TRAUMA

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Ninth Edition

Editors

David V. Feliciano, MD

Clinical Professor of Surgery, University of Maryland
School of Medicine
Attending Surgeon, Shock Trauma Center/Department of Surgery,
University of Maryland
Master Surgeon Educator, American College of Surgeons
Baltimore, Maryland

Kenneth L. Mattox, MD

Master Surgeon Educator, American College of Surgeons
Distinguished Service Professor
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Chief of Staff
Chief of Surgery
Ben Taub Hospital
Houston, Texas

Ernest E. Moore, MD

Director of Research, Ernest E. Moore Shock Trauma Center at Denver Health
Distinguished Professor of Surgery, University of Colorado Denver
Editor, *Journal of Trauma and Acute Care Surgery*
Denver, Colorado

Version 1.0

The Founding Co-Editors dedicate the Ninth Edition to our families; to our surgical and medical colleagues; to our former fellows, surgical residents, and medical students; and to fallen and wounded warriors.

To my wife, Grace F. Rozycki, MD, MBA, for her unwavering love and support.
To my sons, David Joseph Feliciano and Douglas Donald Feliciano, JD.
In memory of my parents, Vincent Feliciano, MD, and Anita Hessler Feliciano.

—David V. Feliciano, MD

To my wife, Camella June Mattox, whose love and support began even before medical school. To my daughter, Kimberly Renee Toth, and her husband, Dan Toth.
To my grandchildren, Charlie, Alex, and Kelsey.
In memory of my parents, Bill and Carrie Mattox.

—Kenneth L. Mattox, MD

To my wife, Sarah Van Duzer-Moore, MD, for her unconditional love and support.
To our sons, Hunter B. Moore, MD, PhD, and Peter K. Moore, MD, and daughters-in-law, Brook Brenneman and Tiffany Tello, MD.
To our granddaughters, Estelle and Simone.
In memory of my parents, Ernest Moore, MD, and Sarah Moore.

—Ernest E. Moore, MD

In Memoriam

Henry C. Cleveland, MD	1924–2016
J. Alex Haller, Jr., MD	1927–2018
Norman E. McSwain, MD	1937–2015
Basil A. Prutt, Jr., MD	1930–2019
Gerald W. Shaftan, MD	1926–2019
Erwin R. Thal, MD	1936–2014
Donald D. Trunkey, MD	1937–2019
Alexander J. Walt, MD (Author of Foreword to First Edition, 1987)	1923–1996

With Gratitude To Our Mentors

David V. Feliciano, MD

Anna. M. Ledgerwood, MD	b. 1941
Charles E. Lucas, MD	b. 1937

ABOUT THE FOUNDING EDITORS

DAVID V. FELICIANO, MD

Place of Birth: New York City, New York
College: Georgetown University, 1966
Medical School: Georgetown University, 1970
Residency: General Surgery, Mayo Graduate School of Medicine, 1970–1971; 1973–1977
Fellowship: Trauma, Detroit Receiving Hospital/Wayne State University, 1975; Vascular, Baylor College of Medicine, 1978
Military Service: Lieutenant, USNR, 1971–1973
Academic Career: Ben Taub Hospital/Baylor College of Medicine, 1978–1989; University of Rochester, 1989–1991; Grady Memorial Hospital/Emory University, 1991–2011; Mercer University, 2011–2013; Indiana University, 2013–2017; Shock Trauma Center/University of Maryland, 2017–Present
President of AAST: 2006–2007
President of WTA: 1992–1993
Scudder Orator, ACS: 2010
Lead Editor of *Trauma*: Third Edition, 1996; Sixth Edition, 2008; Ninth Edition, 2020

KENNETH L. MATTOX, MD

Place of Birth: Ozark, Arkansas
College: Wayland Baptist University, 1960
Medical School: Baylor College of Medicine, 1964
Residency: General Surgery, Baylor College of Medicine, 1967–1971; Cardiothoracic Surgery, Baylor College of Medicine, 1972–1973
Military Service: Captain, USAR, 1965–1967
Academic Career: Ben Taub Hospital/Baylor College of Medicine, 1973–Present
President of AAST: 1995–1996
Scudder Orator, ACS: 1999
Lead Editor of *Trauma*: First Edition, 1988; Fourth Edition, 2000; Seventh Edition, 2013

ERNEST E. MOORE, MD

Place of Birth: Pittsburgh, Pennsylvania
College: Allegheny College, 1968
Medical School: University of Pittsburgh, 1972
Residency: General Surgery, University of Vermont, 1972–1976
Academic Career: Ernest E. Moore Shock Trauma Center at Denver Health/University of Colorado, 1976–Present
President of AAST: 1993–1994
President of WTA: 1988–1989
Scudder Orator, ACS: 2002
Editor-in-Chief: *Journal of Trauma and Acute Care Surgery,* 2011–Present
Lead Editor of *Trauma*: Second Edition, 1991; Fifth Edition, 2004; Eighth Edition, 2017

CONTRIBUTORS

Hampton Addis, MD
Resident Physician
Department of Ophthalmology and Visual Sciences
University of Maryland School of Medicine
Baltimore, Maryland
Chapter 23: Eye

Hasan B. Alam, MD
Loyal and Edith Davis Professor of Surgery
Chair, Department of Surgery
Feinberg School of Medicine, Northwestern University
Surgeon-in-Chief, Northwestern Memorial Hospital
Chicago, Illinois
Chapter 59: Respiratory Failure

Roxie M. Albrecht, MD
Professor and Vice Chair of Quality, Department of Surgery
Division Chief, General Surgery, Trauma, and Surgical Critical Care
College of Medicine, University of Oklahoma Health Sciences Center
Oklahoma City, Oklahoma
Chapter 50: Wounds, Bites, and Stings

Juan A. Asensio, MD, KM
Professor and Vice-Chairman of Surgery
Chief, Division of Trauma Surgery & Surgical Critical Care
Director of Trauma Center & Trauma Program
Department of Surgery Creighton University School of Medicine
Creighton University Medical Center
Professor of Clinical & Translational Science
Department of Translational Science Creighton University School of Medicine
Adjunct Professor of Surgery, Uniformed Services University of the Health Sciences
F. Edward Hébert School of Medicine
Walter Reed National Military Medical Center
Bethesda, Maryland
Chapter 38: Abdominal Vessels

Chad G. Ball, MD, MSc
Professor of Surgery
University of Calgary
Foothills Medical Centre
Editor, *Canadian Journal of Surgery*
Calgary, Alberta, Canada
Chapter 42: Trauma Damage Control

Robert D. Becher, MD, MS
Assistant Professor of Surgery
Department of Surgery
Yale School of Medicine
Yale-New Haven Hospital
New Haven, Connecticut
Chapter 62: Nutritional Support and Electrolyte Management

Gregory J. Beilman, MD
Associate Dean of Clinical Affairs
Owen H and Sarah Davidson Wangensteen Chair of Surgical Research
University of Minnesota
Minneapolis, Minnesota
Chapter 52: Temperature-Related Syndromes

Brian C. Beldowicz, MD
Assistant Professor of Surgery
Harborview Medical Center
University of Washington
Seattle, Washington
Assistant Professor of Military & Emergency Medicine
Uniformed Services University of the Health Sciences
Bethesda, Maryland
Chapter 41: Trauma in Pregnancy

Elizabeth R. Benjamin, MD, PhD
Associate Professor of Surgery
Division of Trauma and Surgical Critical Care
University of Southern California
LAC + USC Medical Center
Los Angeles, California
Chapter 52: Temperature-Related Syndromes

Denis D. Bensard, MD
Professor of Surgery
University of Colorado SOM
Director Pediatric Trauma
Denver Health Medical Center
Denver, Colorado
Chapter 48: Pediatric Trauma

Robel T. Beyene, MD
Assistant Professor of Surgery
Division of Trauma and Critical Care
Vanderbilt University Medical Center
Nashville, Tennessee
Chapter 61: Renal Failure

Ben E. Biesterveld, MD
General Surgery Resident
University of Michigan
Ann Arbor, Michigan
Chapter 59: Respiratory Failure

Walter L. Biffl, MD
Medical Director, Trauma and Acute Care Surgery
N. Paul Whittier Chair of Trauma
Scripps Memorial Hospital La Jolla
La Jolla, California
Chapter 32: Diaphragm

Jessica A. Bowman, MD
Chief Resident, General Surgery
Department of Surgery
UC Davis Health
Sacramento, California
Chapter 31: Trauma Laparotomy: Principles and Techniques

Nori L. Bradley, MD, MSc(Kin), MSc(HSQ)
Assistant Professor of Surgery
University of Alberta
General and Trauma Surgeon, University of Alberta Hospital
Edmonton, Alberta, Canada
Assistant Professor of Surgery
University of British Columbia
Intensivist, Medical Director for Organ Donation
Royal Columbian Hospital
New Westminster, British Columbia, Canada
Chapter 58: Cardiovascular Failure

Scott C. Brakenridge, MD
Associate Professor of Surgery and Anesthesiology
Division of Acute Care Surgery, Department of Surgery
University of Florida
Gainesville, Florida
Chapter 9: Genomics and Acute Care Surgery

Susan M. Briggs, MD, MPH
Associate Professor of Surgery, Harvard Medical School
Director, International Trauma and Disaster Institute
Massachusetts General Hospital
Boston, Massachusetts
Chapter 12: Disaster and Multiple/Mass Casualties

Carlos V.R. Brown, MD
Professor of Surgery
Chief, Division of Acute Care Surgery
Dell Medical School, University of Texas at Austin
Austin, Texas
Chapter 14: Management of the Airway

Joshua Brozek, MD
Resident Physician
Department of Ophthalmology and Visual Sciences
University of Maryland School of Medicine
Baltimore, Maryland
Chapter 23: Eye

Brandon Bruns, MD
Associate Professor of Surgery
University of Maryland School of Medicine
Attending Surgeon, Shock Trauma Center
Trauma Medical Director, Capital Region Health
Cheverly, Maryland
Chapter 33: Liver and Biliary Tract

Eileen Bulger, MD
Chief of Trauma
Professor of Surgery
Harborview Medical Center
University of Washington
Seattle, Washington
Chapter 21: Infections

Clay Cothren Burlew, MD
Professor of Surgery
Director, Surgical Intensive Care Unit
Program Director, SCC and TACS Fellowships
The Ernest E. Moore Shock Trauma Center
Denver Health Medical Center
Denver, Colorado
Chapter 17: Resuscitative Thoracotomy

Amanda Celii, MD
Assistant Professor, Department of Surgery
Division of Trauma and Surgical Critical Care
College of Medicine, University of Oklahoma Health Sciences Center
Oklahoma City, Oklahoma
Chapter 50: Wounds, Bites, and Stings

Howard R. Champion, FRCS (Edin., Eng.)
Professor of Surgery
Uniformed Services University of the Health Sciences
Bethesda, Maryland
CEO SimQuest
Annapolis, Maryland
Chapter 5: Injury Severity Scoring, Modeling, and Outcomes Research

David J. Ciesla, MD
Professor of Surgery
Division Director of Acute Care Surgery
Morsani College of Medicine
University of South Florida
Medical Director, Regional Level I Trauma Program
Tampa General Hospital
Tampa, Florida
Chapter 4: Trauma Systems, Triage, and Transport

William G. Cioffi, MD
J. Murray Beardsley Professor and Chairman
Department of Surgery
Alpert Medical School of Brown University
Providence, Rhode Island
Chapter 32: Diaphragm

Damon H. Clark, MD
Assistant Professor of Clinical Surgery
Division of Acute Care Surgery
University of Southern California
Los Angeles, California
Chapter 18: Surgeon-Performed Ultrasound in Acute Care Surgery

Christine S. Cocanour, MD
Professor of Surgery
UC Davis Health
Sacramento, California
Chapter 41: Trauma in Pregnancy

Raul Coimbra, MD, PhD
Surgeon-in-Chief, Riverside University Health System Medical Center
Professor of Surgery, Loma Linda University School of Medicine
Emeritus Professor, University of California San Diego
San Diego, California
Chapter 57: Principles of Critical Care

Jamie J. Coleman, MD
Associate Professor of Surgery
University of Colorado School of Medicine
Denver Health Medical Center
Denver, Colorado
Chapter 28: Chest Wall and Lung

Bryan Collier, DO
Professor of Surgery
Section Chief of Acute Care Surgery
Trauma and Surgical Critical Care Medical Director
Surgical Critical Care Fellowship Program Director
Director of Surgical Nutrition
Virginia Tech Carilion School of Medicine
Carilion Roanoke Memorial Hospital
Roanoke, Virginia
Chapter 60: Gastrointestinal Failure

Bryan A. Cotton, MD, MPH
The John B. Holmes Professor of Clinical Sciences
Department of Surgery
McGovern Medical School at the University of Texas Health Science Center
Attending Trauma Surgeon
The Red Duke Trauma Institute at Memorial Hermann Hospital-Texas Medical Center
Houston, Texas
Chapter 58: Cardiovascular Failure

Angela M. Crawford, MD
R Adams Cowley Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland
Chapter 49: Geriatric Trauma

Martin A. Croce, MD
Senior Vice President and Chief Medical Officer, Regional One Health
Professor of Surgery
Department of Surgery
University of Tennessee Health Science Center
Memphis, Tennessee
Chapter 37: Colon and Rectum

Alisa Cross, MD
Assistant Professor, Department of Surgery
Division of Trauma and Surgical Critical Care
College of Medicine, University of Oklahoma Health Sciences Center
Oklahoma City, Oklahoma
Chapter 50: Wounds, Bites, and Stings

James W. Davis, MD
Professor of Clinical Surgery and Chief
Department of Surgery
UCSF/Fresno
University of California, San Francisco/Fresno
Fresno, California
Chapter 47: Social Violence

Kimberly A. Davis, MD, MBA
Professor of Surgery
Department of Surgery
Yale School of Medicine
Yale-New Haven Hospital
New Haven, Connecticut
Chapter 62: Nutritional Support and Electrolyte Management

Raj D. Dedhia, MD
Department of Otolaryngology-Head and Neck Surgery
University of California, Davis
Sacramento, California
Chapter 24: Face

Jose J. Diaz, MD, CNS
Vice Chair Quality and Safety
Department of Surgery
Chief Division Acute Care Surgery
Program Director Acute Care Surgery Fellowship
Program in Trauma
R Adams Cowley Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland
Chapter 60: Gastrointestinal Failure

Rochelle A. Dicker, MD
Professor of Surgery
Vice Chair for Critical Care
Associate Chief of Trauma and Emergency General Surgery
UCLA David Geffen School of Medicine
Los Angeles, California
Chapter 3: Injury Prevention

Benjamin C. Dorenkamp, DO
McLaren Greater Lansing
Orthopedic Surgery Residency
Lansing, Michigan
Center for Spine and Orthopedics
The Spine Education and Research Institute
Thornton, Colorado
Chapter 26: Spinal Cord and Spine

Jay Doucet, MD
Professor of Surgery
Chief, Division of Trauma, Surgical Critical Care, Burns, and Acute Care Surgery
Medical Director, Emergency Preparedness and Response
University of California San Diego
Surgical Director, Perioperative Services, Hillcrest
San Diego, California
Chapter 57: Principles of Critical Care

Joseph J. DuBose, MD, Col, MC, USAF
Professor of Surgery
Uniformed Services University of the Health Sciences
Professor of Surgery
University of Maryland School of Medicine
Director, C-STARS
R Adams Cowley Shock Trauma Center
Baltimore, Maryland
Endovascular Commentary for Chapter 25: Neck and Larynx
Chapter 28: Chest Wall and Lung
Chapter 29: Trachea, Bronchi, and Esophagus
Endovascular Commentary to Chapter 38: Abdominal Vessels

Juan C. Duchesne, MD
The William Henderson Chair of Surgery Endowed Professor of Trauma
Division Chief Acute Care Surgery
Department of Surgery Tulane
TICU Medical Director
Norman McSwain Level I Trauma Center
New Orleans, Louisiana
Chapter 11: Rural Trauma

Shannon C. Eastham, MD
Assistant Professor of Surgery
Division of Trauma and Surgical Critical Care
Vanderbilt University Medical Center
Nashville, Tennessee
Chapter 61: Renal Failure

Philip A. Efron, MD
Professor of Surgery and Anesthesiology
Division of Acute Care Surgery, Department of Surgery
University of Florida
Gainesville, Florida
Chapter 9: Genomics and Acute Care Surgery

Heather L. Evans, MD, MS
Professor of Surgery
Vice Chair of Clinical Research and Applied Informatics
Department of Surgery
Medical University of South Carolina
Charleston, South Carolina
Chapter 21: Infections

Timothy C. Fabian, MD
Professor (Emeritus) of Surgery
Department of Surgery
University of Tennessee Health Science Center
Memphis, Tennessee
Chapter 37: Colon and Rectum

D. Gregory Farwell, MD
Professor and Chair
Department of Otolaryngology-Head and Neck Surgery
University of California, Davis
Sacramento, California
Chapter 24: Face

David V. Feliciano, MD
Clinical Professor of Surgery, University of Maryland School of Medicine
Attending Surgeon, Shock Trauma Center/Department of Surgery, University of Maryland
Master Surgeon Educator, American College of Surgeons
Baltimore, Maryland
Chapter 25: Neck and Larynx
Chapter 36: Duodenum and Pancreas
Chapter 38: Abdominal Vessels
Chapter 42: Trauma Damage Control

Paula Ferrada, MD
Professor of Surgery
Virginia Commonwealth University
Richmond, Virginia
Chapter 36: Duodenum and Pancreas

Ricardo Ferrada, MD
Professor of Surgery
Universidad del Valle
Cali, Colombia, South America
Chapter 36: Duodenum and Pancreas

Adam D. Fox, DPM, DO
Associate Professor of Surgery
Division of Trauma and Surgical Critical Care
Department of Surgery
Rutgers, New Jersey Medical School
Newark, New Jersey
Chapter 13: Initial Assessment

Heidi L. Frankel, MD
Professor of Surgery (retired)
Rancho Palos Verdes, Los Angeles, California
Chapter 18: Surgeon-Performed Ultrasound in Acute Care Surgery

Greg E. Gaski, MD
Orthopaedic Trauma Surgeon
Department of Orthopaedic Surgery
Inova Fairfax Medical Campus
Falls Church, Virginia
Chapter 44: Lower Extremity

Ravi K. Ghanta, MD
Chief Cardiothoracic Surgery
Ben Taub Hospital
Associate Professor of Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas
Chapter 27: Trauma Thoracotomy: Principles and Techniques
Chapter 30: Heart and Thoracic Vessels

Naeem Goussous, MD
Clinical Instructor of Transplant Surgery
Department of Surgery
University of Maryland School of Medicine
Baltimore, Maryland
Chapter 54: Organ Donation from Trauma Patients

John E. Griepentrog, MD
General Surgery Resident
Department of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 8: Acute Care Surgery

F. Lawson Grumbine, MD
Oculoplastic and Orbital Surgery
Department of Ophthalmology
Greater Baltimore Medical Center
Clinical Assistant Professor
Department of Ophthalmology and Visual Sciences
University of Maryland School of Medicine
Baltimore, Maryland
Chapter 23: Eye

Elizabeth Guardiani, MD
Assistant Professor of Otorhinolaryngology—Head and Neck Surgery
University of Maryland Medical Center
Baltimore, Maryland
Chapter 25: Neck and Larynx

Jennifer M. Gurney, MD
Colonel, Medical Corps, US Army
Assistant Professor of Surgery
Uniformed Services University of the Health Sciences
Chief, Trauma Systems Development, Joint Trauma System
US Army Institute of Surgical Research
San Antonio, Texas
Chapter 53: Modern Combat Casualty Care

Katherine Hill, MD, MS
Resident Physician in General Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania
Surgical Education Research Fellow
College of Surgeons of East, Central, and Southern Africa
Tenwek Hospital, Kenya
Chapter 64: Trauma and Global Health

John P. Hunt, MD, MPH
LSU-Pfizer/Hank McCrorie Endowed Professor of Trauma Surgery and Anesthesiology
Trauma Medical Director
Norman E. McSwain-Spirit of Charity Level I Trauma Center
University Medical Center–New Orleans
Program Director
LSU Health New Orleans Trauma/Critical Care Fellowship
New Orleans, Louisiana
Chapter 11: Rural Trauma

Kenji Inaba, MD
Professor and Vice Chair of Surgery
Division of Trauma and Surgical Critical Care
University of Southern California
LAC + USC Medical Center
Los Angeles, California
Chapter 52: Temperature-Related Syndromes

Yohan Jang, DO
Assistant Professor
Department of Orthopedic Surgery
Indiana University School of Medicine
Indianapolis, Indiana
Chapter 44: Lower Extremity

Michael E. Janssen, DO
Spine Surgeon
Spine Fellowship Director
Center for Spine and Orthopedics
The Spine Education and Research Institute
Thornton, Colorado
Chapter 26: Spinal Cord and Spine

Donald H. Jenkins, MD, DMCC
Professor/Clinical, Division of Trauma and Emergency Surgery
Vice Chair for Quality, Department of Surgery
Betty and Bob Kelso Distinguished Chair in Burn and Trauma Surgery
Associate Deputy Director, Military Health Institute
UT Health San Antonio
San Antonio, Texas
Chapter 10: Prehospital Care

Laura S. Johnson, MD
Assistant Professor of Surgery
Georgetown University School of Medicine
Washington Hospital Center
Washington, DC
Chapter 46: Alcohol and Drugs

Carolynn Jones, JD, CHC
Executive Vice President
Chief Compliance and Risk Office
Harris Health System
Houston, Texas
Chapter 56: Trauma, Medicine, and the Law

Catherine J. Juillard, MD, MPH
Associate Professor-in-Residence
Department of Surgery
University of California, Los Angeles
Los Angeles, California
Chapter 3: Injury Prevention

Gregory J. Jurkovich, MD
Professor and Vice-Chairman
Lloyd F. & Rosemargaret Donant Chair in Trauma Medicine
Department of Surgery
UC Davis Health
Sacramento, California
Chapter 31: Trauma Laparotomy: Principles and Techniques

James M. Kempema, MD
Clinical Assistant Professor
Department of Surgery and Perioperative Care
Dell Medical School, University of Texas at Austin
EMS Director Dell Medical School
University of Texas at Austin Emergency Medicine Residency
Medical Director Travis County Emergency Services/STAR Flight
Austin, Texas
Chapter 14: Management of the Airway

Andrew J. Kerwin, MD
Professor of Surgery
Division Chief, Acute Care Surgery
Department of Surgery
University of Florida College of Medicine–Jacksonville
Trauma Medical Director, UF Health Jacksonville
Jacksonville, Florida
Chapter 4: Trauma Systems, Triage, and Transport

Fernando J. Kim, MD, MBA
Chief Emeritus, Denver Health Medical Center
Professor of Surgery/Urology, U Colorado Denver
University of Colorado School of Medicine
Associate Editor, *Patient Safety in Surgery*
Denver, Colorado
Chapter 40: Genitourinary Tract

Lisa Knowlton, MD, MPH
Assistant Professor of Surgery
Section of Trauma, Acute Care Surgery, and Surgical Critical Care
Department of Surgery
Stanford University
Stanford, California
Chapter 39: Pelvis

Leslie Kobayashi, MD
Associate Professor of Surgery
University of California San Diego
San Diego, California
Chapter 57: Principles of Critical Care

Rosemary Kozar, MD, PhD
Professor of Surgery
University of Maryland School of Medicine
Attending Surgeon
Director of Translational Research Shock Trauma Center
Co-Director of Shock Trauma Anesthesia Research (STAR) Center
Baltimore, Maryland
Chapter 33: Liver and Biliary Tract

Amy M. Kwok, MD, MPH
Associate Clinical Professor
Department of Surgery
University of California, San Francisco/Fresno
Fresno, California
Chapter 47: Social Violence

David Leshikar, MD
Assistant Professor of Surgery
UC Davis Health
Sacramento, California
Chapter 41: Trauma in Pregnancy

Benjamin Levi, MD
Assistant Professor of Surgery
Division of Plastic Surgery
University of Michigan
Ann Arbor, Michigan
Chapter 51: Burns and Radiation

Anthony J. Lewis, MD
Vascular Surgery Fellow
Department of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 8: Acute Care Surgery

