avoiding nephrectomies; and utilization of interventional radiologic vascular technology. Reconstructive surgeries can be achieved endoscopically in cases of urethral realignment and laparoscopically to treat bladder injuries. Further research will continue to impact the urologist's role and approach in dealing with genitourinary injury (Fig. 40-40).

Trauma in Pregnancy

Brian C. Beldowicz • David Leshikar • Christine S. Cocanour

KEY POINTS

- Motor vehicle crashes account for 50% of trauma injuries during pregnancy and 82% of trauma-related fetal deaths, many of which are related to improper seat belt use.
- The disproportionate increase in plasma volume compared to red blood cell volume during pregnancy allows 35% of maternal blood to be lost before the mother exhibits clinical signs of shock.
- When supine, the gravid uterus compresses the inferior vena cava and causes a decrease in venous return to the heart and a drop in cardiac output. Placing the mother in the left lateral decubitus position restores venous flow and improves cardiac output.
- Imaging in the pregnant patient should be similar to the nonpregnant patient if life-threatening injuries are suspected.
- Pelvic fractures are the most common maternal injury that results in fetal death.
- Consider emergency cesarean delivery within 5 minutes in women who are beyond 20 weeks and have cardiopulmonary collapse because the gravid uterus may interfere with maternal hemodynamics.
- Intimate partner violence is the most common form of intentional trauma in pregnancy.

INTRODUCTION

Pregnancy imparts unique considerations in the evaluation and management of trauma patients. These include the following: epidemiologic distinctions from the general population; changes in anatomy and physiology that can alter injury presentation; concerns for fetal and placental injury; ramifications of trauma on the natural course of gestation; and poorly defined implications for the fetus from cumulative ionizing radiation employed in diagnostic imaging. Trauma during pregnancy has increased dramatically over the past 25 years.[1] Injury is now the leading cause of nonobstetrical maternal death in the United States,[2] and adverse fetal outcomes that have been correlated with trauma during pregnancy include preterm delivery, low birth weight, and fetal demise.[3]

Major trauma is associated with a 40% to 50% risk of fetal death, but the severity of trauma does not always predict the severity of injury to mother and fetus. Minor trauma occurs much more frequently but can still pose a significant risk to the fetus. A study of 5352 expectant mothers classified their injuries as major if hospital admission was required or minor if only emergency department evaluation occurred. They found that women in their first or second trimester with minor injury were 20% more likely to have a child with prematurity or low birth weight.[4]

EPIDEMIOLOGY

Trauma complicates an estimated 1 in 12 pregnancies, and 0.4% of pregnant women require hospitalization for their injuries.[5] Motor vehicle crashes account for 50% of all traumatic injuries during pregnancy and 82% of trauma-related fetal deaths.[6]

A major risk factor for injury is the improper use of a seat belt.[7] Over 40% of pregnant women involved in motor vehicle crashes did not receive counseling on appropriate seat belt use in one study.[8] Correct placement has the lap belt underneath the abdominal dome, with the belt contacting both anterior superior iliac spines and the pubic symphysis and decreasing the pressure transmitted across the uterus during a rapid deceleration. The shoulder harness should overlie the clavicle and run between the breasts.

Pregnancy makes women more prone to falls due to inherent changes such as increased joint laxity, weight gain, and dynamic postural stability.[9] It is estimated that one in four

women will fall at least once during their pregnancy.[10] Nearly 80% percent of pregnant women hospitalized after a fall were in their third trimester, and the most common injury was fracture in a lower extremity. Falls are associated with an 8-fold increase in placental abruption, a 4.4-fold increase in preterm labor, a 2.1-fold increase in fetal distress, and a 2.9-fold increase in fetal hypoxia.[11]

ANATOMIC AND PHYSIOLOGIC CHANGES UNIQUE TO PREGNANCY

Understanding the many anatomic and physiologic changes that occur with pregnancy will help the treating physician better manage the mother and the fetus (Table 41-1). The most obvious change seen in pregnancy is uterine growth. Figure 41-1 illustrates the uterine position throughout pregnancy.

At 12 weeks of gestation, the uterus becomes an intra-abdominal organ as it rises above the pelvic brim. At 20 weeks, the top of the uterus is at the level of the umbilicus, and at 36 weeks, it reaches the costal margin. Toward the end of pregnancy, the fetal head drops back into the pelvis, lowering the fundal height. This descent makes the fetal head more susceptible to injury, particularly if the mother suffers a pelvic fracture.[12] Uterine growth also shifts the maternal organs within the abdominal cavity, altering the typical findings on a physical examination and x-rays.