David H. Livingston, MD
Wesley J. Howe Professor of Surgery
Chief, Division of Trauma and Surgical Critical Care
Department of Surgery
Rutgers New Jersey Medical School
Newark, New Jersey
Chapter 13: Initial Assessment
Chapter 35: Stomach and Small Bowel

Jana Macleod, MD, MSc
Faculty
Kenyatta University & Pan-African Academy of Christian Surgeons
Nairobi, Kenya
Professor of Surgery (Adjunct)
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 64: Trauma and Global Health

Ronald V. Maier, MD
Jane and Donald D. Trunkey Professor and Vice Chair of Surgery
University of Washington
Surgeon-in-Chief, Department of Surgery
Harborview Medical Center
Seattle, Washington
Chapter 15: Management of Shock

Alan B. Marr, MD
Vice Chair of Informatics
Professor of Clinical Surgery
Trauma/Critical Care/Acute Care Surgery
LSU Health New Orleans
New Orleans, Louisiana
Chapter 11: Rural Trauma

Kazuhide Matsushima, MD
Assistant Professor of Surgery
Division of Acute Care Surgery
University of Southern California
LAC + USC Medical Center
Los Angeles, California
Chapter 18: Surgeon-Performed Ultrasound in Acute Care Surgery

Kenneth L. Mattox, MD
Master Surgeon Educator, American College of Surgeons
Distinguished Service Professor
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Chief of Staff
Chief of Surgery
Ben Taub Hospital
Houston, Texas
Chapter 27: Trauma Thoracotomy: Principles and Techniques
Chapter 30: Heart and Thoracic Vessels
Chapter 56: Trauma, Medicine, and the Law

Caitlin L. McAuliffe-Gray, MD
Formerly, Department of Rehabilitation Medicine
F. Edward Hébert School of Medicine
Walter Reed National Military Medical Center
Bethesda, Maryland
Chapter 55: Rehabilitation

Ashley D. Meagher, MD, MPH
Assistant Professor, Department of Surgery
Indiana University School of Medicine
Indianapolis, Indiana
Chapter 2: Epidemiology

Kirsten Meenan, MD
Resident
Department of Otorhinolaryngology—Head and Neck Surgery
University of Maryland Medical Center
Baltimore, Maryland
Chapter 25: Neck and Larynx

Richard S. Miller, MD
Chair, Department of Surgery
Chief of Surgery
JPS Health Network
Senior Executive, Surgery
Acclaim Physician Group
Professor of Surgery
TCU/University of North Texas Health Science Center
Fort Worth, Texas
Chapter 61: Renal Failure

Joseph P. Minei, MD, MBA
Professor and Executive Vice Chair
C. James Carrico, MD, Distinguished Chair in Surgery
Department of Surgery
UT Southwestern Medical Center
Surgeon-in-Chief
Parkland Health and Hospital System
Dallas, Texas
Chapter 34: Spleen

Lyle L. Moldawer, PhD
Professor and Vice Chairman of Research
Director, Laboratory of Inflammation Biology & Surgical Science
Department of Surgery
University of Florida
Gainesville, Florida
Chapter 9: Genomics and Acute Care Surgery

Ernest E. Moore, MD
Director of Research
Ernest E. Moore Shock Trauma Center at Denver Health
Distinguished Professor of Surgery
University of Colorado Denver
Editor, *Journal of Trauma and Acute Care Surgery*
Denver, Colorado
Chapter 7: Critical Appraisal of Trauma Research
Chapter 16: Trauma-Induced Coagulopathy
Chapter 17: Resuscitative Thoracotomy

Hunter B. Moore, MD, PhD
Transplant Surgery Fellow
University of Colorado, Denver
Aurora, Colorado
Chapter 16: Trauma-Induced Coagulopathy

Lynne Moore, PhD
Professor
Department of Social and Preventive Medicine
Faculty of Medicine
Université Laval
Quebec City, Quebec, Canada
Chapter 5: Injury Severity Scoring, Modeling, and Outcomes Research

Benjamin Moran, MD
Associate Program Director, Surgery
Department of Surgery
Einstein Medical Center
Philadelphia, Pennsylvania
Chapter 63: Postinjury Inflammation and Organ Dysfunction

Andrew Muck, MD
Vice Chair of Education and Program Director
Professor, Department of Emergency Medicine
Faculty, Center for Medical Humanities and Ethics
UT Health San Antonio
San Antonio, Texas
Chapter 10: Prehospital Care

Sydne Muratore, MD
General Surgery Faculty
Medical Student Clerkship Director
Department of Surgery
Saint Joseph Hospital General Surgery Residency
Denver, Colorado
Chapter 52: Temperature-Related Syndromes

Lena M. Napolitano, MD
Massey Family Foundation Professor of Surgery
Associate Chair, Department of Surgery
Associate Director, Center for Integrative Research in Critical Care
University of Michigan Medical Center
Ann Arbor, Michigan
Chapter 57: Principles of Critical Care

Aussama Nassar, MD, MSc
Clinical Assistant Professor of Surgery
Program Director, Surgical Critical Care Fellowship
Department of Surgery
Stanford University School of Medicine
Stanford, California
Chapter 39: Pelvis

James V. O'Connor, MD
Professor of Surgery
University of Maryland School of Medicine
Chief of Thoracic and Vascular Trauma
R Adams Cowley Shock Trauma Center
Baltimore, Maryland
Chapter 28: Chest Wall and Lung
Chapter 29: Trachea, Bronchi, and Esophagus

Charles F. Opalak, MD
Resident, Department of Neurosurgery
Virginia Commonwealth University
Richmond, Virginia
Chapter 22: Brain

Ingrid A. Parrington, DO
Lieutenant Commander, Medical Corps, United States Navy
Regimental Surgeon and Senior Medical Officer
4th Marine Regiment
Third Marine Division
Okinawa, Japan
Chapter 55: Rehabilitation

Paul F. Pasquina, MD
Colonel, US Army (Ret.)
Professor and Chair
Department of Rehabilitation Medicine
F. Edward Herbert School of Medicine
Chief, Department of Rehabilitation
Walter Reed National Military Medical Center
Bethesda, Maryland
Chapter 55: Rehabilitation

Andrew B. Peitzman, MD
Mark M. Ravitch Professor of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 8: Acute Care Surgery

Raymond Pensy, MD
Associate Professor of Orthopedics
Division of Orthopedic Traumatology
R Adams Cowley Shock Trauma Center
Program Director, University of Maryland Hand, Upper Extremity, and Microvascular Fellowship
University of Maryland School of Medicine
Baltimore, Maryland
Chapter 43: Upper Extremity

Fredric M. Pieracci, MD, MPH
Associate Professor of Surgery
University of Colorado School of Medicine

PREFACE

This Ninth Edition of *Trauma* is another milestone in the now 35-year journey of the textbook. Originally conceived at a time (1984) when prospective randomized and multicenter studies were rare in the field, the management of injured patients was based on the following: history/physical examination/routine laboratory tests/routine x-rays; decreasing role for diagnostic peritoneal lavage; increasing usage of computed tomography (CT); and clinical guidelines passed on from teachers and mentors.

The evolution in the field of trauma since that time has been extraordinary. The following advances have truly changed the evaluation and management of injured patients during the history of the textbook: goal-directed resuscitation; surgeon-performed ultrasound; multidetector CT and CT angiography; magnetic resonance imaging; nonoperative management of injured viscera and vessels; damage control surgery; endostents and stent grafts; advances in surgical critical care and increased numbers of surgeon-intensivists; and the development of a formal training pathway in acute care surgery.

The major issue for the Founding Co-Editors (D.V.F., K.L.M., E.E.M.) when organizing and editing a "new" textbook every 4 years or so has been updating the contents enough to justify another edition. Changes in the Ninth Edition have been substantial, and many have been based on the comments from readers of previous editions. Most important has been the addition of six Associate Editors—Hasan Alam, Chad Ball, Kenji Inaba, Rosemary Kozar, David Livingston, and Marty Schreiber. All of these individuals have made substantial contributions to the knowledge behind evaluation and management of injured patients, all have been in leadership positions in trauma professional societies, and all were well known to us. We thank the Associate Editors for their efforts in making *Trauma,* Ninth Edition, an improved reference book in the field.

Other changes in the Ninth Edition include two new chapters, Chapter 28: Chest Wall and Lung, and Chapter 64: Trauma and Global Health; a reorganization of the chapters in the book; added content including a special section on injuries to the larynx in Chapter 25, now entitled Neck and Larynx; and revisions in the Atlas. In addition, there is now a section entitled Endovascular Commentary after Chapter 25: Neck and Larynx, Chapter 38: Abdominal Vessels, and Chapter 45: Peripheral Vessels. The Trauma Video section organized by Demetrios Demetriades and Kenji Inaba has been retained as well. Finally, over 45% of the chapters in the Ninth Edition have new senior authors.

We thank all of our chapter authors for updating the content and Mike de la Flor, PhD, for his excellent art work in the Atlas. Also, we thank our colleagues in the Medical Publishing Division of McGraw Hill, our longtime publisher, especially Andrew Moyer, Senior Editor, and Christie Naglieri, Senior Project Development Editor. And, of course, we offer special thanks to our administrative assistants for their endless work and tolerance: Josanne Walker (D.V.F.) and Mary Allen (K.L.M.).

TRAUMA OVERVIEW

This page intentionally left blank

1 Kinematics

Carrie A. Sims • Patrick M. Reilly

KEY POINTS

- A body in motion stays in motion, moving at the same speed and direction, unless acted on by a force.
- The energy of an object and its potential to do damage are directly proportional to its mass and the square of its velocity ($E_k = \frac{1}{2}MV^2$).
- The total energy of a system cannot be destroyed, although it may be transferred between objects or transformed into work.
- All injuries can be explained by four different types of strain (tensile, shear, compressive, and/or overpressure).
- If a force causes a decrease in the original volume of a fluid- or air-filled structure, there must be a concomitant increase in the pressure.
- The shape (and thus the sectional density) of a bullet is subject to change within the tissue and directly impacts the degree of tissue damage.
- A projectile creates both a permanent cavitation or "bullet track" and a hydrostatic pressure wave that stretches and damages adjacent tissues.
- In explosions, more energy is transferred if the shock wave travels through a medium of similar density (eg, water and the human body).

INTRODUCTION

Although patients suffer what initially may appear to be a unique constellation of injuries, all trauma can be described using physical principles. As such, understanding how the physical properties of force, mass, and velocity contribute to energy transfer can help the treating surgeon anticipate, identify, and subsequently treat injuries based on mechanism. This chapter will discuss the basic laws of physics that dictate the interaction between the injuring mechanism and the victim. This is followed by a discussion of blunt trauma, with special consideration of specific body regions and populations. Finally, the science of ballistics and the injuries caused by firearms and explosions are presented.

BASIC PRINCIPLES OF MOTION

In the late 17th century, the English physicist Sir Isaac Newton (1642–1727) first described how mechanical events could be explained using laws of motion and gravity. This section will provide a brief overview of Newtonian physics and how its principles directly apply to injury.[1]

Newton's first law is as follows: Every object persists in its state of rest or in uniform motion in a straight line unless it is compelled to change that state by forces impressed on it.

According to Newton's first law, a body in motion stays in motion, moving at the same speed and direction, unless acted on by a force. The state of being in motion, otherwise known as momentum (p), is described by both the object's mass (m) and its velocity (v).

$$p = mv$$

A motorcycle crash provides a classic example of this principle. Both rider and motorcycle have their individual mass and are traveling at the same velocity. When the motorcycle encounters an object, its velocity becomes zero. In contrast, the rider continues in a straight line until acted on by a force, usually the ground or another vehicle.

In order to change an object's momentum, a force must be introduced that either causes the object to speed up or slow down. When a force causes a change in momentum, it is referred to as an impulse. This is, however, a bidirectional exchange. A force causes a change in momentum and, conversely, a change in momentum will generate a force.

The momentum of an object is also a measure of its kinetic energy (E_k). In other words, the energy an object possesses is due to its motion and is directly proportional to both its mass and its velocity.

$$E_k = \frac{1}{2}MV^2$$

This principle can be used to explain the mortality differences from falls. For any given mass, a five-story fall is associated with greater velocity than a fall from standing. Therefore, higher falls are theoretically associated with more energy and, thus, more tissue damage on impact. This principle holds true until air resistance prevents further acceleration and terminal velocity is reached. For humans, this translates to a terminal velocity of 53 m/s and is achieved by falling 450 m in 12 seconds.

Newton's second law states the following: The acceleration of an object produced by a net force is directly proportional to the magnitude of the net force, in the same direction of the net force and inversely proportional to the mass.

Stated differently, force (F) equals mass (m) times acceleration (a), where acceleration is the change in velocity over the change in time.

$$F = ma$$

Newton's third law states: *For every action, there is an equal and opposite reaction*.

When two objects of equal velocity and mass strike each other, their velocities are reduced to zero at the moment of impact. Each exerts a force on the other and, because these forces are exactly equal and opposite, the net force is zero. Therefore, the net change in momentum is zero. This means that these two objects would change their direction and "bounce" in opposite directions at the same velocity and momentum if 100% of the energy were transferred. In real trauma scenarios, however, collisions are inelastic. Although they conserve momentum, their kinetic energy "does work" by deforming the materials they encounter.

Work (W) is defined as a force exerted over a distance, but can also be defined in terms of a change in kinetic energy. Therefore, the work being done by one object in motion on another equals the kinetic energy of the object before the interaction minus the kinetic energy after the interaction. In other words, the work done is equal to the change in kinetic energy of the first object. When this interaction sets the other body in motion, the second body now has kinetic energy of its own equal to the work that has been done, assuming no deformation. The greater the momentum of the first object, the greater the magnitude of work that can be done.

We can understand Newton's third law using the example of two cars colliding in various ways. Figure 1-1A represents a head-on collision of two vehicles with equal mass and velocity and, thus, equal kinetic energy and momentum in opposite directions. The total momentum for the system is zero prior to the crash and, by the law of conservation of momentum, must be zero after the crash. If the cars were made of a perfectly nondeformable material, all kinetic energy would be exchanged and the cars would bounce in opposite directions at the exact same speed. In reality, however, these vehicles will be deformed by this interaction. Because the final velocity is zero, all the kinetic energy is converted to work that stops the other car and causes deformation such as broken glass, bent metal, or physical intrusion into the passenger compartment.

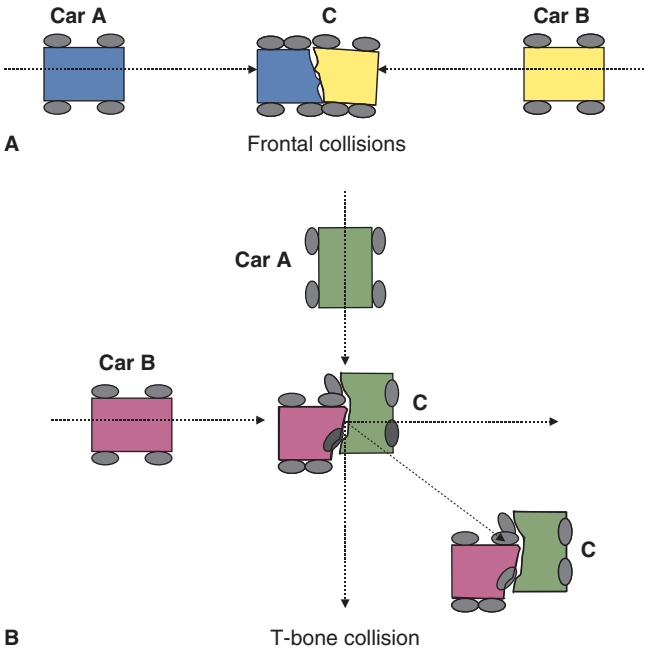

FIGURE 1-1 Energy and momentum available in various motor vehicle crash scenarios. (**A**) Frontal collisions have the greatest change in momentum over the shortest amount of time and hence the highest forces generated. (**B**) T-bone collision. When cars A and B collide, their resultant momentum directs them toward their final position C; the individual momentums in the x and y axes are dissipated over a greater time, resulting in smaller forces than in head-on collisions.

Assuming that both cars come to rest as a single entangled mass (referred to as object C), the change in momentum represents a force, which is equally applied to both cars. If the momentum of car A was greater than that of car B, the resultant mass C would have the momentum, and direction, of car A prior to impact. As such, the kinetic energy transferred to the occupants of car A would be less than that transferred to the occupants of car B. In order to illustrate this point, let's assume car A is an SUV and car B is a compact. The collision of these two vehicles results in predictable damage and consequences.

In T-bone type crashes, the directions of the momentum of cars A and B are perpendicular and momentum is conserved in a third direction, C (Fig. 1-1B). Because kinetic energy is partly conserved in this new momentum, less energy is transferred to the vehicles (and their occupants) with less deformity. Finally, in rear-end collisions, the energy exchange is a function of the net difference in momentum, not absolute momentum. The more momentum conserved by the

conglomerate of the two vehicles (mass C), the less energy is transferred into deforming the vehicles or their occupants.

STRESS, STRAIN, AND BIOMECHANICS

Stress and strain are two biomechanical principles that directly impact the degree of physical injury.[2] Stress, defined as a force per unit area or load, causes deformation of a given material. Strain, on the other hand, is the distance (or depth) of the deformation divided by the length over which the stress is applied. Injuries can be caused by four different types of strain as follows: tensile, shear, compressive, and overpressure (Fig. 1-2). Tensile strain occurs when applied forces are opposing and concentrated upon a *shared* point. As such, the integrity of the structure is literally pulled apart. Shear strain, on the other hand, occurs when opposing forces are applied to *different* points within a structure. Shear strain can either be caused by opposing *external* forces or arise from a relative difference in the change of momentum *within* a single structure (or between structures that are attached). Compressive strain is the direct deformation that occurs as a result of an impact. The energy transferred on impact does work on the structure, causing a crushing-type injury with disruption of the organ's structural integrity. Finally, overpressure is a type of compressive strain that is applied to a gas- or fluid-filled structure, causing deformation and a decrease in the volume of the structure. According to Boyle's law:

$$P_1V_1 = P_2V_2$$

the product of the pressure (P) and volume (V) before a force is applied must equal the product of these two variables afterward.[3] Therefore, if a force causes a decrease in the original volume, there must be concomitant increase in the pressure. This change in pressure (ie, force) could overcome the tensile strength of the structure, causing it to rupture.

How well a tissue tolerates a specific insult varies with the type of force applied and the properties of the tissue. The higher the density of a particular tissue, the less elastic it is and the more energy is transferred. For example, the lung is air filled, is extremely elastic, and tends to dissipate energy easily. In contrast, solid organs such as spleen, liver, or bone tend to absorb energy and will have greater tissue destruction as a consequence. Notably, air-filled structures such as the lung and bowel tend to be injured in explosions because the blast wave causes a localized pressure increase that overcomes the organ's structural failure point.[4]

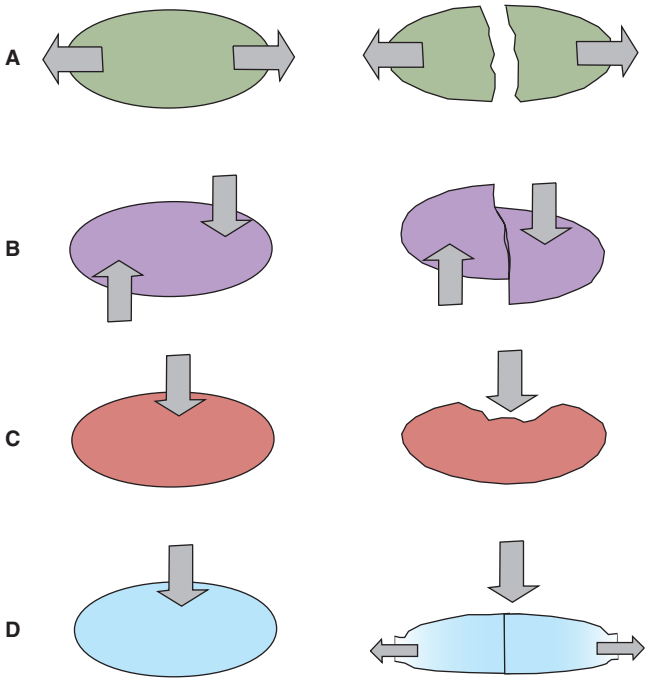

FIGURE 1-2 Biomechanical mechanisms of injury. (**A**) Tensile strain—opposite forces stretching along the same axis. (**B**) Shear strain—opposite forces compress or stretch in opposite direction but not along the same axis. (**C**) Compressive strain—stress applied to a structure usually causing simple deformation. (**D**) Overpressure—a compressive force increases the pressure within the viscus passing the "breaking point" of the wall.

BLUNT TRAUMA

The transfer of energy and application of forces in blunt trauma are more complex than in penetrating trauma. The most frequent mechanisms of blunt trauma include motor vehicle crashes, motor vehicles striking pedestrians, and falls from a significant height.

Mechanisms

MOTOR VEHICLE CRASHES

Understanding the changes in momentum, forces generated, and patterns of energy transfer between colliding vehicles can help predict how occupants of the passenger compartment will respond.[5,6] In frontal collisions, the front of the vehicle decelerates as the unrestrained front-seat passengers continue to move forward in keeping with Newton's first law. Lower extremity loads, particularly those to the feet and knees, occur early in the crash sequence. Because both the occupants and floor/dashboards are still moving forward, the relative contact velocity and change in momentum are still low. Contact of the chest, the steering column, and head with the windshield occur later in the crash sequence; therefore, contact velocities, change in momentum, degree of deceleration, and contact force are higher. Compression and continued movement of solid organs result in lacerations to the liver or spleen. Compression of the chest can result in rib fractures, a blunt cardiac injury, or a pneumothorax as the lung is popped like a paper bag. Finally, the sudden deceleration can cause shear forces on the descending thoracic aorta, resulting in a partial or full-thickness tear. As the driver is launched up and over the steering wheel, the head becomes the lead point, striking the windshield with a starburst pattern. The brain can sustain direct contusion or can bounce within the skull, causing

brain shearing and a contrecoup injury. Once the head stops, forces are transferred to the neck, which may undergo hyperflexion, hyperextension, or compression injuries, depending on the angle of impact. Once the head and neck stop, the chest and abdomen strike the steering wheel.

Lateral collisions, specifically those that occur on the side of the occupant, can be devastating because of the small space between the striking car and the passenger. If the side of the car provides minimal resistance (ie, no airbag), the passenger can be exposed to the entire change in momentum. These loads are usually applied to the lateral chest, abdomen, and pelvic acetabulum. As such, injuries to the abdomen and thorax are more frequent in lateral collisions.[7]

Rear-end collisions are classically associated with cervical injuries and provide an excellent example of Newton's first law. When the victim's car is struck from behind, the body, buttressed by the seat, undergoes a forward acceleration and change in momentum that is not experienced by the head. The forward push of the vehicle is associated with a sudden backward movement of the head, causing hyperextension of the neck. This injury pattern can also be seen in frontal collisions, where a sudden decelerating vehicle is associated with a continued forward movement of the head causing hyperflexion of the neck.[8,9]

Although there are frequently confusing vectors in a motor vehicle crash, mortality is directly related to the total amount of energy (or change in velocity) and direction of force. In a review of data collected by the Crash Injury Research and Engineering Network, higher speeds (40–80 km/h) were associated with greater mortality (17% vs 9%) and unrestrained patients were more likely to die than those who were restrained (17% vs 9%).[10] Interestingly, although frontal collisions have been historically associated with the greatest risk of death, new data suggest lateral impacts are actually more lethal (17% vs 11%).[9] Moreover, after adjusting for age, gender, and body mass index, the risk of death in a lateral collision has an odds ratio of 3.06.

In contrast, rollover crashes have a lower than expected mortality (<1%) because the momentum is dissipated and the forces projected to the passenger compartment are random.[11] That being said, mortality increases significantly regardless of mechanism if the vehicle's occupant is ejected. Ejected patients have the same velocity as their vehicle when they are ejected and typically strike a relatively immobile object such as the ground. When compared to restrained patients, ejected victims are three times more likely to sustain a significant traumatic brain injury, four times more likely to require admission to an intensive care unit, and five times more likely to die of their injuries.[12]

PEDESTRIAN INJURIES

Pedestrians struck by automobiles demonstrate a well-described pattern of injury depending on the size of the vehicle and the victim. Most adults struck by a car will have injuries to the lower extremities. If the car attempts to stop before hitting the pedestrian, the front bumper dips downward, striking at the level of the patient's knee. If the car does not stop, the force is transferred to the thigh. During the pedestrian–car interaction, the force applied to the knee (or thigh) causes an acceleration of the lower portion of the body that is not shared by the torso and head, which, by Newton's first law, tend to stay at rest. As the lower extremities are pushed forward, they will act as a fulcrum, bringing the trunk and head forcefully down on the hood of the car, applying a secondary force to those regions. As the car abruptly decelerates, the victim is then typically thrown to the pavement. This typical injury mechanism results in a tibia/fibula fracture, injuries to the torso such as rib fractures or a splenic laceration, and injuries to the skull and brain. If the patient is a child or if the vehicle involved is a truck, the transmitted force frequently results in serious injuries to the pelvis, abdomen, and/or chest.[13,14]

FALLS

Falls from height can result in a large amount of force transmitted to the victim. The energy absorbed by the victim at impact will be the kinetic energy at landing and reflects the potential energy prior to the fall, the height of the fall, the mass of the victim, and the gravitational acceleration. Given that the mass and gravitational acceleration are constant for the falling body, its kinetic energy is directly related to height. Therefore, the injuries sustained will depend on the elasticity of the ground and how the victim strikes.[3]

The majority of free falls in urban settings occur from moderate heights (≤20 ft). Fractures are the most common injury and occur in 76% of victims. Nearly 25% of victims sustain spinal column injuries, with 3.7% demonstrating a neurologic deficit. Intra-abdominal injuries are surprisingly rare.[15]

Specific Blunt Injuries

TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) represents the single most important factor contributing to death and disability after trauma. TBI accounts for over 282,000 hospitalizations and over 56,000 deaths annually.[16] Our knowledge of the biomechanics of brain injury comes from a combination of experiments conducted with porcine head models, biplaner high-speed x-ray systems, and computer-driven finite element models.[17,18] Surrounded by a hard skull and bathed in a layer of cerebrospinal fluid, the brain is composed of different tissues with different densities. Loads applied to the head, therefore, result in different deceleration forces between the different components of the brain. For example, a brain contusion can result from direct impact and with associated compressive strain. The brain, however, is only loosely attached to the surrounding cranium. After a load is applied, the skull has momentum along the line of force but the brain lags behind. As the skull comes to rest (or even recoils), the brain is still moving along the line of the initial load and will strike the calvarium on the opposite side, creating a *contrecoup injury*.

Similarly, the forward acceleration of the brain relative to the skull can create tensile strain in the subdural bridging veins, causing their laceration and the formation of a hematoma.

Diffuse axonal injury (DAI) is a more complicated phenomenon. Although DAI can be explained by differences in shear strain between different parts of the brain in the setting of linear and/or rotational acceleration, there is increasing interest in how blunt (and overpressure) trauma can cause spatiotemporal pressure variations or "waves" within the brain.[19,20] Following trauma, the skull vibrates. The concavity of the cranium focuses these vibrations as multiple waves of energy to a focal point deep within the brain while sparing more superficial surface structures. Importantly, this "wave propagation" can disrupt the structural integrity of deeper structures, such as the reticular-activating system, leading to loss of consciousness.[21]

THORACIC INJURY

Musculoskeletal injury of the chest is dependent on both the magnitude and rate of the deformation of the chest wall and is usually secondary to compressive strain.[22] With blunt force to the chest, the sternum is deformed and rib cage compressed. Depending on the force and rate of impact, the ribs may fracture from compressive strain applied to their outer surface and consequent tensile strain on their inner aspects. Indirect fractures may also occur at the lateral and posterolateral angles of the rib due to the concentration of stress.

In addition to fractures, blunt chest trauma is associated with overpressure injuries. A direct load applied to the chest can result in a pneumothorax because lung compression increases the pressure within this air-filled structure beyond the failure point of the alveoli and visceral pleura. This overpressure mechanism may also be seen in the heart. As a blood-filled organ, compression causes an increase in pressure, leading to blunt cardiac rupture, which typically occurs in the thinnest portion of the heart, the right atrium.[23]

Patterns of injury for the internal organs of the thorax frequently reflect the interactions between organs that are fixed and those that are relatively mobile. This arrangement allows for differentials in momentum between adjacent structures that can lead to compressive, tensile, and shear stress. Blunt rupture of the descending thoracic aorta during deceleration provides a classic example. In frontal and lateral impacts, the heart moves in a horizontal motion relative to the aorta, which is fixed to the spinal column by ligamentous attachments. This causes a shear force applied at the level of the ligamentum arteriosum.[24] When the stress is applied in a vertical direction, such as a fall from a height, there is also a relative discrepancy in momentum, and a tensile strain is generated at the root of the thoracic aorta (Fig. 1-3).

Injury to a major bronchus is another example of deceleration shear injury. Depending on the direction of the load applied to the chest, there is a difference in the momentum between the relatively pliable and mobile lung compared to the tethered trachea and carina. This creates a shear force at the level of the mainstem bronchus (Fig. 1-4) and explains

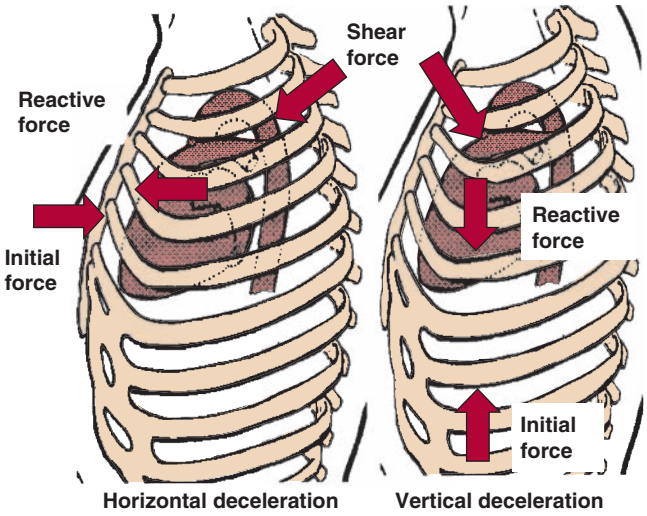

FIGURE 1-3 Various mechanisms of injury to the thoracic aorta. In a horizontal deceleration, the heart and arch move horizontally away from the descending aorta, causing shear strain and tearing at the ligamentum arteriosum. A vertical deceleration causes caudad movement of the heart, causing a strain at the root of the ascending aorta.

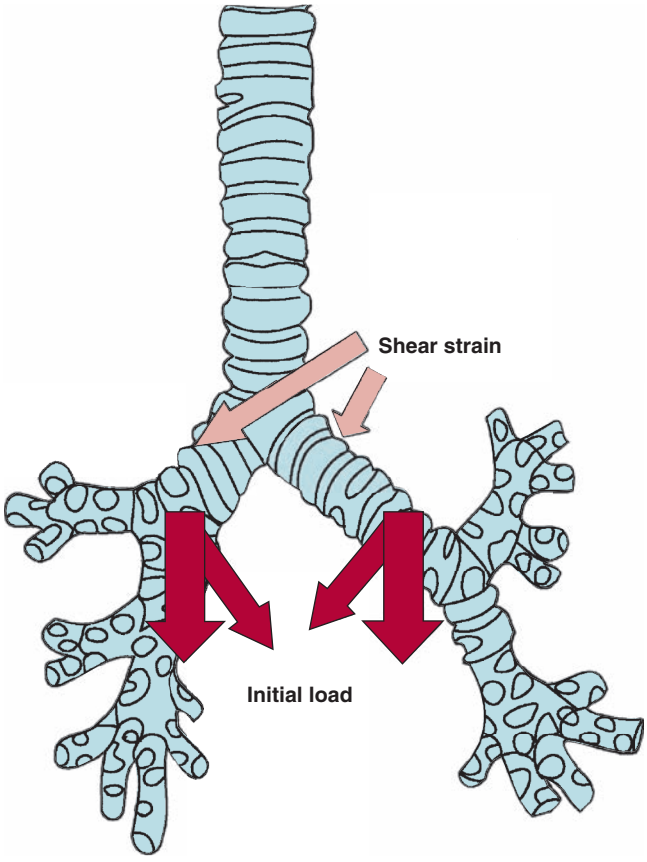

FIGURE 1-4 Mechanisms of injury for bronchial injury. The carina is tethered to the mediastinum and spinal complex, whereas the lungs are extremely mobile, setting up shear strain in the main stem bronchus upon horizontal or vertical deceleration.

why the majority of blunt bronchial injuries occur within 2 cm of the carina.[25]

ABDOMINAL INJURY

Abdominal organs are more vulnerable than those of the thorax, and a number of different mechanisms account for the spectrum of injury observed following blunt trauma. Without protection from the ribs and sternum, direct compressive force can lead to parenchymal destruction of the liver, spleen, or kidney. Shear strain at points of attachment can also lacerate these organs. As previously described, strain force requires a point of attachment in order to exacerbate a difference in momentum. This can occur at the falciform ligament, the hepatic veins, the splenic hilum, or the ligamentous attachments between the kidney and diaphragm. The body's tolerance to such biomechanical forces decreases with a higher speed of impact, resulting in an injury of greater magnitude with higher velocity collisions.[26]

Shear injury can also occur at vascular transitions, leading to intimal disruption, with thrombosis or complete transection. For example, the renal artery is attached proximally to the abdominal aorta, which is fairly immobile secondary to its attachments to the spinal column, and distally to the kidney, which is more mobile. A discrepancy in momentum between the two results in shear stain on the renal artery and a tear in the intima (or intima-media) approximately 3 cm from the aorta.

Injuries to hollow viscera are relatively rare in blunt abdominal trauma and occur in approximately 0.3% of patients.[27] Most injuries to the small bowel result from shear stress, typically occurring within 30 cm of the ligament of Treitz or ileocecal valve or at the site of adhesions. Although injuries do occur away from these points of fixation, they are infrequent and occur in the setting of "pseudo-obstruction" with overpressure.[28] The most common example of this injury pattern is blunt duodenal rupture where the closed pylorus and acute angle of the ligament of Treitz create a "pseudo-obstruction." When a compressive load is applied, the retroperitoneal duodenum is compressed. Because gas cannot adequately escape, high pressures develop and the duodenum ruptures.

Another important example of overpressure injury is rupture of the diaphragm. A large blunt abdominal force, such as the impact of a steering wheel, can cause a temporary deformation of the peritoneal cavity and a concomitant decrease in its volume. The subsequent abrupt increase in peritoneal pressure ruptures the diaphragm. Because the right hemidiaphragm is protected by the liver, the left side is the preferred route of pressure release.[29]

MUSCULOSKELETAL INJURY

By far, musculoskeletal injuries are the most common type of injury following blunt trauma, with orthopedic procedures outnumbering all other surgical interventions by nearly fivefold.[30] Although seatbelt laws, improved restraint systems, and airbags have decreased the incidence of intracranial and intra-abdominal injuries, the incidence of lower extremity trauma, in particular, has increased. It is possible, however, that this increase merely represents a survival bias. In the past, these patients may have suffered fatal injuries to the brain or torso, perhaps dying at the scene. Their associated extremity fractures, therefore, would not have been included in the overall list of injuries.[31] Alternatively, the final forces applied to the lower extremity are changed when airbags are used *without* seatbelt restraints. In simulated models of crashes with airbag deployment, muscle activation significantly increased the axial force and bending moment of the femur and tibia, and thus increased the risk of significant extremity trauma (Abbreviated Injury Scale score ≥2) by more than fivefold.[32]

Although each fracture is probably a consequence of multiple stresses and strains, there are three basic biomechanisms (Fig. 1-5).[33] *Lateral loads* provide compressive strain that leads to bowing and the subsequent development of tensile strain of the contralateral cortex. Initially, small fractures will occur in the cortex undergoing tensile strain because bone is weaker under tension than it is under compression. Once the failure point on the contralateral cortex is reached, the compressive

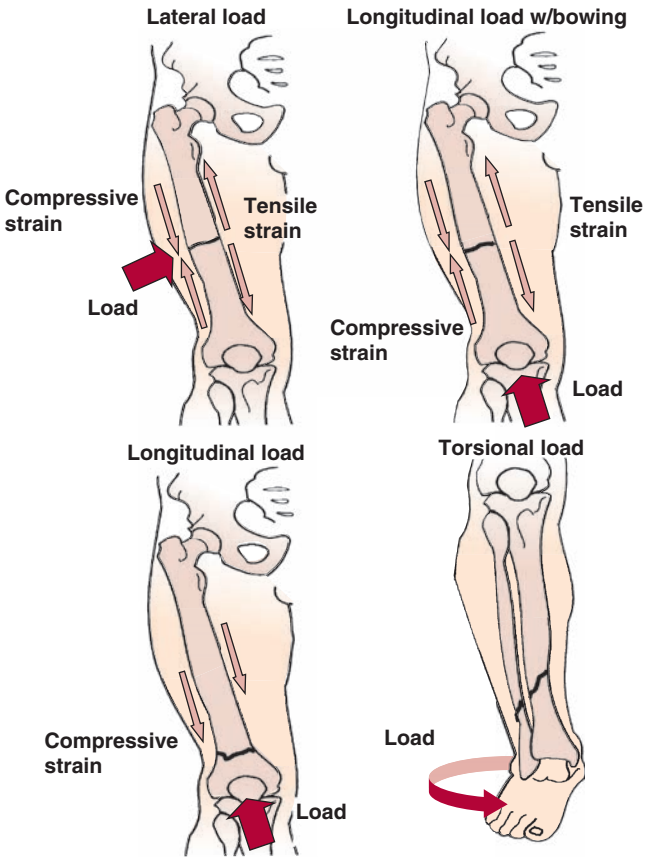

FIGURE 1-5 Fracture mechanics. A lateral load causing "bowing" will create tensile strain in the cortex opposite the force and compressive strain in the adjacent cortex. If a longitudinal stress causes "bowing," a similar strain pattern occurs. If no bowing occurs, the strain is all compressive. A torsion load will cause a spiral fracture.

strain on the ipsilateral cortex increases markedly. When its failure point is reached, a complete fracture occurs.

Similarly, *longitudinal loads* result in compressive and tensile strain patterns. If bowing does not occur, then compressive strain leads to fracture. For example, in falls or head-on collisions, the shaft of the distal femur is driven into the condyles. In contrast, the twisting force applied in a *torsional load* creates shear stress that is perpendicular to the torque axis, resulting in a spiral fracture pattern.

The type and extent of associated injuries to soft tissue are determined by the momentum and kinetic energy associated with the impact, the underlying tissue characteristics, and the angle of stress. High-energy injuries can involve extensive loss of soft tissue, neurovascular compromise, and highly comminuted fracture patterns. Low-energy injuries are often associated with a compressive strain that crushes soft tissues and results in simple fractures. Tensile and shear strain mechanisms, on the other hand, result in degloving and avulsion injuries, respectively.

INJURY TO THE SPINE

Injury to the spine can be devastating and is frequently the result of a complex combination of specific anatomic features and transmitted forces. Deceleration forces, such as those observed in motor vehicle crashes, create inertial differences between the head and torso. Injuries are related to the degree of flexion, extension, and lateral rotation; the extent of loading; and the magnitude of tension or compression forces generated during impact of the head.[34] The cervical spine is most frequently injured, due to its relatively unprotected position compared to the thoracic and lumbar regions.[35] A flexion mechanism can result in anterior atlantoaxial subluxation, an odontoid fracture, or a flexion teardrop fracture. Facet dislocation and fractures can occur when flexion is combined with rotatory forces. Similarly, traumatic spondylolisthesis of the axis, otherwise known as a hangman's fracture, results from extension and distraction of the cervical spine. Extension injuries can also lead to odontoid fractures with posterior displacement or extension teardrop fractures. Alternatively, axial compression of the cervical spine maintained in neutral position can lead to a C1 burst fracture or compression fractures of the lower vertebral bodies. Finally, distraction injuries can result in occipitocervical dissociation, a rare but frequently lethal event.[36] In contrast to trauma to the cervical spine, injuries to the thoracic or lumbar spine are more likely related to compressive mechanisms.

Whiplash refers to a musculoligamentous sprain typically seen following rear-end motor vehicle collisions where the momentum of the head creates an acceleration–extension injury, with or without rotational force. Patients typically experience neck pain and muscle spasm, although injury to cervical nerve roots or the spinal cord can occur.[37] Although whiplash can been treated with immobilization, routine activity, or active physical therapy, no treatment strategy appears to decrease long-term symptoms, with nearly 50% of victims reporting pain and disability 1 year after injury.[38]

Special Populations

PEDIATRICS

There are significant differences in patterns of injury between adults and children. Compared to adults, any given force is more widely distributed throughout the body of a child, making multiple injuries significantly more likely to occur. In addition, children also have a greater head-to-body ratio with thinner cranial bones and a less myelinated brain. Therefore, despite sustaining comparable degrees of blunt trauma, children are more likely to suffer a serious TBI and less likely to incur thoracic, spinal, and pelvic injuries.[39]

Although injury to the spinal cord is rare in children (~1%–2% of pediatric trauma), there are several anatomic features that impact the biomechanics of this injury. The pediatric spinal column is incompletely ossified, has flatter facet joints with a more horizontal vertebral orientation, and demonstrates significant ligamentous laxity. Moreover, the proportionally larger head and less developed neck musculature of younger children (10 years old) result in more torque and acceleration stress. Thus, younger children have high rates of transient upper cervical dislocation, resulting in spinal cord injury without radiographic abnormality (SCIWORA). In contrast, older children have a lower fulcrum of cervical motion (C5–C6), more ossification of the vertebral bodies, and more developed interspinous ligaments. Thus, they are more likely to have fractures in the lower cervical spine and less likely to present with SCIWORA.[40]

Another significant difference between adults and children is the compliance of the chest wall. In children, the chest wall is significantly more compressible and can absorb a greater impact while demonstrating less external signs of injury. As such, rib fractures, flail chest, hemopneumothorax, and injury to the thoracic aorta occur less frequently in children. The presence of these injuries, therefore, suggests significant blunt force. In contrast, the incidence of pulmonary contusion is higher because the compliant chest wall transmits force to the underlying compressible lung.[41]

Finally, a number of anatomic differences predispose children to more serious abdominal injuries than adults given the same degree of force. Children have proportionally larger and more anterior solid organs with less subcutaneous fat and poorly developed abdominal musculature. Their flexible cartilaginous chest wall allows for more pressure to be displaced to the abdomen and more compression of its internal organs. In addition, children also have relatively larger kidneys with fetal lobulations that predispose them to renal injury.[39]

PREGNANCY

On review of the National Trauma Data Bank of the American College of Surgeons, the majority of pregnant women are injured in the context of motor vehicle crashes (70.4%).[42] Several studies have demonstrated that the most common cause of fetal demise in motor vehicle crashes is placental abruption. The biomechanics of this injury involves the generation of tensile and shear forces within the circumferential uterine wall, which then induce a shear strain across

the placental surface. The resulting placental strain leads to a separation from the uterine wall (ie, abruption). The use of restraints and airbags decreases the force applied to the occupant, thereby increasing survival in both pregnant women and fetuses.[43]

GERIATRICS

Over 3 million Americans age 65 years or older are affected by trauma annually, and trauma is the seventh leading cause of death in this age group.[44] Falls from the standing position represent the most common mechanism of injury in the elderly, with an annual incidence of approximately 30% in those over 65 and approximately 50% in those over 80 years of age. Because aging is associated with a loss of bone density, falls frequently result in hip fractures. Unfortunately, elderly patients are also at a higher risk of a TBI given age-related cerebral atrophy and increased strain along subdural bridging veins.[45] Nearly 30,000 elderly patients die annually after falling, and a TBI accounts for the majority of these deaths.[46] Of interest, an estimated 25% of elderly patients will die within 120 days of discharge, signifying the important relationship between falls and geriatric frailty.[45]

Kinematics in Prevention of Blunt Trauma

By understanding the forces and patterns of energy transfer in motor vehicle crashes, automotive engineers have created a number of features designed to reduce injury. In order to decrease the force transmitted to the passenger compartment, Mercedes-Benz began making cars with "crumple zones" in 1959. This novel design allowed the front (and rear end) of a car to collapse upon impact. The change in momentum experienced by the passenger compartment, therefore, occurs over a longer period of time. Because more "work" is done on the vehicle, passengers experience less kinetic energy. Another feature designed to decrease the force transmitted to the passenger includes the redirection of the engine and transmission. Rather than intruding, the engine block in modern vehicles is directed downward and not into the passenger compartment.[47]

Passenger restraint systems, which include safety harnesses and child car seats, keep the passengers' velocity equal to that of the car and prevent the passengers from generating a differential in momentum and striking the interior of the car. In addition, these devices more evenly distribute loads applied to the victim across a greater surface area, thus decreasing stress.

Even with restraint systems, passengers can develop relative momentum and, therefore, kinetic energy during a crash. Airbags can dissipate this momentum and energy by converting it into "work" (ie, using the energy to compress the gas within the airbag device). Many studies have demonstrated the benefits of using seatbelts and airbags, with mortality reductions of 51% for seatbelts, 32% for airbags, and 67% for both.[48] Seatbelts and airbags have also significantly reduced the incidence of injuries to the brain, maxillofacial region, and cervical spine by keeping the forward momentum of the passenger to a minimum and preventing the head from striking the windshield.[18] Similarly, in rear-end collisions, headrests prevent a difference in momentum between the head and body and significantly decrease hyperextension of the neck. It is estimated that headrests decrease the incidence of whiplash-type injury by 70%.[49] As such, the US National Traffic Safety Administration mandated that all new vehicles be equipped with headrests in 1969.

Despite their effectiveness, restraint devices can also cause injuries. Lap seatbelts, particularly if worn incorrectly, can cause compressive injuries such as rupture of the bowel, pelvic fractures, and mesenteric avulsions. They can also act as a fulcrum for the upper portion of the trunk, leading to hyperflexion injuries such as compression fractures of the lumbar spine. As a consequence, newer automobiles are required to have three-point restraints with both lap and shoulder harness style belts. Unfortunately, shoulder harnesses can also cause intimal tears or thrombosis of the great vessels of the neck and thorax, particularly if the shoulder strap is malpositioned or the victim slides down under or out of the restraint system during lateral impact. Even when worn correctly, shoulder restraints have been associated with fractures of the clavicle, chest wall trauma, and injuries to hollow viscera secondary to compression.[50]

Approximately 10 to 20 deaths per year are thought to be directly attributable to the use of airbags. Over 90% of these are associated with the improper restraint of small adults or children or infants in front-seat locations.[51] In addition, there are a number of minor injuries that can occur as the result of airbag deployment including corneal abrasions, facial lacerations, and burns.[52]

PENETRATING TRAUMA AND BALLISTICS

Ballistics is the study of objects, or projectiles, in flight. *Internal ballistics* refers to the study of the objects themselves, whereas *external ballistics* is the study of how wind speed, drag, and gravity impact the objects. What happens when projectiles reach their target is known as *terminal ballistics.*

A projectile in motion is influenced by three forces. These include the force of the propellant (eg, a discharge or release of a bowstring), the force of gravity, and the force of resistance caused by the medium (eg, air, water, or tissue). How much damage a projectile imparts depends not only on its construction, mass, and velocity, but also on the physical properties of its target. Thus, if one knows all of these variables, projectiles have predictable trajectories and effects. This section will discuss how projectiles create injury in human tissues.

Physics of Penetrating Trauma

Both the mass of a projectile and its velocity determine its kinetic energy according to the following equation:

$$E_k = \frac{1}{2} MV^2$$

TABLE 1-1: Velocity and Kinetic Energy Characteristics of Various Guns

Caliber	Velocity (ft/s)	Muzzle energy (ft-lb)
Handguns		
0.25 in	810	73
0.32 in	745	140
0.357 in	1410	540
0.38 in	855	255
0.40 in	985	390
0.44 in	1470	1150
0.45 in	850	370
9 mm	935	345
10 mm	1340	425
Long guns/military weapons		
0.243 Winchester	3500	1725
M-16	3650	1185
7.62 NATO	2830	1535
Uzi	1500	440
AK-47	3770	1735

Given this equation, it is easy to see why a 9-mm bullet traveling at 935 ft/s has less kinetic energy than a similar round fired from an AK-47 rifle traveling at 3770 ft/s (Table 1-1). Because the energy of a system must be conserved, some (or all) of the kinetic energy of the projectile is transferred as its momentum is lost. It is the transfer of this kinetic energy that disrupts and damages tissues. How much energy is actually transferred, however, depends on the interaction between the projectile and the medium through which it travels. This interaction, also known as resistance, can be described by the formula for drag:

$$\frac{CD \times d \times v^2}{M/A}$$

where CD is the drag coefficient of the projectile, d is the density of the medium, v is the velocity of the projectile, M is the mass of the projectile, and A is the cross-sectional area. The drag coefficient, however, is difficult to measure, and the ballistic coefficient (BC) is more frequently used. The BC is directly proportional to the sectional density of the projectile, or the ratio of the surface area of its leading edge (the arrow, bullet, or fragment tip) relative to its overall mass. The higher the sectional density, the higher is the BC, and the less impedance the projectile has going through a medium. In contrast, projectiles with low sectional density will be subject to greater drag that retards their movement, thus losing their kinetic energy to the surrounding environment.