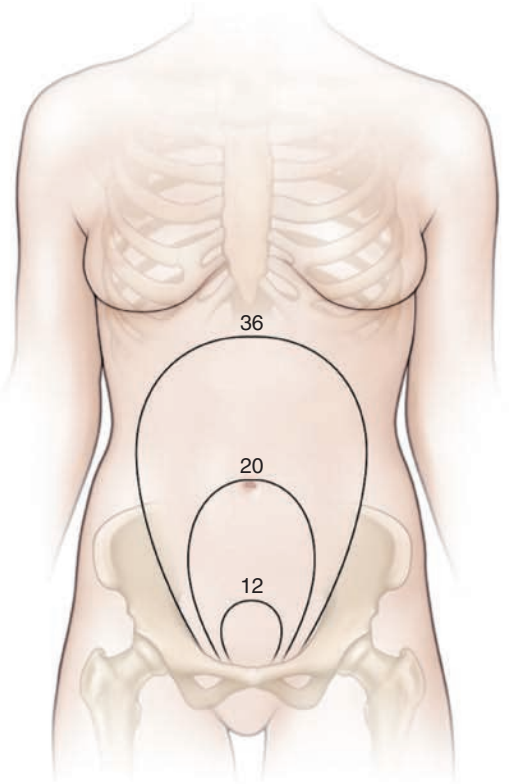

FIGURE 41-1 Representation of fundal height at 12, 20, and 36 weeks of pregnancy.

Cardiovascular System

The growing fetus requires a marked increase in oxygen delivery from the mother, and this is through an increase in

TABLE 41-1: Summary of Normal Physiologic Changes During Pregnancy

System	Change	Potential implication
Cardiovascular	↓ Peripheral vascular resistance, ↓ venous return, ↓ blood pressure (10–15 mm Hg)	Supine hypotensive syndrome (10–15 mm Hg)
Blood volume	↑ Plasma volume, ↑ RBC volume, ↑ WBC (20,000 cells/mm^3)	Physiologic hypervolemia may mask hypotension secondary to blood loss
Coagulation	Hypercoagulable; ↑ fibrinogen; ↑ factors VII, VIII, IX, X, XII; ↓ fibrinolysis	↑ Venous thromboembolism
Respiratory	↑ Subcostal angle (68–103°), ↑ chest circumference (5–7 cm), ↑ diaphragmatic excursion (1–2 cm), elevated diaphragm, ↑ tidal volume, ↑ minute ventilation, ↓ FRC, ↓ Pco_2, ↓ HCO_3	Alteration in FRC and lung volume, chronic compensated respiratory alkalosis
Gastrointestinal	↓ Motility, ↓ intestinal secretion, ↓ nutrient absorption, ↓ sphincter competency (progesterone)	Aspiration
Hepatobiliary	Organ displacement, ↑ gallbladder volume, ↓ albumin, ↑ AP, ↓ bilirubin (free), ↓ GGT	Clinical examination unreliable
Renal	↑ Glomerular filtration rate, ↑ renal plasma flow, ↑ creatinine clearance, ↓ serum creatinine, ↓ BUN	Hydronephrosis, hydroureter, bladder/urethral muscle tone
Endocrine	↑ Parathormone, ↑ calcitonin	↑ Calcium absorption
Musculoskeletal	Pelvic ligaments soften (relaxin, progesterone)	Pelvic widening, lordosis, shift in center of gravity

AP, alkaline phosphatase; BUN, blood urea nitrogen; FRC, functional residual capacity; GGT, γ-glutamyl transferase; RBC, red blood cell; WBC, white blood cell.

oxygen-carrying capacity, cardiac output, and minute ventilation. The maternal plasma volume begins to increase at 10 weeks of gestation and expands by 45% at full term, whereas the red blood cell volume only increases by 18% to 30%.[13] The disproportionate increase in plasma compared to red blood cells is protective because the mother will lose a large amount of blood during delivery. A higher plasma volume relative to red blood cell volume results in fewer lost red cells during hemorrhage. This physiologic anemia of pregnancy, with hematocrit falling to 32% to 34% at its nadir, occurs between the 30th and 34th weeks of gestation. Importantly, the extra blood volume may give a false sense of security for the treating traumatologist because approximately 35% of maternal blood volume may be lost before any clinical signs of shock are observed.

During pregnancy, the normal blood pressure drops by 5 to 15 mm Hg, and the resting heart rate increases by 10 to 15 bpm to increase cardiac output.[14] It is important not to attribute tachycardia or hypotension after trauma to physiologic changes associated with pregnancy without adequately evaluating for sources of hemorrhage. The uterine arteries supply the majority of blood to the fetus and are maximally dilated during pregnancy. Hypovolemia may cause vasoconstriction to divert blood to the mother's vital organs, and this will significantly decrease placental blood flow. Shunting of blood away from the placenta may manifest as fetal distress before systemic signs of hemorrhage are seen in the mother. As the growing uterus displaces the diaphragm, it pushes the heart to the left and upward along its long axis, producing an enlarged cardiac silhouette on chest radiographs. Most pregnant women will have some degree of benign pericardial effusion, while an electrocardiogram will show a slight left axis deviation from the altered position of the heart.[15]

During the middle of the second trimester, maternal position greatly affects cardiovascular physiology. While supine, the gravid uterus compresses the inferior vena cava, leading to a decrease in venous return to the heart and a drop in the cardiac output by as much as 25%. The *supine hypotensive syndrome* leads to dizziness, pallor, tachycardia, diaphoresis, nausea, and hypotension. The uterus also compresses the aorta, causing decreased blood flow to itself. With the uterine arteries maximally dilated during pregnancy, autonomic regulation is lost and blood flow is entirely dependent on maternal mean arterial pressure.[16] Placing the mother in the left lateral decubitus position restores venous flow and improves cardiac output.

Respiratory System