Although bullets generally travel through the air in a straight trajectory and strike their target tip first, they do not necessarily continue on a straight course in the victim. In addition, the degree to which a projectile's tip deviates from its flight path is its yaw, and this motion directly impacts its sectional density (Fig. 1-6). For example, an arrow remains stable with minimal yaw and thus has very high sectional density. As such, it passes easily through tissues. In contrast, a short bullet is much more prone to extreme yaw, flipping on its axis as it slows and "tumbling" through the medium. This motion produces an immediate decrease in the bullet's sectional density, increasing drag and thus releasing more kinetic energy into the surrounding tissue. Importantly, this transfer of energy occurs almost instantaneously. Given that force is a function of both mass and the change in speed over time (acceleration), destruction occurs because tissues are displaced extremely rapidly. The overall degree of tissue damage depends on both the velocity of the projectile and its surface density along the track.[53]

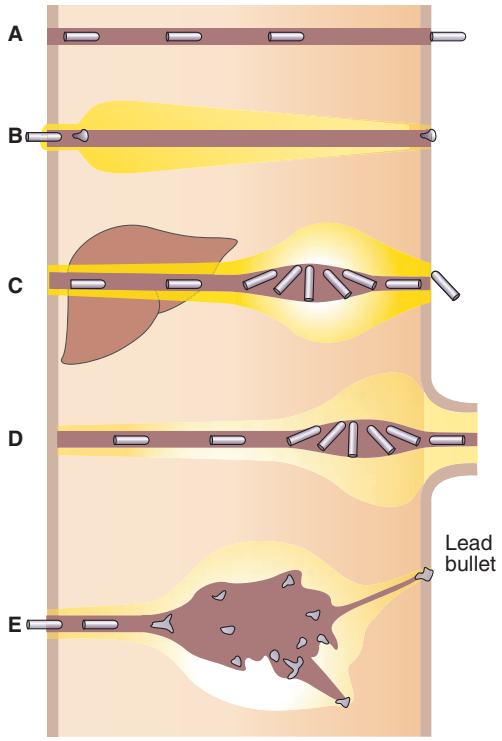

FIGURE 1-6 Wound profile of (**A**) nonfragmenting bullet through tissue with minimal yaw, (**B**) mushrooming bullet, (**C**) bullet tumbling through solid organ, (**D**) bullet tumbling with large exit skin flaps due to hydrostatic pressure wave, and (**E**) bullet fragmenting.

The shape (and thus the sectional density) of a bullet is subject to change within the tissue and directly impacts the degree of tissue damage. Projectiles that are small, hard, and fine-tipped produce minimal cavitation when compared to those that are large, soft, and broad. This important difference was noted by British soldiers in the late 1890s after their munitions were changed to hard-jacketed sharp bullets. To their disappointment, these new bullets were not as successful at stopping an advancing enemy. The bullets were subsequently modified by cutting off the tip and exposing the soft lead core. These expanding or mushrooming bullets were originally developed by the Dum Dum Arsenal in India and

became known as *dum-dums*. They were so destructive that the 1899 International Convention at the Hague banned their use in warfare.[53]

The most extreme change in sectional density occurs when the bullet breaks up into smaller pieces or fragments that then produce separate injury tracks and patterns. In their experimental model, Fackler et al[54] noted that fragmentation of a bullet caused far greater tissue injury than did a single bullet in striated muscle. The greater injury was due to the greater number of "projectiles" lacerating and crushing tissue.

As a projectile traverses the medium, the tissue is crushed and displaced, creating a permanent cavitation or "bullet track" (Fig. 1-6). The bullet also creates a hydrostatic pressure wave as it travels, stretching the adjacent tissues and creating a temporary cavity. In the 1890s, Sir William MacCormack described the destructive nature of this hydrostatic wave in a series of ballistics experiments in which a metal can filled with water was shot. When the metal pieces of the can were examined, it was obvious that the bullet exited first, creating a small hole. However, the hydrostatic pressure wave that followed created a larger and more irregular final exit hole that tore the can asunder.[53,55]

Unlike water, the human body is composed of tissues with variable density, elasticity, and compliance. Thus, the transfer of energy is far less perfect and harder to accurately predict. Moreover, each tissue has unique thresholds of stress and strain beyond which permanent destruction occurs. In general, tissues with low density (eg, fat, lung) do not impart much resistance. As such, a projectile will not fragment or yaw significantly and passes through these tissues with minimal damage. In contrast, projectiles traversing highly inelastic and dense tissues (eg, liver, kidney) create significant tissue destruction.

Blast Injuries

Blast injuries are among the most dramatic and devastating wounds treated by the trauma team. Although the vast majority of these injuries occur in the context of war on foreign lands, the United States is not immune, with 699 explosions reported by the Bureau of Alcohol, Tobacco, and Firearms in 2016.[56]

Blast injuries are broadly categorized as primary, secondary, tertiary, quaternary, and quinary, based on a taxonomy developed by the Department of Defense.[57] The trauma surgeon should be familiar with and able to predict associated injuries from each category (Table 1-2).

The damage imparted by the initial shock wave after an explosion is called the *primary blast*. Injuries are caused by overpressurization and typically affect gas-filled structures such as the lungs, intestines, and middle ear. The force of a primary blast is determined by the type and size of the explosive charge, the distance from the charge to the target, the medium through which the wave passes, and the composition of the target.

The strength of the charge is typically benchmarked against TNT (trinitrotoluene), with a detonation velocity of approximately 6900 m/s. Some modern plastic explosives such as Semtex and C-4 have detonation velocities in excess of 8000 m/s. The medium through which the primary blast wave travels will also determine how much energy reaches the target. Air is extremely compressible and will absorb much of the energy of the initial blast. Water, being relatively incompressible, transmits much more of the energy.

The characteristics of the target are important for several reasons. First, when the shock wave travels through a medium less dense than the target, such as air versus a human body,

TABLE 1-2: Department of Defense Classification of Blast Injuries from Explosive Devices

Classification	Definition	Common injuries
Primary	Blast overpressure injury (blast wave) Direct tissue damage from the shock wave Air-filled organs at highest risk (ears, lungs, gastrointestinal tract)	Tympanic membrane rupture Blast lung Gastrointestinal tract perforation/hemorrhage Ocular Concussion
Secondary	Primary fragments—from the exploding device (either from pieces of the device itself or from projectiles placed intentionally into the device to increase the lethality of the device) Secondary fragments—from the environment (glass, small rocks, etc)	Lacerations Penetrating injury Significant soft tissue injury (including traumatic amputations) Ocular
Tertiary	Acceleration/deceleration of the body onto nearby objects or displacement of large nearby objects onto an individual	Blunt trauma Traumatic amputation Crush injury
Quaternary	Injuries due to other "explosive products" effects—heat, toxidromes from fuel and metals, and so on	Burns Inhalation injury
Quinary	Clinical consequences from postdetonation environmental contaminants including bacteria, radiation, and tissue reaction to fuels and metals	Radiation Sepsis

much of the wave is reflected and not absorbed by the victim. In contrast, when the medium and the target have similar densities, such as water and the human body, the energy of the sound wave is almost entirely transmitted to the victim. Underwater explosions, therefore, are severalfold more dangerous than those occurring on land. Although blast injuries are less common in open terrain, the blast wave can reflect off the walls in contained spaces, increasing the incidence of injury to more than 90%.[58] Whether on land or under water, when the blast wave goes from one medium to a less dense medium, rarefaction waves cause shear stress within the tissues and cavitation.

Although the most common injury associated with primary blast is ruptured tympanic membranes, the most fatal injury is "blast lung." With this injury, the blast wave causes tissue disruption at the capillary–alveolar interface, resulting in pulmonary edema, pneumothorax, parenchymal hemorrhage, and, occasionally, air embolus from alveolovenous fistulas.[58] Clinical diagnosis of blast lung injury is dependent on the presence of hypoxia, respiratory distress, and the pathognomonic central "butterfly" infiltrates on a chest x-ray. The infiltrates are usually present on admission and can worsen with aggressive fluid resuscitation. Management is supportive and includes positive-pressure ventilation if needed, minimization of positive end-expiratory pressure (PEEP), and judicious fluid resuscitation. Fluid management in these patients can be challenging due to associated injuries from secondary and tertiary blast effects.

Secondary blast injuries are created by debris from the explosive device itself or from the surrounding environment. Many improvised explosive devices contain additional munitions such as nails, pellets, ball bearings, and scrap metal and are designed to increase the lethality of the explosion. Secondary blast injuries are more common than primary because the debris and fragments travel further than the primary shock wave. Lacerations, penetrating injury, and significant soft tissue defects are the most common injuries seen from secondary blast.[57]

Tertiary blast injuries are caused by the body being physically thrown a distance or from a solid object falling onto a person as a result of the explosion. Most tertiary injuries are the result of blunt trauma. Finally, *quaternary* and *quinary blast* injuries have only recently been defined. They are miscellaneous blast injuries caused directly by the explosion but often due to other mechanisms, such as burns, inhalation injuries, and radiation effects.[57]

Contact Shots

Gunshot wounds where the muzzle is in contact with the skin are termed *contact shots* and have a very different wounding profile than projectiles. In addition to discharging a projectile, the muzzle releases expanding gases that are contained by the skin and subcutaneous tissue.[59] Given that the blast velocity of gunpowder is upward of 20,000 ft/s, this contained explosion is far more destructive than the temporary cavity of a passing projectile (<4000 ft/s). As such, the tissue injury beneath the skin surface may be significantly greater than expected. In 1984, American television actor Jon-Erik Hexum killed himself on set when he fired a revolver loaded with blanks at his temple. Despite the absence of an actual projectile, the muzzle blast was contained by the skin and focused into his temple with sufficient force to cause a devastating brain injury that killed him instantly.

Epidemiology

Ashley D. Meagher • Ben L. Zarzaur

KEY POINTS

- Injuries are the leading cause of death for Americans age 1 to 44 years and the third leading cause of death overall.
- Disease of injury has a bimodal age distribution of mortality, with peaks for those 16 to 40 years old and for those over 65 years old.
- Injury deaths have risen in the United States over the past 2 decades, from 52 per 100,000 in 2000 to 72 per 100,000 in 2016.
- The International Classification of Diseases, Tenth Revision, Clinical Modification external cause of injury code is known as an E-code and is used when a patient presents to a health care provider with an injury.
- Deaths from drug overdose now account for 27.4% of injury-related deaths in the United States, more than from motor vehicle collisions.
- Approximately 50% of all traffic fatalities (driver, occupant, bicyclist, or pedestrian) have been found to have a blood alcohol concentration of 0.08 g/dL or greater.
- Firearm-related mortality is eight times higher in the United States than in other high-income countries in the world.

INTRODUCTION

Injury is not an "accident" but rather a disease, much like infectious diseases such as malaria or tuberculosis or health diagnoses such as cancer, diabetes mellitus, or heart disease. Injury, like other diseases, has variants such as blunt or penetrating. It has degrees of severity, rates of incidence, prevalence, and mortality that can differ by race and other sociodemographic factors. In addition, injuries have a predictable pattern of occurrence related to age, sex, alcohol, illicit or prescription drugs, and, again, sociodemographic factors, among others. Finally, they have a predictable prognosis, based on age, sociodemographic factors, and injury severity.

This characterization of injury as a disease is an important one and a matter of more than just semantics. When public health concepts are applied to injury, the first step after recognition is to characterize the disease such that control strategies can be applied. Epidemiology is the study of patterns of disease occurring in human populations and the factors that influence these patterns.[1]

Descriptive epidemiology refers to the distribution of disease over time and place as well as within or across specific subgroups of the population. It is important for understanding the impact of injury in a population and identifying opportunities for intervention. The burden of injury can be described as the most common, most fatal, most debilitating, or most costly within a specific population.

In contrast, analytic epidemiology refers to the more detailed study of the determinants of observed distributions of disease in terms of causal factors. The epidemiologic framework traditionally identifies these factors as related to the host (characteristics intrinsic to the person), the agent (physical, chemical, nutritive, or infectious), and the physical or sociocultural environment (characteristics extrinsic to the person that influence exposure or susceptibility to the agent). The importance of this epidemiologic approach is the direction it gives to injury prevention efforts as well as to areas requiring further research.[2]

Injuries can result from acute exposure to physical agents such as mechanical energy, heat, electricity, chemicals, and ionizing radiation in amounts or rates above or below the threshold of human tolerance. The transfer of mechanical energy accounts for more than three-fourths of all injuries.[3] The extent and severity of injury are largely determined by the amount of energy outside the threshold of human tolerance. Both the exposure to energy and the consequences of

TABLE 2-1: Analysis of a Motor Vehicle Collision Using Haddon's Matrix

	Human (or host)	Vector	Physical environment	Socioeconomic environment
Pre-event	Substance misuse, poor driving habits	Faulty brakes, bald tires	Slippery road due to rain	Social acceptance of high levels of alcohol use by males
Event	Not wearing a seatbelt	No airbag	Tree too close to the road	Ineffective enforcement of DUI offenses
Postevent	Elderly man, preexisting medical condition		Slow emergency response, poor rehabilitation program	Little help for reintegrating rehab patients into society

DUI, driving under the influence (of alcohol).

that exposure are greatly influenced by a variety of factors both within and beyond individual or societal control.[4]

The public health approach applied to injury control seeks to modulate factors related to the host and agent and/or their interactions within the environment using a number of strategies. These strategies encompass engineering, education, the enactment and enforcement of laws, and economic incentives and disincentives.

The public health approach as it applies to injury was first conceptualized by the late William Haddon in the late 1960s.[2] He developed and promulgated a phase-factor matrix that incorporated the classic epidemiologic framework of host, agent, and environment in a time sequence that encompasses three phases: pre-event, event, and postevent. This allows for simultaneous consideration of the factors and the stages of an event. Factors (eg, host, agent, or environment) in the pre-event phase determine whether the event will occur. Factors in the event phase determine whether an injury will occur as a result of the event and the degree of injury severity. Factors in the postevent phase influence the outcome from, or consequences of, any injuries of any severity that do occur. An example of the Haddon Matrix applied to a motor vehicle collision is depicted in Table 2-1.[5]

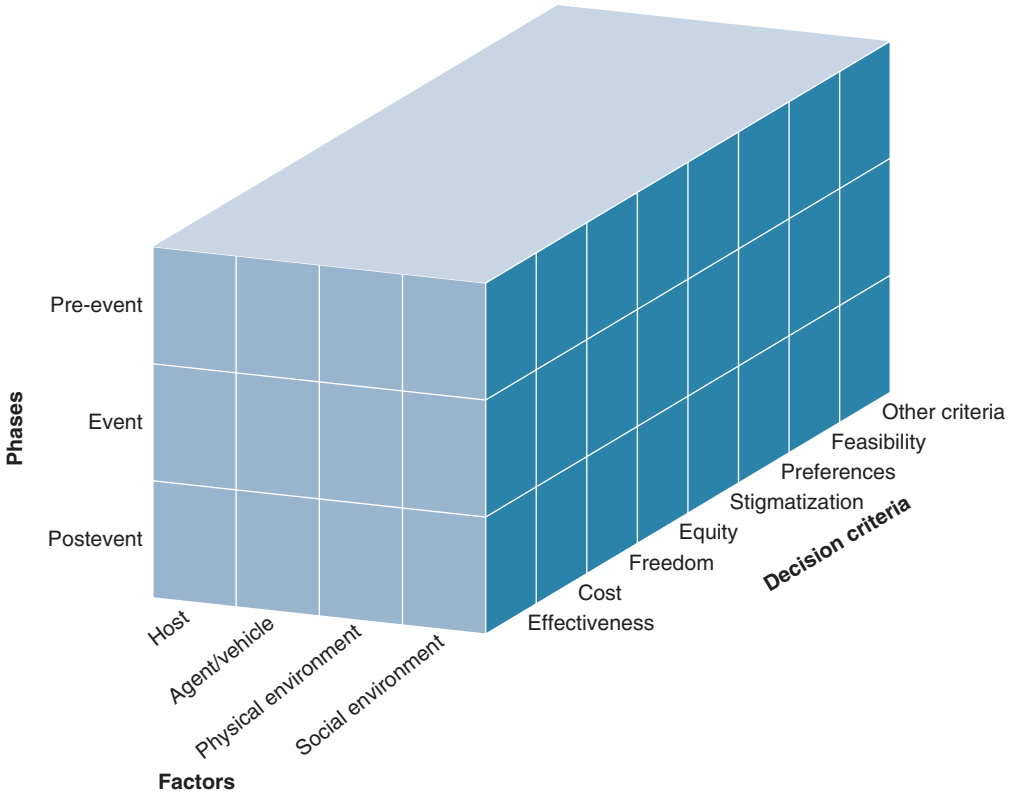
Although the Haddon Matrix is the foundation of injury epidemiology, it is not enough to direct robust injury prevention and control efforts. The addition of potential control strategies to the matrix in a three-dimensional fashion results in an "injury control cube." This suggests that injury prevention and control are not unidimensional or unifactorial and that the greater the number of sections of the "cube" that are addressed, the greater the control of the injury event. Runyan[6] has proposed using this third dimension of the matrix to incorporate and analyze the factors and value relative to each policy option (Fig. 2-1).

OVERVIEW OF INJURY EPIDEMIOLOGY IN THE UNITED STATES

Injuries are the leading cause of death for Americans age 1 to 44 years and the third leading cause of death overall. In 2016, 231,991 persons died in the United States as a result of an injury, up from approximately 190,000 in 2013 and resulting in an age-adjusted injury rate per 100,000 population of 68.78 (Fig. 2-2).[3] The predominance of injury deaths among the young results in another measure of the burden of injury—years of productive life lost. This measure makes the assumption that individuals are most productive to society before the age of 65; however, given the ever-increasing length of productive life, this is frequently an incorrect assumption. Nevertheless, it does give some measure of comparison of the effect of various causes of mortality. In 2016, all causes of death contributed to nearly 12 million years of productive life lost (YPLL). Deaths from unintentional injury were responsible for 23% of YPLL, more than any other individual category. The next two categories, malignant neoplasm and heart disease, accounted for 14% and 11% of YPLL, respectively.[7] As the American population ages, there is an increase in injury deaths for those over the age of 65. In 2016, 62,904 persons older than age 65 years died (127.7 per 100,000), up from 43,153 in 2006 (116.1 per 100,000).

There has been an intensive effort over the past 3 decades to decrease the rate of injury-related death in the United States. Some of these interventions have included the development of trauma systems, increased safety mechanisms in motor vehicles, and educational programs aimed at at-risk populations. The effect of these interventions can be seen in the mortality trends over time. These trends can also reveal areas in need of further intervention. For example, deaths from motor vehicle collisions have trended from 27% of injury-related deaths in 2001 to 16.7% in 2016 (Fig. 2-3).[8] Alarmingly, deaths from drug overdose have increased from 12.3% of injury-related deaths in 2001 to 27.4% in 2016, more than motor vehicle collisions.

The timing of deaths due to injury, classically described as trimodal, has changed due to advances in resuscitation and intensive care that have essentially eliminated the last peak of deaths from multisystem organ failure.[9-12] The majority of all deaths still occur within minutes of the injury, either at the scene prior to arrival of the emergency medical services (EMS), en route to the hospital, or in the first hours of care. A recent analysis found that 26% of all in-hospital deaths occurred within 1 hour of hospital arrival and 59% occurred within 24 hours.[12] These immediate deaths are typically the result of massive hemorrhage or severe neurologic injury.



Steps to Complete the Three-Dimensional Haddon Matrix	
Step	Activity
1	Use community needs assessment data to determine the problem in need of intervention.
2	Define dimension #1 (columns) of matrix as the targets of change.
3	Define dimension #2 (rows) of matrix by delineating the precise event and phases of change.
4	Define dimension #3 (depth) of matrix by delineating value criteria, defining each in clear terms.
5	Determine weights to be applied to each value listed in dimension #3.
6	Brainstorm potential interventions and fill in cells formed by columns and rows.
7	Use data to assess each criterion for each intervention under consideration.
8	Assess each intervention according to its attributes relative to each value criterion.
9	Conduct an overall assessment using weights for each value criterion across the set of interventions and criteria.
10	Make decisions about best options.
11	Explain decisions based on criteria applied and assessment of each intervention option according to the criteria.
12	Document the assessment process to assist future reanalyses.

FIGURE 2-1 Three-dimensional Haddon matrix as described by Runyan,[6] and steps to complete the matrix.

The second peak of the bimodal death distribution occurs within several hours to days of the event, with 78% of deaths by postinjury day 3. These deaths are primarily due to injury to the central nervous system (CNS) (Fig. 2-4).

Deaths represent only one small aspect of the injury disease burden. Each year, over 32 million people suffer a nonfatal injury. The vast majority of these patients are seen in emergency departments (EDs) or urgent care centers without requiring hospital admission; however, over 2.6 million people require hospitalization. Many of these nonfatal injuries have far-reaching consequences with the potential for reduced quality of life and high costs for the health care system, employers, and society. In 2013, the estimated total lifetime costs associated with both fatal and nonfatal injuries amounted to over $671 billion, including $457 billion for nonfatal injuries and $214 billion for fatal injuries (Figs. 2-5 and 2-6).[13-15]

The costs associated with injury deaths account for a disproportionate share of total injury costs. Estimates show that deaths account for less than 1% of all injuries, but are responsible for 31% of total injury costs. The remaining 69% of costs due to injury are associated with nonfatal injuries. These costs include direct expenditures for health care (30%) and other goods and services purchased as a result of the injury. The value of lost productivity due to temporary and permanent disabilities is also taken into account and represents 41% of the total costs. These are merely the financial costs

and do not reflect the pain and suffering of patients, their families, and associates after nonfatal injuries.[14-18]

AGE-RELATED INJURY EPIDEMIOLOGY

Injury is a disease predominantly affecting young males, including 70% of deaths and more than 50% of nonfatal injuries. For nonfatal injuries, males are only 1.3 times as likely as females to be affected. This gender-related risk reverses after the age of 65, with females 1.3 times as likely as males to suffer nonfatal injury. Therefore, injuries account for more premature deaths than cancer, heart disease, or HIV infection.[8,18]

The disease of injury has a bimodal age distribution of mortality that peaks for both genders in the 16- to 40-year-old age group and then again in those older than 65 years of age (Fig. 2-7). Persons under the age of 50 account for 51%

of all injury fatalities, just over 50% of hospitalizations, and nearly 80% of ED visits.[3,9] Hospitalizations and ED visits follow this pattern of a bimodal peak related to age and a male predominance, as well.

The number of elderly (age ≥65 years) individuals in the United States is rapidly growing and is projected to reach 90 million adults by 2050.[19] Although patients over age 65 represent less than 25% of trauma admissions, they are more likely to die from injuries with a lesser severity than their younger counterparts.[19,20] In addition, the costs associated with geriatric trauma patients are higher than those of their younger counterparts, as they frequently have longer hospitalizations and need posthospital rehabilitation.[20-23] Representing 15% of the US population, those over the age of 65 account for approximately 27% of all injury deaths and 36% of all injury-related hospitalizations, and it is expected that the elderly will account for approximately 40% of all injury deaths and hospitalizations in the near future.[8,18] Current research is focusing on identification of risk factors for poor outcome as well as projecting posthospitalization needs for these elderly trauma patients.[21,24,25] Discussion continues on the need to alter triage criteria, admission protocols, and admission location as the physiology of aging results in different responses to injury.[26,27]

EPIDEMIOLOGY BY MECHANISM AND INTENT

Injuries are typically categorized by their mechanism, intent, and place of occurrence. Mechanism refers to the external agent or particular activities that were associated with the injury (eg, motor vehicle related, falls, firearm related). Intent of the injury is classified as either unintentional or intentional.

Injuries that are intentionally inflicted can be further subcategorized into interpersonal (eg, homicide) or intrapersonal (eg, suicide); however, intent may not always be determinable. Injuries resulting from legal interventions and operations of war are typically classified separately as an "other intent" category.

The classification system most often used in describing the specific mechanism and intent of injury is the International Classification of Diseases (ICD). This classification system was developed and promulgated by the World Health Organization and is now in its 10th edition.[28] The E-code, or external cause of injury code, provides detailed information about the circumstances associated with injury-related ED visits and hospitalizations. These codes are essential to the epidemiology of injury and its accurate study. They provide critical public health information for monitoring health status, setting injury prevention priorities, and developing and evaluating injury prevention programs at the local, state, and national levels.

E-codes can also be useful for quality initiatives associated with injury-related claims (eg, motor vehicle crash–related injuries) that may assist the Centers for Medicare and Medicaid Services (CMS) in making payment decisions. Hence, numerous professional organizations including the American College of Surgeons Committee on Trauma, the American College of Emergency Physicians, the Emergency Nurses Association, and the National Safety Council have published position statements to endorse the need for improving E-coding in state mortality and morbidity data systems. In addition, they have urged that at least three fields be captured as part of the E-code. Two of the E-code fields can be used for coding the precipitating and immediate causes (eg, the mechanism/intent of injury such as falls, motor vehicle traffic, fire/burn, cut/pierce, assault, self-harm), and one other field is used to delineate the place of occurrence (eg, home, street/highway, residential, institution). Unfortunately, E-codes are not mandated by all payors, all states, or CMS as a part of ICD-10.

The distribution of injuries by mechanism varies for deaths, hospitalizations, and ED visits. The leading mechanisms of fatal injury are drug overdose, motor vehicle collisions, and firearms. Although nearly 30% of all injury deaths are violence related, 93% of nonfatal injuries and 69% of fatal injuries are unintentional.[3]

The Bureau of Labor Statistics within the US Department of Labor tracks injury in the workplace. A total of 5190 fatal work injuries were recorded in the United States in 2016, representing 3.6 fatal work injuries per 100,000 full-time equivalent workers, a concerning uptrend over the past 5 years. Overall, transportation-related incidents accounted for the majority (40%) of occupational injury deaths. Assaults and violent acts accounted for 16% of fatalities, contacts with objects and equipment 14%, and falls 16%. Homicides accounted for 9% of occupational-related deaths in 2016.[29]

In addition to the fatalities associated with work-related activities, there were a total of 2.9 million nonfatal injuries recorded by the Bureau of Labor Statistics (2.9 cases per 100 workers). Of interest, 71% occurred in service-providing industries, and nearly half produced disability.[30]

LEADING MECHANISMS OF INJURY

Drug Overdose

The United States is in the midst of an opioid epidemic, with over 72,000 drug poisoning deaths in 2017, up 6.6% from 2016.[31] Drug overdoses have more than tripled since 1999 and, as previously noted, exceeded motor vehicle–related injury as the leading cause of injury-related death in 2011.[8] In 2016, there were 21.3 drug overdose deaths per 100,000 population, up from 12.3 per 100,000 in 2010.[32] As the number of drug overdose deaths has increased, so have the number of nonfatal drug overdoses. In 2010, there were 355 per 100,000 nonfatal overdoses, whereas there were 613 per 100,000 in 2016.[18]

The opioid epidemic is multifactorial, driven by a rise in the availability of prescription opioids as well as increased availability of illicit opiates such as heroin and fentanyl. Currently, the sharpest increase in opiate-related deaths involves heroin and synthetic opiates other than methadone. In 2017, 35 states (including Washington, DC) saw an increase in

drug overdose deaths, 7 states were stable, and 9 states saw a decrease.[31]

Similar to other mechanisms of injury, males are two-thirds more likely to die from a drug overdose as compared to females. Overdoses remain a disease primarily affecting adults and are the leading cause of injury-related death for adults age 25 to 64 years. Of interest, approximately 5% of drug overdose deaths are in adults over the age of 65, and 8% of drug overdose deaths are in young adults age 15 to 24.[8]

It is important to note that the impact of drug-associated injuries is not included in these data. Prior to the onset of the opioid epidemic, 33% of motor vehicle crashes and 8% of fall-related fractures were associated with illicit drugs.[33,34] As opiate use has increased, it is probable that injuries and deaths secondary to drug abuse disorders are increasing. It is important that health care providers recognize the potential for drug abuse disorders in injured patients and offer intervention.

In 2017, the opioid crisis was declared a national public health emergency, with the aim of releasing federal funds, developing harm reduction strategies, and tightening regulations on opiate prescribing practices among physicians.[35] Harm reduction strategies range from safe syringe programs, provision of naloxone to known heroin abusers and first responders, and improving access to treatment for opiate disorders. Increased attention on physician prescribing has led to restrictions on licensed prescribers, increased prescription drug monitoring programs, and more guidelines for the treatment of pain.[32,35] This epidemic will only abate with a multifaceted approach, integrating public health experts, physicians, and public and private partnerships.

Motor Vehicle–Related Injury

Traffic-related incidents involving motor vehicles were the second leading cause of injury-related death in 2016 and rank second as a cause of nonfatal injury in the United States. It is the leading cause of injury-related death in the 5- to 24-year age group and the second leading cause of injury-related death in the 25- to 84-year age group. Each year, more than 4 million people are injured in traffic-related crashes, resulting in over 40,000 deaths.[8]

Adolescents and young adults are at the highest risk for both fatal and nonfatal injuries due to motor vehicle collisions. Their rates of death, hospitalization, and ED visits are approximately twice the rate for all ages combined. White males age 15 to 24 are at particular risk. For black males in that same age group, traffic-related injury ranks second as a cause of death, behind firearm-related injuries. Individuals age 75 and older are also at relatively high risk for dying from motor vehicle accident–related injury.

Males are more than twice as likely as females to die from motor vehicle crashes. Males under the age of 45 are also more likely to be hospitalized as a result of motor vehicle–related injuries, although the gender differential is not as great as for fatalities. Males and females age 45 and older, in contrast, are equally likely to be hospitalized.

Determinants of injury occurrence and severity in a motor vehicle–related incident include speed of impact, vehicle crashworthiness, and the use of safety devices and restraints including safety belts, airbags, and helmets. This is an area where epidemiologic analyses have truly had an impact in reducing the burden of injury. When used, restraint devices have been shown to reduce fatalities to front-seat occupants by 45% to 60% and the risk of moderate-to-critical injury by 50%. It is estimated that over 2000 deaths could be prevented with appropriate use of restraint devices. Currently, usage rates for restraint devices in the United States range from 69% in South Dakota to 98% in Oregon, with a national average of 87% in 2013.[36] This is an increase of 1% over 2012 and 6% over 2006. Mandatory restraint device laws are present in 49 states. In 34 states, these are primary enforcement laws, meaning police may stop vehicles solely for restraint law violations.[37] The presence of an airbag in front of a belted driver provides increased protection, resulting in an estimated 51% reduction in fatality rate.

Despite some success in reducing the role of alcohol in motor vehicle collisions, it remains a major factor in fatal crashes among adolescents and young adults. Approximately 50% of all traffic fatalities including the driver, occupant, bicyclist, or pedestrian have been found to have a blood alcohol concentration (BAC) of 0.08 g/dL or greater. The proportion of fatally injured drivers with elevated BAC varies with age. For all age groups, it has remained relatively constant, at approximately 26% for women and 43% for men, since 1999.[38] In contrast, the proportion of drivers under the influence of other drugs, including narcotics, depressants, and cannabinoids, has increased significantly.[39]

Firearms

In 2016, there were approximately 39,000 intentional (98%) and unintentional (2%) gun-related deaths in the United States. This represents 107 firearm-related deaths per day, or 12 deaths per 100,000 population. The majority of firearm-related deaths among males age 15 to 34 in the United States (67%) are homicides.[3] Suicide deaths and firearm deaths have been increasing over the past 5 years. In addition, nonfatal firearm injuries have increased as well. In 2016, there were 116,414 reported nonfatal injuries caused by firearms, or 36 per 100,000 population. This represents an increase from 23 per 100,000 in 2010.[18]

Firearm-related injuries disproportionately affect males (85%) and younger people. In the 15- to 34-year age group, firearm-related death rates for males are nearly seven times that for females. Firearm-related injuries are the leading cause of death in black males age 15 to 34 and are the third leading cause of injury-related death in those age 10 to 84. From a global and cultural standpoint, firearm-related mortality is eight times higher in the United States than other high-income countries in the world.[3,8]

There has been a significant increase in the suicide rate in the United States, with 45,000 deaths and 50% of these being firearm related. Suicide in those age 65 or greater is

also a significant problem, with 5756 firearm-related suicides in 2016, representing 25% of all firearm-related injuries for both genders and all ages. Over 90% of the suicides in the elderly population were among males.[8]

Both fatal and nonfatal firearm injuries accounted for just over $39 billion in 2010 in direct medical costs and productivity losses.[16] This is related to the fact that firearms of some type are present in about 30% of all US households, including 46% of rural and 19% of urban residents.[40] Studies suggest that those who live in homes that have a firearm are more likely to die from homicide and suicide in the home than are residents of homes without firearms.[41,42]

Data on fatal and nonfatal firearm-related injuries are not as complete as data from motor vehicle collisions. This is secondary to the political and emotional environment that surrounds the discussion about gun violence. Since 1997, with the addition of the Dickey Amendment to the Omnibus spending bill, federally funded research on gun violence has been curtailed.[43] This has led to inadequate data collection and hindered public health professionals from developing and implementing prevention strategies. In 2015, eight medical professional groups, including the American College of Surgeons, released an organized call for repeal of the Dickey Amendment and increased federal funding into research on gun violence and prevention.[44]

Falls

There were 34,673 fatal falls in 2016; falls represent the third most common cause of injury-related deaths and 15% of all injury deaths. In addition, there were 9.2 million nonfatal injuries following falls. Falls account for over one-third of all injury hospitalizations, resulting in over $95 billion in lifetime costs.[8,13,18]

Unlike the other common mechanisms of injury, falls primarily occur in younger and older age groups; however, the severity profile in the two groups is quite different. Falls are the leading cause of injuries for all children age 0 to 14, although these are rarely fatal or cause severe injuries. Approximately 8000 children are treated daily in United States for fall-related injuries, totaling almost 2.8 million children each year; however, less than 3% of these need hospitalization.[45] Approximately half of all pediatric falls occur in the home and one-quarter occur at school. Falls in children age 0 to 4 years are most commonly from furniture or stairs. In older children, falls are commonly from standing and/or associated with recreational activities related to playground equipment, bicycling, or sports.

In adults of working age, most fatal falls are from buildings, ladders, and scaffolds. Falls on stairs increase in significance starting at age 45.[3] ED visit rates for falls have an interesting trend, with males predominating in the 0- to 19-year age groups, whereas the incidences in the sexes are nearly even from ages 20 to 44. Females then predominate above age 44, accounting for nearly 70% of nonfatal injuries in the age group over 85.[18] This finding is consistent with the increased fracture risk in women after menopause and, specifically, those with osteoporosis.

In the elderly, falls are a significant cause of mortality and morbidity and are the leading cause of injury-related deaths for those 65 and over. Falls account for 22% of injury-related deaths in those age 65 to 74 years and 65% in those age 85 years or older. The death rate from falls after age 85 is over three times that for people age 75 to 84 years.[8] Falls are also the most common cause of nonfatal injury in the elderly, accounting for nearly 60% of injury-related ED visits and approximately 80% of injury-related hospitalizations for persons age 65 years and older.[18] In the United States, 1 in 5 people over the age of 65 will sustain a fall annually. Of these, about one-quarter will be injured and another quarter will restrict their daily activities for fear of another fall.[46] The economic impact of falls in the elderly is sizable and was more than $50 billion in 2015, with an average hospitalization costing $30,000.[13,46]

Major risk factors for falls among the elderly include the following: those related to the host (eg, advanced age, history of previous falls, hypotension, psychoactive medications, dementia, difficulties with postural stability and gait, visual disturbances, cognitive and neurologic deficits, or other physical impairment) or environmental factors (eg, loose rugs and loose objects on the floor, ice and slippery surfaces, uneven flooring, poor lighting, unstable furniture, absent handrails on staircases). The risk of falling increases linearly with the number of risk factors present, and it has been suggested that falls and some other geriatric syndromes may share a set of predisposing factors. All of these factors are potentially modifiable with combinations of environmental, rehabilitative, psychological, medical, and/or surgical interventions.[47]

EPIDEMIOLOGY BY NATURE AND SEVERITY

Cataloging and analyzing the distribution of injuries by their nature and severity is important to efforts at establishing priorities for prevention as well as treatment, trauma system development, and research. The International Collaborative Effort on Injury Statistics was formed through the Centers for Disease Control and Prevention and National Center for Health Statistics to develop a uniform framework for using ICD codes to categorize injury diagnosis by the body region involved and the specific nature of the injury.[48] This collaboration aims to develop injury statistics, such as the Abbreviated Injury Scale (AIS) and the Injury Severity Score (ISS), that are internationally comparable to allow information exchange among researchers.[49] Several other systems for classifying the nature and severity of injury exist, and a number of these are described elsewhere in this textbook.

The American College of Surgeons has led the effort to aggregate trauma registry data in order to provide insight into the nature, severity, and types of injuries occurring across the United States.[50] Trauma centers are mandated to submit their registry data into the standardized National Trauma Data Bank (NTDB), allowing researchers to query a large database of quality injury-related data. Since the adoption of the

National Trauma Data Standard and with increasing adoption of electronic medical records, this data set has increased in quality and utility.[51] In the past, some of what has been known about the overall nature of trauma deaths was based on a limited number of studies conducted in selected geographic regions using coroners' reports and autopsy records; unfortunately, these types of records, much like the death certificates, are variable in completeness, accuracy, and utility.[52]

Frequently, injury patterns are mediated by the mechanism of injury. This allows for monitoring of injury types in relation to mechanisms. For example, recognition of the rate of traumatic brain injury in sports-related injuries has led to increased efforts at diagnosis and prevention.[53] Certain types of injuries carry a higher likelihood of death and are targets for aggressive treatments and prevention, such as hemorrhage. The American College of Surgeons Committee on Trauma, in collaboration with The Hartford Consensus, has launched a nationwide campaign to teach hemorrhage control to lay people, in order to save lives prior to arrival of first responders.[54] This campaign arose after analysis of several mass casualty events in which lay people were the only available initial "medical" providers. "Stop the Bleed" is an example of an initiative aimed at empowering public stakeholders with training and education.

INJURY BY GEOGRAPHIC LOCATION

The overall incidence and patterns of injury vary between urban and rural populations across the country (Fig. 2-8).[3] Unintentional injury and motor vehicle death rates are highest in rural areas, whereas homicide and firearm death rates are several times higher in urban areas. Evaluation of injury by rural versus urban is a difficult undertaking. There are numerous ways to divide a locale in order to designate rural, suburban, or urban.

Injury death rates also vary by region of the country. For example, death rates for unintentional injury tend to be highest in the west and south, whereas suicide rates are highest in the west and homicide rates highest in the south. There is, however, substantial state-by-state and even county-by-county variation. It is important to know that the observed differences related to geographic location and population

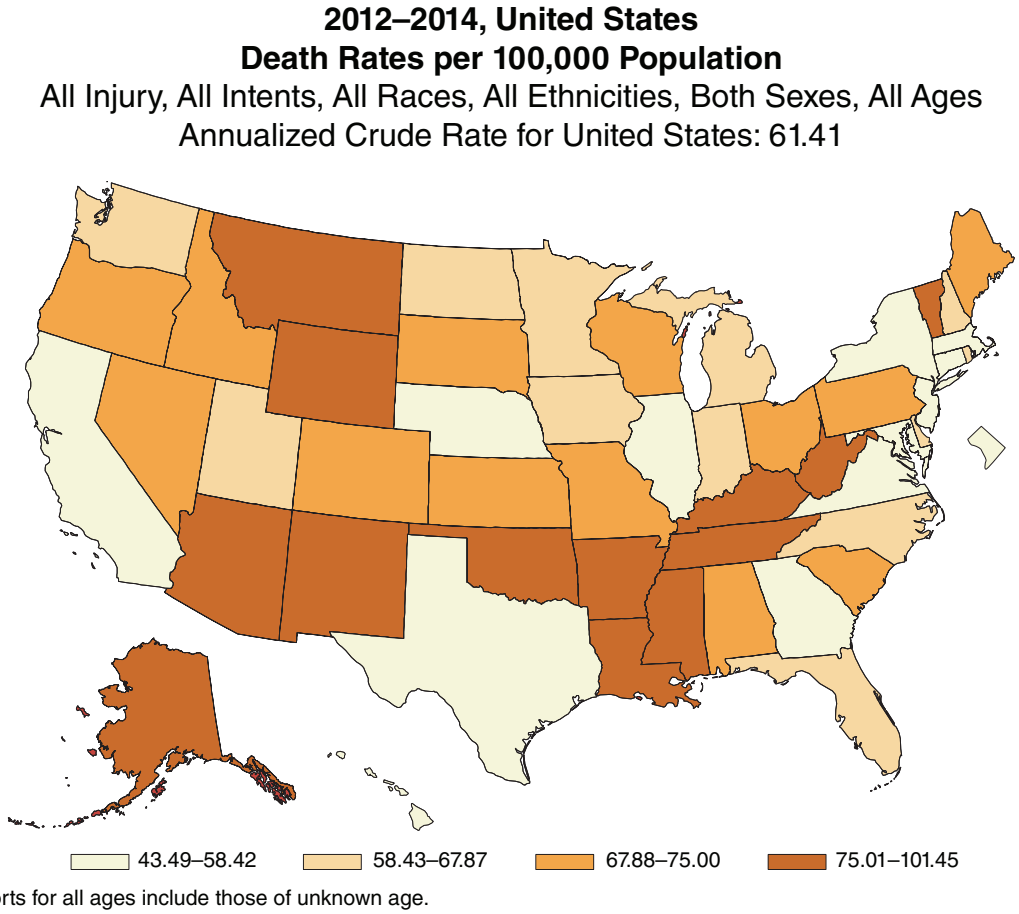

FIGURE 2-8 Death rate per 100,000 population, by state. (Data obtained from Centers for Disease Control and Prevention Web-Based Injury Statistics Query and Reporting System data, https://www.cdc.gov/injury/wisqars/index.html. Reproduced from the Statistics, Programming, and Economics Branch, National Center for Injury Prevention and Control, Centers for Disease Control and Prevention.)

density may be a function of a number of confounding factors such as access to care, economic disadvantages, education level, or even geographic barriers.[55,56]

CONFOUNDERS

There are a number of confounding factors that may influence results and, more critically, the interpretation and conclusions drawn from epidemiologic analyses of injury. These include race, ethnicity, culture, socioeconomic status, access to health care, mental health, and alcohol and other drugs. Due to their number and multiplicity, adequate control for these confounding factors is difficult and requires forethought and caution prior to embarking on epidemiologic research. Similarly, publications need to be critically appraised to avoid erroneous conclusions.

Data that are stratified by race and/or Hispanic origin must be interpreted carefully. In data often used to populate registries and in-hospital discharge data, the patient is often assigned a race by administrative staff. The patient does not chose which race he or she identifies with most. The color of the skin or patient language may be more of a determining factor than the patient's own preference when race and ethnicity are chosen by administrative means. This can lead to confounding through misclassification.[57,58] Additionally, the population that is used as the denominator in the calculation of the death rate generally comes from US Census Bureau estimates, whereas the characteristics of those who died (numerator) come from data collected by funeral directors or medical examiners. This results in inconsistent results due to the inherent errors in each set of data. Bias in estimates by race and ethnicity also can result from undercounting of specific populations in the census, thereby potentially producing an overestimation of death rates.

Differences in health status by race and Hispanic origin also are known to exist and may be explained by factors including socioeconomic status, health practices, psychosocial stress and resources, environmental exposures, discrimination, and access to health care.[59] As these factors are not routinely collected or controlled for, analysis of injury mortality and morbidity by race and ethnicity may lead to incorrect inferences. With specific regard to data on violence, estimates may be misinterpreted because attention may have been directed to the victim rather than to the perpetrator, for whom sufficient data are not routinely collected.

Although this chapter emphasizes the concept of injury being a disease entity in and of itself, data suggest that, for a significant number of trauma patients, injuries may be an unrecognized symptom of underlying alcohol or drug abuse. Therefore, it may be that injury is actually a comorbidity of a disease, which is alcohol or substance abuse. Nearly 50% of injury deaths are alcohol related, and injuries account for roughly the same number of alcohol-related deaths as cirrhosis, hepatitis, pancreatitis, and all other medical conditions associated with excessive alcohol use combined. A multicenter study that included data on more than 4000 patients admitted to 6 trauma centers demonstrated that 40% had some level of alcohol in their blood upon admission and up to 60% of patients tested positive for one or more intoxicants.[38,60] Therefore, it is clear that alcohol and substance abuse must be considered in the epidemiology of injury as well as in the equation leading to effective injury control. Recognition of this fact, along with evidence that intervention to address alcohol use disorder in the acute setting was beneficial, helped drive the recommendation from the American College of Surgeons Committee on Trauma to provide screening and brief intervention for alcohol use disorder at Level I and Level II trauma centers.[61]

DATA SOURCES

With the increasing use of electronic medical records (EMRs), there has been a significant increase in administrative data on health information. Administrative data refers to the fact that these data are originally collected for administrative purposes, rather than specific research questions. As such, there are frequently numerous variables available, such as demographic details, health diagnoses, complications, outcomes, and procedures. These databases have the potential for evaluating a patient's course through the hospital or health care system, as derived from the EMR. Most nationally available data sets are deidentified to protect patient and hospital privacy and typically require a fee for access, as well as a research proposal and clearance by an institutional review board (Table 2-2).

Selection of the appropriate administrative data set for research requires consideration of the population and outcome of interest. Administrative databases typically aggregate data from hospital billing and coding in the EMR. They are generally less useful when attempting to analyze detailed clinical issues, such as specific complications or severity of illness, despite available methods to estimate injury severity using ICD codes.[69,70] Use of hospital-level data may limit the generalizability of a study, whereas use of a national data set may decrease the granularity of available data. An additional confounder in the reliability and accuracy of administrative databases is the extent, prioritization, and accuracy of ICD coding. The fidelity of the data is only as good as the coding that is entered. There are frequently examples of "upcoding"—making a patient seem sicker than he or she is. In addition, if codes are omitted, then the patient may appear less sick. Also, it should be pointed out that these data sets only represent the population of hospitalized patients. They do not capture all deaths and will not ever include patients with minor injuries not seeking treatment at hospitals.

A number of the publicly available data sources have been used in the production of this chapter and are referenced. Table 2-2 gives a broad description of the most commonly used national data sets, as well as access information. National data can be used for drawing attention to the magnitude of the injury problem, for monitoring the impact of federal legislation, and for examining variations in injury rates by region of the country and by rural versus urban/suburban environments. They can also be useful in aggregating sufficient numbers of cases of a particular type of injury to analyze causal

TABLE 2-2: Administrative Databases Available for Injury Research

Database Name	Administration	Data Sources	Details	Website
Web-Based Injury Statistics Query and Reporting System (WISQARS)[3,8,13,18,62]	Centers for Disease Control and Prevention (CDC), National Center for Injury Prevention	National Vital Statistics System, National Center for Health Statistics, National Electronic Injury Surveillance System, National Violent Death Reporting System	Publicly available, interactive, state level. Filters for subpopulations.	https://www.cdc.gov/injury/wisqars/index.html
Healthcare Cost and Utilization Project (HCUP)[63]	Agency for Healthcare Quality and Research	Administrative data from state, hospital, and federal resources	National resource of encounter-level health care data. Numerous databases available through application and purchase.	https://www.hcup-us.ahrq.gov/
National Health Interview Survey (NHIS)[64]	CDC, National Center for Health Statistics	Cross-sectional household interview survey administered annually	Sample of approximately 35,000 households. Provides information on nonfatal injuries that do not result in hospital admission.	https://www.cdc.gov/nchs/nhis/index.htm
National Ambulatory Medical Care Survey (NAMCS)[65]	CDC, National Center for Health Statistics	Data abstracted from physician offices, emergency departments, and ambulatory surgery centers	A nationwide sample of physician, hospital outpatient, and emergency department services; the conditions most often treated; and the diagnostic and therapeutic services rendered, including medications prescribed.	https://www.cdc.gov/nchs/ahcd/index.htm
National Trauma Data Bank (NTDB)[50]	American College of Surgeons	Deidentified incident-level data submitted to national registry by institutions	Clinical registry of incidents of traumatic injury and hospital course. Data are available through application and purchase.	https://www.facs.org/quality-programs/trauma/tqp/center-programs/ntdb
Trauma Quality Improvement Program (TQIP)[66]	American College of Surgeons	Institutional-level quality improvement initiative	Provides institutions with risk-adjusted benchmarking that provides national comparisons across similar level trauma centers. Data access requires submission to TQIP as an institution.	https://www.facs.org/quality-programs/trauma/tqp/center-programs/tqip
National Emergency Medical Services Information System (NEMSIS)[67]	Federal funding with state-level cooperation; administered through University of Utah	Standardized emergency medical services (EMS) data registry from every state	30 million EMS activations in 49 states. Data available through application and purchase.	https://nemsis.org/
Uniform Data System for Medical Rehabilitation (UDSMR)[68]	Not-for-profit organization affiliated with the University at Buffalo and The State University of New York	Data submission by rehabilitation centers across the United States	Patient functionality throughout rehabilitation course. Data available through application and purchase.	https://www.udsmr.org/

patterns and clinical or other outcomes on an individual or systems basis. Often, however, these national data sources are not appropriate for developing and sustaining injury prevention programs at the state and local level.

State and local data are more likely to reflect specific injury problems and are, therefore, more useful in setting priorities and evaluating the impact of policies and programs. Additionally, local data may be more useful when advocating for local policy change or funding of injury control programs. Some of the national databases described in Table 2-2 do provide subsets of data at the state or even county level; however, many do not. Availability, accuracy, and completeness of local injury data vary substantially by state and county. Vital statistics and death certificate data are generally available for all injury-related deaths; however, these data are limited in the information they provide about the nature and circumstances of the injury, cause of death, and risk factors associated with the death. Medical examiner and coroner reports can be a useful adjunct to death certificate data, but, once again, the completeness and quality of these data vary substantially from state to state. Autopsy rates are equally variable and are generally biased toward being performed in cases of suspected homicide.

State and local data on trauma hospitalizations are generally available from two principal sources, either uniform hospital discharge data or trauma registries. Trauma registries typically include more detailed information regarding the cause, nature, and severity of the injury than standard hospital EMR data. Trauma registries suffer from selection bias and inconsistent inclusion criteria, as well as variable data integrity. In both types of databases, ICD coding is not uniform. In addition, trauma registries do not include patients not admitted to nontrauma hospitals. Hospital discharge databases and trauma registries do not include information on trauma deaths that occur at the scene or in transport, nor do they routinely include patients who are treated and released. It is important to reemphasize that caution should be exercised in using these databases for describing the epidemiology of trauma, as neither is population based. Uniform data on trauma patients treated and released from EDs, hospital clinics, and physicians' offices are generally even less accessible than hospital-level EMR data.

The utility of existing data at the state and local level can be significantly enhanced by linking data across multiple data sources. Single data sources are often limited in their content or scope of coverage, or both. Techniques have been developed and are continually being improved to facilitate linkage of these databases to avoid the high costs of gathering new data. Several states have now linked hospital discharge data, vital statistics, police crash reports, and prehospital run sheet data.[71,72]

Local, state, and national data are extremely expensive to collect, and there is more expense to ensure they are reliable and accurate. As a result, funding for registry or database initiatives is often hard to come by, and those resources supported by federal dollars are ever at risk for budget cuts. Despite the limitations listed earlier, administrative data are incredibly important because they form the cornerstone for research, advocacy, and prevention efforts in trauma patients.

CONCLUSION

In summary, injury imposes a heavy burden on society in terms of both mortality and morbidity, along with its sizable economic burden on the health care system. Largely unrecognized is the fact that many fatal and nonfatal injuries are preventable using specific strategies guided by the analysis of injury epidemiology. Hence, there is no societal level of intolerance and fear of incidence as there is for HIV or West Nile virus and H1N1 influenza. Yet, these diseases contribute much less to the burden of public health disease than do injuries.

Risks of injury death vary by age and gender. The majority of injury deaths are unintentional, with elderly people at a particularly high risk. Considering intentional injuries overall, suicide greatly exceeds homicides, but rates again vary by age, gender, and urban or rural residence. Mechanisms of injury death also vary by age. The risk of injury death on the job varies by occupation. From a global perspective, the United States compares less than favorably with other countries in terms of fatal injury, particularly those related to firearms (Figs. 2-4 and 2-5).

Injury deaths have risen in the United States over the past 2 decades from 52 per 100,000 in 2000 to 72 per 100,000 in 2016. There is significant variation by mechanism of injury, with a gradual decline in motor vehicle–related deaths, but sharp increases in drug overdoses and fall-related deaths. Injury morbidity rates have demonstrated declining trends among all age groups except the elderly. Alcohol and other drugs continue to be intimately associated with all types and mechanisms of injury.

In conclusion, although significant strides have been made in reducing the rate at which injury occurs, trauma remains a major public health issue. More efficient ways of treating injuries as they occur, or tertiary prevention, should and will continue to be the major thrust of clinical care providers and researchers. It is equally and perhaps more important, however, that efforts to develop appropriate programs and policies that prevent injuries be prioritized. Education of policymakers and the public that this public health epidemic can and must be controlled is an essential component of this effort. Accurate, easily obtainable, and understandable data are a key first step in this process.

Integrated efforts at primary, secondary, and tertiary prevention, along with public information and education programs, are the only means to effect injury control and reduce the burden of injury on individuals, the health care system, and society at large. Understanding the importance of high-quality data as a building block for the study of injury science is important for all who participate in the care of the injured. Studying the epidemiology of injuries provides the opportunity for understanding how, when, and with whom to intervene.

Injury Prevention

Rochelle A. Dicker • Catherine J. Juillard

KEY POINTS

- Injury is responsible for more deaths worldwide than HIV, tuberculosis, and malaria combined.
- Injury remains the leading cause of death in the United States in people age 1 to 46 years old.
- The financial cost of injury is tremendous. Road traffic injuries alone cost most countries 1% to 2% of their gross national product.
- The social determinants of health, including poor employment opportunities, food deserts, poor education, and poverty, contribute significantly to risk of sustaining injury; addressing these factors represents a targeted strategy to reduce injury and recidivism.
- Evaluation of injury prevention programs begins at inception with feasibility and incorporates quantitative and qualitative measures.
- Broad public health principles can be applied to prevention of intentional and unintentional injuries.
- Prevention programs focus on risk reduction and thoughtful evaluation.

INTRODUCTION

Injury is a leading cause of death, disability, and health care costs worldwide. The Global Burden of Disease Study, which creates a unique framework to assess national trends in all-cause and cause-specific mortality and morbidity, has shed light on the burden of injury relative to the denominator of all morbidity and mortality.[1] This research and other prominent publications have been instrumental in moving injury to a level of recognition commensurate with its level of disease burden. Injury has begun to gain recognition as a prominent public health issue as thought leaders, researchers, and clinicians are vigorously studying the issues within a framework by which prevention efforts, trauma systems, and advocacy strategies can be developed and maintained.

Approximately 5.8 million people die around the world annually from injury-related causes. As a consequence of inadequate surveillance in many parts of the world, that number is likely to be much higher. Injury is responsible for more deaths worldwide than HIV, tuberculosis, and malaria combined. The impact is projected to increase over time relative to other leading causes of death (Table 3-1).[2] Greater than 90% of injury deaths occur in low- and middle-income countries, and within individual countries, vulnerable populations tend to be of lower socioeconomic status. This further hampers the progress of already struggling communities.

In several ways, the burden and demographics of injury in the United States provide an example of the patterns seen worldwide: injury is most prevalent in communities of lower socioeconomic status, rates of injury are higher in men than women, and young people are disproportionately affected by injury. According to the Centers for Disease Control and Prevention (CDC), in 2016, unintentional injury remained the leading cause of death in the United States for persons age 1 to 44 years. Unintentional injury, suicide, and homicide are the first, second, and third leading causes of death in those age 15 to 34 years, respectively. Homicide remains the leading cause of death in the United States in African Americans age 15 to 34 years old and the second cause in Hispanics of the same age. Unintentional injury is the third leading cause of death of all Americans, with motor vehicle crashes and falls, particularly in the elderly, having a significant impact.[3] As the population ages in the United States, the contribution of falls to the burden of unintentional injury will continue to rise, with an estimated 1 in 4 adults over the age of 65 expected to sustain a fall each year, resulting in an estimated $31 billion in annual Medicare costs. Furthermore, it is believed that approximately 50% of people over 65 years of age who sustain a fall will fall again within a year.[4]

Death is the "tip of the iceberg" in understanding the impact of injury. In order to understand the true magnitude

TABLE 3-1: Injury Deaths Rise in Rank, Leading Causes of Death, 2012 and 2030 Compared

Total 2012	Total 2030
1 Ischaemic heart disease	1 Ischaemic heart disease
2 Stroke	2 Stroke
3 Chronic obstructive pulmonay disease	3 Chronic obstructive pulmonay disease
4 Lower respiratory infections	4 Lower respiratory infections
5 Trachea, bronchus, lung cancers	5 Diabetes mellitus
6 HIV/AIDS	6 Trachea, bronchus, lung cancers
7 Diarrhoeal diseases	7 Road traffic injuries
8 Diabetes mellitus	8 HIV/AIDS
9 Road traffic injuries	9 Diarrhoeal diseases
10 Hypertensive heart diseases	10 Hypertensive heart diseases
11 Preterm birth complications	11 Cirrhosis of the liver
12 Cirrhosis of the liver	12 Liver cancer
13 Tuberculosis	13 Kidney diseases
14 Kidney diseases	14 Stomach cancer
15 Suicide	15 Colon and rectum cancer
16 Birth asphyxia and birth trauma	16 Suicide
17 Liver cancer	17 Falls
18 Stomach cancer	18 Alzheimer's disease and other dementias
19 Colon and rectum cancers	19 Preterm birth complications
20 Alzheimer's disease and other dementias	20 Breast cancer
21 Falls	21 Endocrine, blood, immune disorders

of injury, it is important to look at disability sustained, along with the age at which a person is killed or injured. Calculations of disability-adjusted life-years (DALYs), or the sum of years of life lost due to premature death and the years of productive life lost due to disability, are performed using a standard disability weight for each particular type of injury such as amputation, paralysis, posttraumatic stress disorder, and so on.[5] Although the DALY calculation has been criticized in its global applicability, it highlights the impact of injury on those who are either very early in their lives or in the middle of their years of economic productivity.

To round out the picture of the impact of injury, cost should be taken into consideration. Direct health care costs can be calculated and modeled. Indirect costs, including the psychological impact, loss of productivity affecting entire families, and societal costs of injury, are more difficult to calculate, but there is a growing understanding of their magnitude. Road traffic injuries alone cost most countries 3% of their gross national product.[6,7] A study in Ghana found that 25% of households affected by injury had a decline in their food consumption.[8] The release of the Lancet Commission on Global Surgery included a discussion on catastrophic expenditures from surgical disease, defined as out-of-pocket payment for treatment services exceeding 10% of annual household income.[9] This is a critical issue in surgical care, and injury is a leading part of that. In the United States, lifetime medical and work loss costs associated with fatal and nonfatal injuries were $671 billion in 2013.[10]

A chapter focused on injury prevention cannot properly be discussed without first understanding injury's influence on health and wealth. Understanding the global, national, and local impact of injury by mechanism and demographics is a critical start to launching into a strategy of targeted injury prevention appropriate for a particular location and population. A detailed investigation into these components along with understanding risk factors and protective factors allows us to understand the target population for prevention efforts. It can also be the cornerstone for creating a strategic plan for appropriate measures in education, engineering, and enforcement. In addition, understanding the public health impact of injury allows targeted advocacy for legislation and financial resources necessary to initiate many prevention plans. Understanding the direct and indirect costs of injury creates opportunities to conduct studies in cost-effectiveness, a compelling tool when advocating for prevention measures, particularly in an environment of limited resources.

THE IMPORTANCE OF PREVENTION IN TRAUMA SYSTEMS

The importance of injury prevention efforts is pointed out by trauma mortality patterns. Approximately one-third to one-half of trauma deaths still occur in the field, before any access to even the most advanced trauma treatment system.[11,12] Such deaths can only be decreased by prevention efforts. In terms of severely injured persons who survive long enough

to be treated by prehospital personnel, very few "preventable deaths" occur in a modern trauma system with well-run emergency medical services and designated trauma centers. Even among patients who survive to reach the hospital, a significant portion of in-hospital deaths are directly related to injuries to the brain and occur despite optimal available therapy. In one study of 753 consecutive deaths, over 50% were deemed possibly preventable only by prevention efforts, with only 13% due to pulmonary embolus, multiorgan failure, or sepsis.[13] Hence, injury prevention is critical to further significantly reduce the toll of death caused by trauma. Moreover, prevention efforts can also decrease the severity of injuries and the likelihood of disability that arises after trauma.

The American College of Surgeons (ACS) recognizes the critical role prevention plays in reducing the societal burden of injuries. The Committee on Trauma (COT) has mandated that all Level I trauma centers and recommended that Levels II through IV centers include a prevention program whose priorities reflect the dominant injury epidemiology in their community.[14] Additionally, Level I centers are mandated to have a prevention professional, who holds a separate position from the trauma program manager. This individual coordinates injury prevention efforts, including partnerships with community stakeholders and local governmental leaders. Level I trauma centers are also required to demonstrate that the trauma medical director has an active role in injury prevention, identification of priorities, and developing interventions to address root causes of injury. Currently, there is a working group within the ACS COT that is revising prevention criteria based on updated research and best practices review.

This chapter provides the historic and scientific framework by which prevention efforts are implemented today. Although the list is not comprehensive, topics that cover both unintentional and intentional injury and strategies that represent best practices and some newer promising practices in the United States are discussed. Many of these practices have evaluation and cost-effectiveness built in from program inception and stand as examples of the scientific principles presented in the chapter. Additionally, disparities in access to trauma care and the role social determinants of health play in injury incidence and treatment are important issues to address at a systems level and will also be addressed. Finally, the global implications of injury are reviewed. This includes injury as it affects low- and middle-income countries and developing strategies in surveillance, prevention, and injury control necessary to make a difference among populations at greatest risk.

SCIENCE AND ADVOCACY

History of Injury Prevention

Historically, injuries were seen as "accidents" that could not be predicted and, therefore, could not be prevented. This limited perspective resulted in an unaggressive and restricted approach to injury prevention that had little effect.[15,16] Over the past 100 years, several visionary individuals had successive insights that established the public health basis for injury prevention. These frameworks resulted in a rational approach that now guides effective injury prevention.

The epidemiologist John E. Gordon pointed out that injuries can be evaluated using the standard epidemiologic framework of host, agent, and environment. Just like any other condition affecting human health, Gordon explained that injuries were not random, but occurred with recognizable patterns across time and populations.[17] This was a paradigm shift from single-cause explanations that inadequately described the injury event and, therefore, limited prevention opportunities, to a multifactorial understanding of the components of injury. This would allow injuries to be studied from several perspectives and opportunities for prevention to be identified.[18]

The fundamental work done by Gordon applying public health principles to injury set the stage for the most notable of the early pioneers of injury prevention, William Haddon. He was the first director of the National Highway Traffic Safety Administration (NHTSA) and is most well-known for his expansion of Gordon's epidemiologic framework for injury prevention. This was by incorporating a temporal element to the host-agent-environment schema, which ultimately became known as Haddon Matrix (Table 3-2).[19]

TABLE 3-2: Application of Haddon Matrix to a Common Injury (elderly falls)

	Human factors	Agent factors	Environmental factors[a]
Pre-event	Visual impairment, agility Prevention of weakness or depression	Padding or softening of floor or other surface Kinesthetically friendly stairs	Handrails Removal of slippery rugs/low objects Adequate lighting
Event	Prevention of osteoporosis, social isolation	Removal of sharp objects potentially in the way Easily accessible alert system	Short emergency medical services response time Family members present
Postevent	Optimize nutrition Early and aggressive physical rehabilitation	Repair damage to home	Mitigation of health care costs Support for possible loss of independence (assisted living)

[a]Environmental factors can include social, political, and cultural factors. Some versions of Haddon Matrix include this element separately as a fourth factor (sociocultural environment).

Source: Adapted from Haddon W Jr. Advances in the epidemiology of injuries as a basis for public policy. *Public Health Rep*. 1980;95(5):411-421.

The pre-event phase allows us to examine the factors surrounding host, agent, and environment that influence the likelihood that an event capable of producing an injury will occur (eg, a motor vehicle crash). An example of a host factor in the preinjury phase would be alcohol impairment, agent factors could include brakes or maintenance, and an environmental factor could be road condition. During the event phase, there are factors influencing the probability that the event (ie, motor vehicle crash) will result in an injury and, if so, to what extent. A host factor during the event could be seatbelt use, an agent factor might be crush resistance of the car, and an environmental factor could be the presence or absence of dividers that would keep the car from ricocheting into ongoing traffic. In the postevent phase, these three components (host, agent, and environment) can be evaluated for factors that influence the ultimate consequences of injury.

This conceptual framework was further leveraged by Haddon to develop 10 strategies that formed the foundation of most current injury prevention and control efforts (Table 3-3).[19] Haddon's work marks the most pronounced shift in the transition from a simplistic, single-cause, individual-level perspective of injury events to complex, multifactorial, societal-level causation. Haddon's approach also integrated multidisciplinary involvement into injury prevention, including clinicians, epidemiologists, engineers, law enforcement agencies, policy experts, educators, and mental health experts.

Principles of Injury Prevention

Most interventions can be thought of as either being active or passive on the part of the person being protected. *Active* interventions involve a behavior change and require people to perform an act such as putting on a helmet, fastening a seatbelt, or using a trigger lock for a handgun. *Passive* interventions require no action on the part of those being protected and are built into the design of the agent or the environment, such as airbags or separation of vehicle routes and pedestrian walkways. Passive interventions are generally considered more reliable than active ones[19,20]; however, many interventions that are considered passive still inherently carry an active component, even if it is at the societal or political level, such as passing legislation to require certain safety features in automobiles.

Another framework often applied to injury prevention strategies is that of the following "three E's": (1) enforcement and legislation; (2) education and behavior change; and (3) engineering and environmental modifications. Initially, education was the main area of focus for injury prevention. If applied uncritically without a strong framework and thorough evaluation, behavior change through educational interventions in isolation can be difficult to achieve. A comprehensive report has suggested that the most effective interventions are engineering/environment, followed by enforcement, and lastly by education.[20] Educational interventions are usually most effective when complemented with modalities from the

TABLE 3-3: Haddon's 10 Strategies That Form the Foundation of Most Current Injury Prevention and Control Efforts

Phase	Strategy	Example
Pre-event		
	1. Prevent the creation of the hazard; prevent the development of the energy that would lead to a harmful transfer.	Prevent manufacture of certain poisons, fireworks, or handguns
	2. Reduce the amount of the hazard.	Reduce speeds of vehicles
	3. Prevent the release of the hazard that already exists.	Place a trigger lock on a gun
Event		
	4. Modify the rate or spatial distribution of the release of the hazard from its source.	Seatbelts, airbags
	5. Separate in time or space the hazard being released from the people to be protected.	Separation of vehicular traffic and pedestrian walkways
	6. Separate the hazard from the people to be protected by a mechanical barrier.	Protective helmets
	7. Modify the basic structure or quality of the hazard to reduce the energy load per unit area.	Breakaway roadside poles, rounding sharp edges of a household table
	8. Make what is to be protected (both living and nonliving) more resistant to damage from the hazard.	Fire- and earthquake-resistant buildings, prevention of osteoporosis
Postevent		
	9. Detect and counter the damage already done by the environmental hazard.	Emergency medical care
	10. Stabilize, repair, and rehabilitate the damaged object.	Acute care, reconstructive surgery, physical therapy

Source: Adapted from Haddon W Jr. Advances in the epidemiology of injuries as a basis for public policy. *Public Health Rep*. 1980;95(5):411-421.

other "E's"; that is, the most effective injury strategies typically have components of all three. An example is the child safety seat, an engineering solution for injury prevention, which was only successfully implemented through successful education campaigns and careful law enforcement.[21]

Other factors that must be considered when choosing and implementing injury control strategies are fidelity versus adaptability. Fidelity refers to the measure to which a program is implemented as intended and has been found to influence the measured effectiveness of an outcome.[22] While fidelity to the program's intended implementation is critical to achieving desirable outcomes, contexts may differ widely in a number of ways. These range from socioeconomic characteristics of the population served to cultural nuances that may influence implementation of the program. Adaptability is the ability of a program to be modified so that it is applicable in a specific context. An effective injury control program needs to strike an appropriate balance between fidelity to established, evidence-based methodology, while being adaptable enough to maintain relevance to the specific population being served. Often, the fidelity and adaptability of a specific program will influence its prioritization among potential interventions in injury control.

Prioritization of targets in injury control for intervention depends on multiple factors. The frequency and severity of a type of injury are fundamental to whether investments should be made to prevent or improve treatments for that injury; that is, having a solid base of evidence for the epidemiology of injury is key to prioritization. The cost of injuries in terms of direct health care costs and indirect societal and economic effects must also be considered. Effective arguments for implementing an injury control program can be made if savings in terms of averted injury-associated costs are demonstrated. Awareness of the importance of cost-effectiveness analyses and their potential as a tool for advocacy is steadily increasing.[22-25] Understanding of the resources available to fund and sustain the intervention is of primary consideration, as well, and will clearly influence the intervention chosen. Finally, less easily quantifiable but equally important are the acceptability and feasibility (including political) of a program in the community. When several strategies for injury control are available and found to be acceptable as potential interventions, prioritizing them may be difficult. Sustainability of a potential program is essential if it is to provide long-term effect. Therefore, assessing the ability of a program to become ultimately accepted and sustained may play into the decision as to whether or not to adopt it. An "institutionalized" program is one that achieves ongoing support and commitment from the agency, organization, or community in which it is based.[15]

Certain common characteristics run through many successful injury prevention programs. These include a multidisciplinary approach and community involvement, and there should be ongoing evaluation of both the process and outcome of the program. Depending on the targeted injury type, a program might involve contributions from the following: health care professionals, public health practitioners, policymakers, engineers, urban planners, epidemiologists, psychologists, manufacturers, traffic safety and law enforcement officials, experts in biomechanics, educators, and individuals associated with the media, advertising, and public relations. Health care professionals might include those in primary care, such as pediatricians, and those involved in acute trauma care. Finally, individual members of the public might be involved.[19,26]

Social Determinants of Health

The World Health Organization (WHO) defines "social determinants of health" as "the conditions in which people are born, grow, live, work and age," and these are largely determined by the unequal distribution of resources and power among populations.[27] Social determinants of health include factors such as education level, local availability of healthy foods, wealth attainment, employment opportunities, and gender equity, and all contribute to health inequities seen nationally and globally. One stark example of health inequity in the United States is the grossly unequal distribution of youth violence, which disproportionately affects African American and Latino communities. This can be tied to social factors such as disparities in housing, education, criminal justice, and economic development, among others.[28,29] This known inequity is further compounded in communities where trauma centers are located geographically far from those populations most affected by violence, resulting in prolonged transport times and potentially increased mortality.[30] Understanding the contribution of social determinants of health to a population's vulnerability to certain injury mechanisms and the limitations to access to care are critical. These identify risk and protective factors that inform coordinated prevention efforts to support those populations at highest risk. Any injury prevention initiative should incorporate a thorough assessment of the social determinants of health influencing the communities affected by injury and include these elements from program design through evaluation. Many of these social determinants, on an individual and ultimately on a community level, are modifiable. Efforts in modifiable risk factors often represent the backbone of injury prevention programs.

Injury Control: From Surveillance to Dissemination

The public health approach can be applied to injury prevention and control as it is applied to any problem at the population level. This approach is composed of the components described below:

1. Surveillance
2. Risk factor identification
3. Ascertaining natural history
4. Intervention
5. Evaluation
6. Dissemination

The components of a comprehensive injury prevention program are discussed in Table 3-4.

TABLE 3-4: Components of an Injury Prevention Program

Components	Role of the surgeon
1. Problem identification and targeted intervention	
Focus on severe and/or common problems (significant morbidity and mortality)	Evidence-based prioritization of problems
Identify potential intervention	Exploration of injury epidemiology through hospital-based data
Evaluate available information on the problem and possible interventions	
Choose appropriate and effective intervention	
2. Stakeholder engagement	
Identify potential coalition members, including clinicians, public health practitioners, community partners, government agencies, related industry, among others	Partner with injury prevention efforts
Identify one of the partners as the lead agency	Provide testimony describing the personal consequences of injury to engage stakeholders
	Connect stakeholders to patients (with their consent) for prevention efforts
3. Data gathering	
Identify potential challenges/obstacles (eg, lack of political will, opposition by interest groups)	Contribute to injury metrics (hospital-based data)
Choose metrics (process, outcome, surrogate)	Quantification of the direct cost of injury
Cost-effectiveness analysis	
4. Reduction of barriers to implementation/use of intervention	
A public information campaign to change a dangerous behavior	Advocacy based on human toll of injuries
A change in a law or the enforcement/application of a law	Empower and encourage our patients to be advocates
Change in the availability or characteristics of a product	
Change in a hazardous environment	
5. Funding	
Explore funding sources: community, foundation, governmental, industry, etc.	Collaborating in grant applications
Secure adequate seed funding and establish basis for future funding	
6. Advocacy	
Placing the burden of injury relative to other public health issues	Leverage societal role to call for collective action toward injury reduction
Creating partnerships between trauma centers and "champions" of a particular injury cause to generate groundswell	Experience-based advocacy through media, legislators, health departments, and hospital administration for injury prevention prioritization
7. Surveillance	
Identification of data sources (eg, police, hospital, autopsy, traffic safety administration)	Participation through trauma registry data
Comprehensive surveillance system	
Ongoing data collection	
8. Education/dissemination	
Identify public forums by which to inform: schools, health commission meetings, town hall gatherings, seminars, community organization meetings	Patient education
	Community advocacy
9. Evaluation	
Process measures (eg, legislation or policy change, change in the built environment, educational goals met, increased use of devices)	Participation through trauma registry data
	Continued injury surveillance
Outcome measures (reduction in injury events, deaths, or severity)	
10. Institutionalization (sustainability)	
Program becomes a regular part of the function of government or other groups	Patient education
	Advocacy to interest groups
Guard against successful programs being rolled back by opposing interest	

PROGRAM EVALUATION

Evaluation of an injury prevention program allows implementers to assess program effectiveness and make appropriate improvements. It also provides quantitative information for funders, increasing the program's accountability and support, and ensures that resources are being used in a beneficial and cost-effective way.[31,32] Although the science of program evaluation is extensive, a comprehensive review is beyond the scope of this discussion. Therefore, a brief overview of the necessary components and underlying standards is provided.

Program evaluation should be built into the program from inception, including during the development of theoretical frameworks supporting the program's premise. For example, a logic model developed in anticipation of forming a program should be assessed for the validity of underlying assumptions before implementation of the program.[32] Early stakeholder engagement is key to this process, as stakeholders can often identify gaps in the theoretical basis of a proposed program and help supply alternatives or solutions. As a program is developed, it is important to have discrete, agreed-upon metrics by which to assess the program, so that progress can be measured and seen by all those involved.

Program evaluation should focus on two broad areas including formative evaluation and summative evaluation (results, impact, and outcome evaluation).[32] Formative measures may include measurable goals inherent to the program's development, such as acquisition of human and capital resources or construction of program components. Summative evaluation measures are specific to the delivery of the program, outcomes of interest that the program is intended to influence, and the impact that the program is having on the community.[32] These measures can be a combination of process measures, impact measures, and outcome measures.[33] Process measures include measuring the success of delivering the program's services to the intended community.

Selection of these measures should be done early in program development, so that evaluation is built into the infrastructure of the program. In order to address these two areas, a combination of qualitative and quantitative evaluation metrics is often needed. When areas of research are novel and established quantitative metrics are unavailable, qualitative evaluation can be very helpful in exploring themes that can then be used to inform future quantitative evaluation measures. This approach helps to avoid investigator bias in terms of what is valued as a meaningful metric by the population served. Qualitative evaluation is also helpful in capturing program effects that are challenging to track quantitatively. One example of this is evaluating the influence and impact of culturally competent peer mentorship for violence intervention programs. The effect of this mentorship may not be evident through standard quantitative evaluation, but allowing program participants to speak to their experience in their own words may allow this theme to emerge.

For injuries, data sources used to evaluate outcome measures vary in terms of capture and resource expenditure (Fig. 3-1). Well-designed community-based surveys with

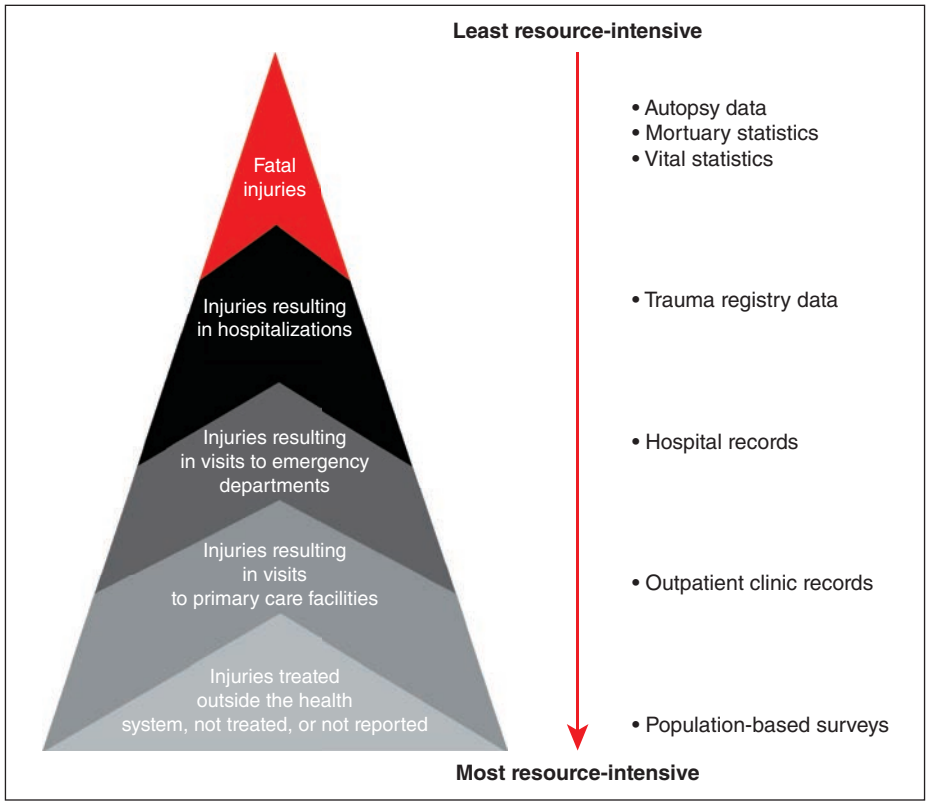

FIGURE 3-1 Examples of data sources used for capturing the burden of injury at different levels of the injury pyramid spectrum. (Reproduced with permission from World Health Organization. *Injuries and Violence: The Facts*. Geneva, Switzerland: World Health Organization; 2014.)

sophisticated sampling strategies are costly and not sustainable on a longitudinal basis, but they provide a good estimate of injury incidence per population. Trauma registries are extremely useful tools for injury surveillance and are present in all Level I trauma centers; however, the population captured is subject to selection biases based on severity and geography. Understanding the nature of the data and its inherent selection biases is critical to building and interpreting an injury surveillance system.[34] Trauma registries can be complemented by other sources of injury data, such as police and emergency medical services (EMS) data, to create a database that approaches representation of the "true" underlying injured population for surveillance purposes. Examples of augmenting individual data sources with complementary data sources through probabilistic linkage and other techniques demonstrate both the utility of this approach and the limitations of each individual data source on its own.[35-37]

Additional data sources that are extremely useful in injury surveillance and prevention efforts include the following:

1. CDC's Web-Based Injury Statistics Query and Reporting System (WISQARS)—https://www.cdc.gov/injury/wisqars/index.html
2. CDC's Wide-Ranging Online Data for Epidemiologic Research (WONDER)—http://wonder.cdc.gov
3. CDC's National Violent Death Reporting System (NVDRS)—https://www.cdc.gov/violenceprevention/nvdrs/index.html
4. ACS's National Trauma Data Bank (NTDB)—https://www.facs.org/quality-programs/trauma/ntdb

The steps in program evaluation have been well defined by the CDC, among others (Fig. 3-2).[38-41] The six steps are listed in Fig. 3-2.

The standards underlying the six steps in Fig. 3-2 strive to ensure that the program evaluation will be useful to users and stakeholders, ethically conducted, and accurate and feasible.[32,33] Ultimately, program evaluation should result in improvement of the program, identification of successful and unsuccessful components, and investment in strategies that work while discontinuing those that do not. For those interested in a more comprehensive review of program evaluation or further in-depth reading on the techniques and tools of program evaluation, references are provided.[32-34,39-41]

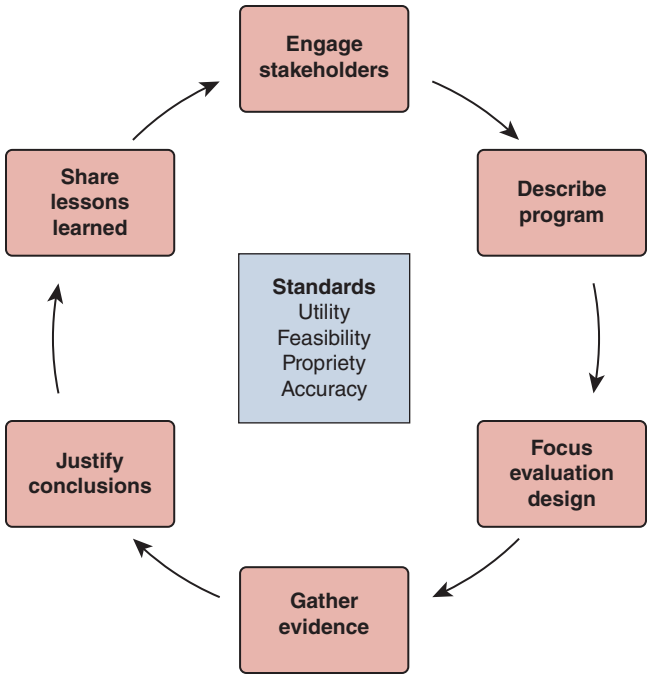

FIGURE 3-2 Example framework for program evaluation.
1. Engage stakeholders (people involved in program operations, the population served, funders, and others affected).
2. Describe the program (needs assessed, expected effects, context, logic model/theoretical framework, activities).
3. Focus the evaluation (identify the measurable effects that are most important to stakeholders).
4. Gather the evidence (indicators, data sources, quality and quantity of data available).
5. Justify conclusions (correlate conclusions using evidence gathered and assess this conclusion against predetermined standards set by the stakeholders).
6. Share lessons (dissemination of results and lessons learned improves the likelihood that the program will be used).

(Adapted from the Centers for Disease Control and Prevention's Framework for Program Evaluation at http://www.cdc.gov/eval/framework/index.htm and the Community Tool Box's Framework for Program Evaluation at http://ctb.ku.edu/en/table-of-contents/evaluate/evaluation/framework-for-evaluation/main.)

SPECIFIC STRATEGIES TO PREVENT UNINTENTIONAL INJURY

Motor Vehicle Safety—Occupants

Motor vehicle safety and injury prevention measures provide a comprehensive example of proven active interventions, passive engineering, legislation, and enforcement strategies that have been modified over decades. In addition, due to detailed surveillance over time, some newer strategies have recently been implemented to address current risk factors such as use of cell phones and targeted strategies for teenage drivers, the highest risk group.

Much has been accomplished to make motor vehicles safer. Engineering features such as "crash avoidance" make it less likely for a vehicle to crash. Other safety features include brakes, headlights, triple brake lights, and signals. Automotive safety also includes engineering features that make occupant injury less likely in the event of a crash. This is referred to as crashworthiness and includes such features as collapsible steering columns, shatterproof glass, and improved side impact protection. These improvements have resulted from both improved car design on the part of the automobile manufacturers and regulations from NHTSA, in the form of Federal Motor Vehicle Safety Standards (FMVSS).

One of the greatest advances in automotive safety was the realization that a significant component of the injuries sustained in crashes was due to secondary collision of the

occupant with the vehicle interior and to ejections. This understanding led to the development of seatbelts to allow occupants to "ride down" the crash, dissipating their kinetic energy more slowly and in a controlled fashion. It is estimated that seatbelt use reduces serious crash-related injury and death by about half. Adding (*not substituting*) airbags provides even greater protection for adults.[41,42] Despite the major progress overall as a result of engineering and enforcement, there remains a population of people least likely to wear seatbelts—teenagers. Of the teenagers who died in motor vehicle crashes in 2012, 55% were not wearing seatbelts.[43] Seatbelt use is an active and necessary prevention measure. Primary enforcement and education by parents and health care providers are strategies that can work, even when facing the challenge of the teen still in a steep behavioral development phase in cognitive growth.

Graduated Licensing

Teen drivers have the highest crash risk per miles traveled of any group; however, newer prevention strategies, most notably graduated licensing, are having positive results on rates of serious motor vehicle crashes. Graduated licensing laws are now present in all 50 states and the District of Columbia and allow for teens to mature and develop skills during an intermediate step. The initial license, for example, may restrict night driving or having young passengers except family members in the car with the new driver. Along with enforcement of drinking and driving laws and properly fitted child car seats, graduated licensing has significantly improved the rate of serious motor vehicle crashes in the United States.[44]

Strategies Regarding Distracted Driving

Along with the convenience of cellular phones for conversations and texting comes the risk of distracted driving. Distracted driving is thought to be responsible for more than 9 deaths and 1100 motor vehicle injuries daily in the United States, an issue that appears to be much worse than in other places with as much cellular access, such as Europe.[42,45] With the raised awareness of the dangers of distracted driving, many states have enacted strict laws regarding texting and driving and have legislated for "hands-free" cellular phone use while driving. A number of laws limiting cellular phone use among federal employees and train operators have also been enacted.

Motor Vehicle Safety—Pedestrians

Injury prevention for pedestrians exemplifies the importance of comprehensive strategic planning among the community, government, and health care agencies. In 2012, over 4700 pedestrians were killed and another 76,000 were injured in the United States. Vulnerable populations include the elderly, children, and the mentally ill.[46] As low- and middle-income countries industrialize at a rapid rate, improvements in road traffic engineering have lagged behind, causing a growing threat to pedestrians in many countries. Passive strategies such as complete separation of pedestrians from motor vehicles have had proven success at reducing risk, but may not be feasible. Other engineering strategies to create a safer environment such as countdown signals (particularly around senior facilities), flashing crosswalks, pedestrian lead time signals, and "bulb outs" have had varying rates of success.

Prevention of traffic injuries often requires a multidisciplinary approach involving community activists, engineering experts, public health departments, police and fire departments, legislators, and public health researchers. An example of a promising practice is the strategic plan called the Vision Zero Initiative. The initiative was created in Sweden and based on the public health principle that "we are human and we make mistakes," but the environmental design should keep us safe, and no loss of life due to traffic injury is acceptable.[47] As such, the initiative places the main burden for safety on comprehensive system design. Plans first enacted in Sweden in 1994 have led to clear reduction in pedestrian deaths and injuries, despite growing amounts of traffic. The initiative has now been adopted in multiple cities worldwide and over 30 cities in the United States, including New York City, Chicago, Los Angeles, Austin, and San Francisco. Central to strategic planning for Vision Zero is surveillance.[48] More recently, Vision Zero has been rolled out in medium-sized cities as well, focusing on implementation of Vision Zero principles, such as speed reduction and road rechannelization projects.

Trauma centers in the United States can play a major role in this initiative, given the evidence that police data only capture a portion of pedestrian and bicycle injuries.[35,37] Trauma center data can serve to augment these data sources to provide more comprehensive injury surveillance and better identify areas of prioritization for strategic planning and policy advocacy. Along with comprehensive plans for road traffic safety, analysis of cost-effectiveness should be rolled into the long-term planning. Therefore, strategies that are cost-effective must include knowledge of the direct and indirect costs of injury.

Prevention of Falls

More than one-third of adults over 65 years of age fall each year in the United States, and for over half, it is not the first fall. One in 10 falls are deemed serious, and over 10% of emergency department visits are due to falls. Individuals who are mentally ill are also at higher risk for falls, but this section will focus on the elderly patient. Risk factors are well known and include visual impairments, polypharmacy leading to disequilibrium and gait disturbances, home hazards such as loose rugs and steps, and lack of grab bars. The costs of falls in the elderly, both personally and financially, are very significant. Severe traumatic brain injury, particularly with increases in usage of antiplatelet therapies, warfarin, and novel oral anticoagulants, poses a serious threat to life and independence.[49,50] The direct medical cost of elderly nonfatal falls exceeds $20 billion annually.[51]

The risk factors listed, however, are preventable. A number of programs in prevention that have reduced falls and

fall recidivism have been implemented over the past decade. Many of these programs focus on home assessments and implementation of safety measures such as securing rugs, creating ramps, and installing grab bars. In addition, physical therapy programs working specifically on gait and balance, reviews of medications and potential medication interactions, and vision screening have all played a successful role in reducing risk. Hospital-implemented efforts in fall prevention, including screening and implementation, have been led in part by the Veterans Administration. These have proven to be promising and have been a way that trauma centers with a high burden of elderly falls can fulfill their injury prevention mandate and provide an active prevention strategy. These are developed in conjunction with senior community resource centers and other groups focused on risk reduction.[52-54]

SPECIFIC STRATEGIES TO PREVENT INTENTIONAL INJURY

Firearm Violence

The leadership of the ACS COT has made prevention of firearm violence a major priority and has adopted a public health approach. Initially, a survey of the ACS Board of Regents and members of the ACS COT and American Association for the Surgery of Trauma was conducted to understand the perspectives and values of surgeons.[55] Subsequent critical initiatives have included engaging owners of firearms in order to promote safety without infringing upon the rights afforded by the Second Amendment. The October 2017 ACS *Bulletin* was devoted entirely to violence prevention and intervention efforts.[56] Members of the COT's Injury Prevention and Control Committee (IPCC), under the leadership of Dr. Deborah Kuhls, have worked in the fields of policy and advocacy and development of a safe storage toolkit. In addition, they have partnered with the Health Alliance for Violence Intervention (HAVI) and supporting groups such as the American Foundation for Firearm Injury Reduction in Medicine (AFFIRM), which works to fund firearm injury research. The development of this group is in part a result of the dearth of federal funding for gun violence research with the passing of the 1996 Dickey Amendment. The COT's IPCC has recently produced a downloadable brochure, "Gun Safety and Your Health," as a guide to keeping families and communities safe.[57] Specific injury prevention strategies are described later in this chapter.

There is an association with the proximity of firearms and risk of death in a variety of populations along the life cycle. Sixty-three percent of firearm deaths in the pediatric population are from suicide, and the availability of a firearm is an independent risk factor.[58] In contrast, the horrific uptick of mass shootings in schools accounts for less than 1% of firearm deaths and unintentional shootings for 2%. Strategies to reduce risk include engaging parents and children in screening for at-risk behavior and providing guidance for safe storage practices. Victims of a domestic dispute are five times more likely to be murdered if a firearm is present. Senior citizens, as with children, are more likely to die from a suicide attempt if a firearm is present in the home.

As outlined in a recent article by leaders of the ACS COT, "Freedom with Responsibility: A Consensus Strategy for Preventing Injury, Death, and Disability from Firearm Violence," there are many Americans who have polarized views about firearms, often leading to a "war of words" when it comes to efforts to reduce firearm injury.[59] One common goal between the groups would be to make firearm ownership as safe as possible. The article presents broad, reasonable policy proposals that have the capacity to bring the two sides together for the health and welfare of the population of the United States.[59]

Prevention of Suicide

In 2016, suicide was the 10th highest cause of death for all ages in the United States. It is estimated that 800,000 people die worldwide from suicide annually. Globally, risk factors are most often present in marginalized and discriminated groups. In many countries, including the United States, risk factors include mental illness, prior suicide attempts, personal loss, financial loss, chronic pain, substance abuse, and trauma. In addition, establishing protective factors and resiliency often requires long-term care and counseling and are dependent upon access to that care.[60] A comprehensive strategy for suicide prevention is well outlined by the CDC in the guide "Promoting Individual, Family, and Community Connectedness to Prevent Suicidal Behavior," along with focused treatment of mental illness and substance abuse.[61] In 2017, the CDC published "A Technical Package of Policy, Programs, and Practices" for suicide prevention.[62] This is an amalgam of best practices and avenues for advocacy in suicide prevention. The trauma center can serve as a portal by which individuals who have attempted suicide can be provided with resources and the means to reduce harm through partnerships with mental health services. The National Suicide Lifeline is another excellent resource.[63]

Prevention of Child Abuse and Neglect and Elder Abuse

According to Child Protective Services, approximately 676,000 children were abused or neglected in the United States in 2016. These toxic experiences are harmful not only to the development of the young brain, but also to the immune system of the child. Similar to the technical guide for suicide prevention, the CDC has published a guide for the prevention of child abuse and neglect.[64]

Physical or sexual abuse, neglect, and financial or emotional deprivation are all examples of elder abuse. The Institute on Aging has teamed with Adult Protective Services in San Francisco to develop a model Elder Abuse Prevention Program.[65] As obligate reporters of child and elder abuse, practitioners need to remain vigilant and aware of the warning signs.

Prevention of Youth/Interpersonal Violence

It has been over 2 decades since the surgeon general at the time, C. Everett Koop, recognized interpersonal or youth violence as a public health issue. Since that time, health providers have adopted a public health model. This has included assessment of individual risk and protective factors and development of strategies for reduction in harm by implementing, evaluating, and exporting programs that are promising. In the United States, there are over 30 hospital-based violence intervention programs that target youth and young adults who have been violently injured. The public health approach follows the principles of Trauma Informed Care as follows: (1) realizes the widespread impact of trauma and understands potential paths to recovery; (2) recognizes the signs and symptoms of all trauma in clients and families; (3) responds by fully integrating knowledge about trauma into policies, procedures, and practices; and (4) seeks to actively resist trauma recidivism.[66] Conversely, programs based on "scared straight" approaches have not been successful.[67] Three specific guiding components for implementation in many hospital-based programs are as follows: (1) recognition that when an individual is injured, there is a "teachable moment" during which time that individual is most open to risk reduction strategies; (2) culturally aware and competent case managers/intervention specialists approach the individual at the bedside and provide long-term follow-up care; and (3) intervention specialists/case managers assess needs and assist individuals over time to find resources for risk reduction available in the community. The majority of these efforts in risk reduction are a reflection of the social determinants of health discussed earlier in this chapter. Evaluation, including feasibility, utility, intermediate- and long-term results, and cost-effectiveness studies, have been conducted. Results have been promising, with demonstration of successful enrollment and retention (feasibility), risk reduction when looking at intermediate outcomes, reduction in the injury recidivism rate when looking at long-term outcomes, and demonstration of cost-effectiveness.[23,68,69] Some programs have been successful at reducing injury in the most vulnerable populations by securing funding within the city budget through working with legislators and departments of public health. Technical support and advocacy are available for trauma centers interested in implementing a violence intervention program through the HAVI (www.thehavi.org). The ACS *Bulletin* published a "Primer" for starting and sustaining a hospital-based violence intervention program (HVIP).[56] HVIPs have teamed with Cure Violence, a successful community-based violence interrupter strategy, in some cities as part of a comprehensive strategic plan for violence prevention. These partnerships are critical because it often "takes a village" to tackle this complex societal issue.

Intimate Partner and Sexual Violence

Intimate partner violence (IPV) is one of the most common forms of violence in the United States. Up to 1 in 4 women and 1 in 7 men report having been physically assaulted by an intimate partner over their lifetime, a burden disproportionately experienced by women and racial minorities.[70] Of women who are murdered, 55% are victims of an intimate partner. Because an encounter with the health care system is often one of the few times a victim of IPV may be able to access help, the ACS has determined that the trauma surgeon plays an important role in screening for IPV and potentially preventing further harm or even death.[71] Additionally, in centers where IPV has a high incidence, prevention programs should be specifically tailored to identify potential victims and provide supportive risk reduction services. IPV is part of a broader spectrum of gender-based violence (GBV) and sexual violence, which can occur between a man and a woman, between members of the same gender, or among any individuals along a gender spectrum. The hallmark feature of GBV is that the violence is incurred by the victim in association with a power imbalance due to his or her gender or gender identity.[72] A number of prevention strategies have been described to prevent GBV, including advocacy, legislation, and community-based interventions aimed at promoting gender equity. A specific form of GBV that can be "hidden in plain sight" of the health care community is human trafficking.[73] Often, the health care system is one of the few institutional encounters a human trafficking victim will have, providing an opportunity for acute intervention, if health care providers are prepared to recognize the signs. The US Department of Health and Human Services has resources to aid health care providers in identifying and supporting victims of human trafficking.[74]

Horizontal Relationship of Violence

The different forms of violence often have distinct and separate resources available for intervention and prevention. Although separated in text, these forms of violence have significant crossover. Victims of one form of violence are frequently exposed to other forms. Programs across the spectrum of violence often have fidelity in their approach of addressing root causes and risk factors. It is also critical to understand that violence is cumulative in vulnerable populations, across the life spectrum. A trauma-informed care approach to victims of violence is important given the recognition that this not often just a singular event in an individual's life.

Mass Shootings in the United States

Approximately 5% of the world's population resides in the United States, yet 31% of all mass shootings occur here.[75] By definition, mass shootings are events that kill four or more people. Although mass shootings make up less than 1% of all homicides in this country, they are deadlier and are increasing in frequency. These horrific events galvanize people to take action through following advocacy for changes in legislation, political representation, funding for gun violence research, Second Amendment freedoms, mental health care, and educational endeavors. As with other aspects of violence prevention, approaching mass shootings with a public health

approach to drive at the root causes is essential. As championed by the article by Stewart et al,[59] it is only together that we can ultimately protect our freedoms and our safety.

INJURY AS A GLOBAL HEALTH PROBLEM (SEE ALSO CHAPTER 64)

Burden of Injury: Global Disparities

Growing attention has been placed on the burden of injury worldwide and highlighting trauma as a global public health issue. As countries industrialize, road traffic increases along with the risk of injury, especially in contexts where commensurate improvements in road safety have not been achieved.[2] As mentioned at the beginning of this chapter, over 90% of the 5.8 million deaths each year due to injury occur in low- and middle-income countries, where trauma systems are least developed.[76] The etiology of this is likely multifactorial. First, most people in the world live in low- and middle-income countries.[77] In addition, industrialization is associated with an increase in vehicle ownership, traffic density, and traffic mix, all of which contribute to an increased incidence of injury.[78] Additionally, the injury case fatality rate in low- and middle-income countries is higher than in high-income countries, likely due to weaker implementation of prevention efforts and less well-developed prehospital and hospital care. A person injured in a low- or middle-income country has twice the likelihood of dying from his or her injuries than a similarly injured person in a high-income country.[11] As surgery is an integral component of trauma care, it is informative to discuss the distribution of surgical services across countries of different economic strata. Although only 15% of the world's population lives in wealthy countries, 60% of the operations done each year are in these countries. Only 3.5% of the operations performed globally each year are in poor countries, which includes 35% of the global population.[79]

Decreasing the Global Burden of Injury: Opportunities and Challenges

The magnitude of the global burden of injury is clearly great, yet trauma is often not discussed among the world's global health priorities. Of the $4 billion budgeted by the WHO each year, less than 1% is spent on injury. This amount is grossly disproportionate to the 12% of the world's disease burden attributable to injury.[80]

Recent attention on the importance of trauma as a public health priority has led to several encouraging initiatives. The WHO has published several guidelines geared toward low- and middle-income countries that establish the essential components of trauma care and offer guidance toward implementing cost-effective programs in trauma quality improvement.[81,82] These were largely in response to a landmark World Health Assembly (WHA) resolution on trauma care (60.22) calling for improved technical support from WHO for stakeholder countries to address the growing burden of trauma.[83]

In 2015, the growing appreciation of the burden of surgically treated diseases in low- and middle-income countries sparked several landmark developments. As previously mentioned, *The Lancet* created a Commission on Global Surgery, representing contributions from 110 countries. This resulted in a series of reports, publications, and recommendations to guide improvements toward equitable access to affordable surgical care globally.[9] In March 2015, the third edition of the Disease Control Priorities was released, and this featured a renewed focus on surgical issues. Additionally, the WHO and the United Nations launched a Decade of Action for Road Safety in 2011 in over 100 countries, emphasizing the importance of prevention of injuries related to road traffic and treatment of associated trauma.[84] With increasing attention on road traffic injuries as a major contribution to death and disability globally, effective prevention measures are needed. The evidence is mounting that legislation, speed reduction measures, public awareness and advocacy, enforcement, and, ideally, multifaceted interventions incorporating more than one of these approaches can result in significant reductions in crash events, injuries, and mortality.[85]

INJURY CONTROL IN LOW- AND MIDDLE-INCOME COUNTRIES

The basic principles of injury prevention previously outlined in this chapter are universal; however, the application of these principles may vary by context. For example, the distribution of injuries related to road traffic has been shown to vary by country, with pedestrians and drivers of two-wheel vehicles found to be particularly vulnerable in certain low- and middle-income countries.[86-89] Some reports estimate that nearly 55% of road traffic deaths in Africa are due to pedestrian injury, compared to 15% or less in the United States or Europe.[90,91] Similarly, scald burns appear to be more frequent in high-income countries than in low- and middle-income countries, whereas flame burns are more frequent in low- and middle-income countries.[92-95] These differences in the patterns of injury underscore the importance of comprehensive and robust injury surveillance systems to inform evidence-based interventions. In high-income countries, a cornerstone of these systems has been hospital-based trauma registries, a surveillance tool that is increasingly used in low- and middle-income countries.[96-100] In addition to injury surveillance data that are regionally accurate, effective injury prevention efforts can only be successful with early engagement of stakeholders and careful assessments of feasibility to tailor interventions to local contexts.

Speed Bumps. An example of a cost-effective method of reducing highway speeds is the strategic placement of speed bumps. One speed bump is estimated to cost about $1000 to build and is expected to last 10 years. When modeled for the world's most dangerous intersections where 10% of deaths occur, speed bumps are among the most effective and cost-effective public health interventions available, costing approximately $100 for life saved and only $3.26 per DALY achieved.[101]

Helmet Use. Helmet laws are another intervention in injury prevention that has been studied in low- and middle-income countries. In Thailand, enactment of a helmet law was associated with a fivefold increase in helmet use among motorcyclists and a concomitant reduction in head injuries by 41% and deaths by 21%.[102] The cost-effectiveness of this intervention was estimated to be $467 per DALY averted.[103] In Vietnam, a helmet law was adopted more recently after it was found that 60% of the over 11,000 annual road traffic fatalities in that country occurred in motorcycle users. Preliminary work suggested that survey respondents were willing to pay for helmets.[104] This public health problem was addressed through a combination of legislation, social marketing, and enforcement, and was ultimately associated with significant decreases in injury events, serious injuries, and deaths captured through hospital and police data sources.[105]

Seatbelts. Improving the use of seatbelts through policy and legislation is another injury prevention strategy recommended by the WHO to improve traffic safety.[2] While seatbelt use has become widespread in high-income countries like the United States, the practice and enforcement in low- and middle-income countries are less prevalent. As part of the Bloomberg Road Safety in 10 Countries project, enforcement campaigns advocating for seatbelt use and speed control in several low- and middle-income countries have shown promise both in increased utilization and decreased injuries.[106,107] Initial interim reports from Russia demonstrate a significant increase in use of seatbelts after implementation of this initiative.[108]

One important concept when considering interventions in road traffic safety is that implementing a multifaceted intervention tends to be both more effective and more cost-effective than implementing a single intervention. For example, implementing a helmet law in combination with a seatbelt law in the same region would not only result in a greater reduction in injuries and deaths, but also be more cost-effective than only one of these interventions. This is because the infrastructure for enforcing one intervention is shared by the other, mitigating the cost.[109] An example of this is the previously mentioned Bloomberg Project, the second phase of which will focus on the following seven interventions: helmet use, seatbelt use, prevention of drunk driving, speed reduction, infrastructure improvements, sustainable urban transport, and improving vehicle transport.

Tertiary Prevention

With the increased focus on injuries as a global public health problem has come an evolving awareness of the importance of strengthening trauma care in resource-constrained settings. The WHO has published several resources aimed at providing technical support to health care providers, policymakers, and hospital administrators to improve trauma care in their context, regardless of resources.[81,82,110] Several programs in low- and middle-income countries have demonstrated improvements in the prehospital care of trauma patients using context-appropriate innovations.[111-115] In the hospital setting, quality improvement (QI) programs have been used as cost-effective means to improve trauma care in all countries.[81] Specific applications of QI techniques, including creation of a trauma registry, the definition of key performance indicators, application of audit filters, and root cause analysis have been associated with a reduction in both preventable deaths and overall mortality in trauma patients in Thailand.[116-118] Similarly, in Pakistan, the utilization of QI principles led to the creation of trauma services. This intervention was associated with significantly decreased odds of both death and complications after implementation.[119] The WHO has also led the implementation of a trauma care checklist that was associated with an improvement in 18 of 19 process measures and a reduction in mortality among the most seriously injured cohort.[120]

CONCLUSIONS: THE SURGEON'S ROLE

The field of injury prevention and control has made dramatic inroads into reducing the toll of death and disability. Particularly in high-income countries, prevention measures against active and passive injury have been successful in increasing the safety of road users, populations at risk for falls or burns, and potential victims of violent injury. Through comprehensive evaluations and the right mix of fidelity and adaptability, efforts in decreasing both intentional and unintentional injury are demonstrating intermediate- and long-term successes. With over 90% of injury deaths occurring in low- and middle-income countries, appropriate attention is now shifting to worldwide surveillance and strategic planning for injury prevention. It is only through this work that the burden of global injury can be improved.

Surgeons have a unique opportunity to participate in all components of prevention from surveillance to programming to evaluation and advocacy. Surgeons see patients during that unique "window of opportunity" after injury, making them powerful advocates not only to individuals and community organizations, but to legislators as well. The injury event, and similarly the hospital itself, is a promising portal of entry into prevention programs. Surgeons have spearheaded projects that have clarified the mechanisms of particular injuries and have implemented and studied programs that can have impact. Surgeons are a vital partner in the multidisciplinary approach necessary to make an appreciable difference in injury-related death and disability globally.

Trauma Systems, Triage, and Transport

David J. Ciesla • Andrew J. Kerwin • Joseph J. Tepas III

KEY POINTS

- Overtriage of minimally injured patients will impair trauma center efficiency, whereas undertriage of severely injured patients will increase the risk of preventable death and disability.
- The major goal of an inclusive trauma system is complete control of all aspects of injury, from effective prevention to successful societal reintegration of injury victims.
- Only 60% of the United States has statewide trauma systems, and approximately 20% has no system at all.
- The numbers and levels of trauma centers should reflect population distribution and the burden of injury within the region.
- Level I trauma centers are distinguished from Level II centers by admission volume requirements, presence of a surgically directed critical care service, educational leadership, and trauma-related research.
- Most current data estimate that 63.1% of the population of the United States can reach a major trauma center within an hour by ambulance, a figure that increases to 90.4% with the inclusion of helicopter services.
- A multiple-casualty incident may exceed the resources of one hospital trauma center, but care can be provided by adjacent hospitals within the city or region without outside help.
- The Simple Triage and Rapid Treatment (START) triage system developed in California includes assessments of the patient's ability to ambulate and the patients' respiratory function, systemic perfusion, and level of consciousness.

TRAUMA SYSTEM DEFINITION

Trauma System Mission

A trauma system is an integrated collaboration of health care providers, agencies, and institutions dedicated to the control of the entire spectrum of injury from effective prevention to efficient societal reintegration of injury survivors. At the system's core is coordinated and comprehensive care of acutely injured patients within a defined geographic area.[1-4] Its services are multidisciplinary and comprehensive and encompass a continuum that includes all phases of patient need.[2,3,5-7]

Trauma System Goals

Because geographical coverage exceeds that of a single hospital or health system, trauma systems provide seamless regionalization of resources to facilitate efficient use of available and qualified health care facilities. Cost-efficient and efficacious coordination of resources is a defining characteristic of an effective trauma system, as is disaster preparedness. The institutions and agencies that form the trauma system provide the regional response to care for victims of natural or manmade disasters. The US Department of Health and Human Services has compiled a set of guidelines and standards for Model Trauma System Planning and Evaluation.[8,9] This comprehensive document was initially released in 2006 and remains an excellent source of information for every aspect of trauma system design and planning. More recently, the National Academies of Sciences, Engineering, and Medicine published its report entitled *A National Trauma Care System: Integrating Military and Civilian Trauma Systems to Achieve Zero Preventable Deaths After Injury*.[9-11] This document recognizes that although there are variations in patterns of injury in civilian and military environments, the spectrum of injury, when assessed across a population, demands access to every appropriate resource from both military and civilian sectors, especially when dealing with a mass casualty event. The document encourages the United States to commit to a national aim of achieving zero preventable deaths after injury and minimizing trauma-related disability. It recommends that the secretaries of Health and Human Services and Defense, together with their governmental, private, and

academic partners, work jointly to ensure that military and civilian trauma systems collect and share common data spanning the entire continuum of care. Within that integrated data network, measures related to prevention, mortality, disability, mental health, patient experience, cost, and clinical outcomes should be made readily accessible and useful to all relevant providers and agencies.

Trauma System Objectives: Transforming from Exclusive to Inclusive Trauma Systems

A modern trauma system is committed to control of the impact of injury on population health. While this is obviously achieved by effective prevention, the system's immediate daily function is focused on the elimination of preventable death. This is predicated on (1) ensuring expeditious access by acutely injured patients at risk of death or disability to the resources of a designated trauma center, and (2) accurate identification of patients who warrant care at these facilities. Although trauma systems evolved as networks of high-capacity centers available for all injury victims, those patients at greatest risk of mortality were the primary focus of triage protocols. As understanding of the requirements for efficacious population-based management of acute trauma has progressed, it has become clear that effective control of this disease requires participation of the entire community.[12] To achieve optimal control of injury on any defined population, trauma systems that had been developed for the exclusive care of the most severely injured required expansion to an inclusive regional enterprise that could address all phases of injury control. Paramount to this is effective integration and collaboration of designated trauma centers with all regional health care facilities. As the American health care system shifts from reactive acute therapy of patient disease to preemptive management of population wellness, all trauma systems must be configured as inclusive. This actually enhances the importance of accurate triage systems. Overtriage of minimally injured patients will impair trauma center efficiency, whereas undertriage of severely injured patients will increase the risk of preventable death and disability.

TRAUMA SYSTEM DEVELOPMENT

The modern timeline of development of comprehensive trauma care began in 1949 when the American College of Surgeons Committee on the Treatment of Fractures, which had been established in 1922, was expanded to become the American College of Surgeons Committee on Trauma (ACSCOT). In 1961, a dedicated trauma unit was opened at the University of Maryland under the leadership of R Adams Cowley, MD, FACS. The National Academy of Sciences and the National Research Council published *Accidental Death and Disability: The Neglected Disease of Modern Society* in 1966.[13] This redefinition of injury as a preventable and treatable disease was a major stimulus to the development and propagation of systems of trauma care.[14]

By 1973, Dr. Cowley's initiative emerged as the Maryland Institute of Emergency Medicine, which became the nation's first completely organized statewide regionalized trauma system. A similar initiative that included designation of trauma centers by state law was initiated by Illinois in 1971.[15] Virginia followed in 1981 and established a statewide trauma system based on volunteer participation and compliance with national standards as defined by ACSCOT.

In 1973, the Emergency Medical Service Systems Act became Public Law 93-154, thereby adding a section to the Public Health Services Act of 1944 (PL 78-410) that encouraged development of comprehensive area-wide emergency medical systems. State and local agencies instituted prehospital care systems to deliver patients to major hospitals where appropriate care could be provided. Prehospital provider curricula were standardized, and training programs were established for paramedics and emergency medical technicians (EMTs).

The American College of Surgeons published the first edition of the *Optimal Hospital Resources for the Care of the Seriously Injured* in 1976, establishing a standard for comprehensive delivery of trauma care. This document was the first to define specific criteria for the categorization of hospitals as trauma centers. The document has been periodically revised to reflect current thought and is recognized nationally and internationally as the standard for hospitals aspiring to be trauma centers. The most recent sixth edition, *Resources for Optimal Care of the Injured Patient*: *2014*, establishes evidence-based criteria to guide prehospital and trauma care personnel and emphasizes the importance of ongoing performance and quality improvement.[5]

ACSCOT developed the Advanced Trauma Life Support (ATLS) course in 1980, motivated in part by the personal experience of a surgeon involved in the crash of his private airplane. His experience and his observations of the care provided to members of his family made him realize that more education about resuscitation and care of the injured patient was critically needed. The resulting ATLS course has contributed to the uniformity of initial care, has developed a common language for all care providers, and has been successfully promulgated throughout the world.

In 1985, the National Research Council and the Institute of Medicine published *Injury in America: A Continuing Health Care Problem*.[16] This document concluded that there had been little progress toward reducing the burden of injury despite considerable funding committed to develop trauma systems. It also recommended investment in epidemiologic research and injury prevention. As a result, the Centers for Disease Control and Prevention (CDC) was designated as the national research center to coordinate efforts in injury control, injury prevention, and all other aspects of trauma care.

In 1987, ACSCOT initiated the Verification/Consultation Program to provide resources for trauma center verification. More recently, ACSCOT added additional focus on systems development with publication of *Consultation for Trauma Systems* to provide guidelines for trauma system evaluation and enhancement.[17] Concomitant with these efforts, the

American College of Emergency Physicians (ACEP) published "Guidelines for Trauma Care Systems."[18] This document also addressed the continuum of trauma care and identified essential criteria for trauma care systems.

In 1988, the National Highway Traffic Safety Administration (NHTSA) established the Statewide Emergency Medical Services (EMS) Technical Assessment Program and the Development of the Trauma Systems Course, both important tools to assess the effectiveness of trauma system components as well as support for ongoing system development. NHTSA also developed standards for EMS quality assessment, including trauma care. These standards required that the trauma care system be fully integrated into the state's EMS system and be supported by appropriate enabling legislation (Table 4-1). In 1990, the Trauma Systems Planning and Development Act created the Division of Trauma and EMS within the Health Resources and Services Administration to improve EMS and trauma care. The program was not funded between 1995 and 2000, as many states were in the process of developing trauma systems. The two most important initiatives from this legislation were provision of competitive planning grants for statewide trauma system development and publication of the Model Trauma Care System Plan as a consensus document. The Model Trauma Care System Plan established an apolitical framework for measuring progress in trauma system development and set the standard for the promulgation of systems of trauma care. The program was again funded in fiscal year 2001 but lost funding in 2006. Presently, the 115th Congress is considering H.R. 880, The Military Injury Surgical Systems Integrated Operationally Nationwide to Achieve ZERO Preventable Deaths (MISSION ZERO) Act. It would establish a grant program for partnerships between the military and civilian trauma centers to allow qualified military personnel to provide trauma care in civilian trauma centers and provide $15 million annually for grants to eligible civilian trauma centers through fiscal year 2022.

TABLE 4-1: Criteria for Statewide Trauma Care System

Criteria	Description
Legal designation authority	State governmental authority to legally designate, certify, identify, or categorize trauma centers
Formal designation process	Formal process for hospital selection, designation, and periodic review
Designation based on American College of Surgeons (ACS) standards	Designation of a hospital's trauma center as Level I through IV based on ACS definitions
On-site verification of standards	On-site external review to verify compliance with trauma center standards
Limited number of trauma centers	Limited number of major trauma centers based on community need to concentrate expertise and scarce resources at key hospitals
Prehospital triage criteria	Prehospital protocols allowing emergency medical services (EMS) to bypass nondesignated hospitals for major trauma patients
Process to measure systems outcomes	Formal process to monitor system-wide performance, which includes a trauma registry and external committee that monitors patient outcomes
Full geographic coverage	Coordination of EMS and hospital resources to ensure access to trauma resources independent of proximity to trauma centers

Modern Challenges

The evolution of trauma systems reflects two very critical elements of modern health care. First is the obvious mandate to ensure that properly trained and experienced personnel with the right resources are immediately available for every injured patient. Linked to this is the reality that this extensive and intensive investment in personnel and resources demands accountability defined by better outcomes, more cost-effective and efficacious care, and good stewardship of expensive resources. Injury care is expensive, and the impact of ongoing chronic care costs and lost human productivity is enormous. The true impact of this global health problem is not completely measurable, especially when diminished quality of life for survivors and their families is considered.

The current transformation of the health care system in the United States is focused on increased patient coverage, improved quality of care, and lower cost. This is often defined in terms of the triple aims of better care, lower cost, and improved population health.[19] From the perspective of trauma systems, these goals demand careful and ongoing review of the overall performance and effectiveness of every component of the system. The critical factor that guides planning of a trauma system is the balance of injury risk versus total cost of disease control provided to the specific population served. While the ideal concept might be a designated trauma center within 5 minutes of ground transport for every citizen, the cost of maintaining such a network and the dilution of skills in management of severe, multiorgan injury that would occur with this model would increase societal cost with no expectation of improved clinical outcomes. Some evidence suggests that too many Level I trauma centers in a region actually *increased* the risk of death in some patients.[20] Moreover, the likelihood of inexperience driving unnecessary or avoidable cost is significant. The converse is also problematic. Too few trauma centers can lead to an increase in preventable mortality, especially if access requires long-distance transport. Careful planning of trauma systems must consider surrounding community resources, traffic patterns, modes of transport, and trauma density to avoid transport delays and achieve the best outcomes for patients.[21]

From a population-based perspective, trauma system performance must be measured in terms of efficacy in maintaining wellness (injury prevention) and efficiency in treatment of injury victims (outcome). The population of injured patients is skewed toward a majority with non–life-threatening injury for whom timely, appropriate care should produce optimal recovery and avoidance of unnecessary expense. To this is added a complex core of severely injured who demand multidisciplinary care from qualified providers whose experience can contribute to optimal outcome in a cost-effective manner. Thus, in the emerging, modern health care environment, an accountable trauma system must balance the competing mandates of immediate access to the care of qualified, experienced personnel in designated facilities against unnecessary cost to the entire population generated by inappropriate replication of these expensive resources.[22,23] In a statement released in February 2015, the American College of Surgeons (ACS) emphasized the importance of controlling allocation of trauma centers. An expert panel was convened by ACS in August 2015 to develop a statistical basis for determination of trauma center need and location. The resulting "Needs Based Assessment of Trauma Systems" attempts to apply objective metrics of patient volume, capability, and support to determine appropriateness of trauma centers.[24] The group's report begins by emphasizing that designation of trauma centers based on regional population need has been recognized as an essential component of trauma system design since the 1980s.[25] To date, few trauma systems have operationalized these concepts, especially when faced with real or potential challenges that stem from powerful health care institutions or providers.

Essential Components of Trauma System Development

The critical milestones necessary to support statewide EMS and trauma system development as initially defined by West et al[1] are listed in Table 4-1. Attainment of these criteria is a stepwise progression that begins with documentation of need.[1,5] Historically, this has been accomplished by reviewing regional trauma case experience with special focus on preventable deaths.[25,26] This is often the critical driver that establishes legal authority for system development. This authority usually proceeds from legislation at a state or local level that authorizes an appropriate agency to define criteria for participation, establish a trauma registry for system quality assurance, and implement processes for verification and designation. The authorizing legislation must also include adequate appropriation of resources for ongoing system management, including periodic needs assessment, assurance of fiscal solvency, and continuous focus on clinical outcomes. The surgeon's leadership and commitment to optimal care in articulating need and in guidance of system planning are critical. Designation requires continuous reporting of objective metrics of accountability from all participating entities. After verification of decreasing injury incidence, improved patient care, and improving outcomes, one of the most critical components to be assessed in the deployment of a trauma system is cost (Table 4-2). The major goal of an inclusive trauma system is complete control of all aspects of injury from effective prevention to successful societal reintegration of injury victims; however, reality dictates that each component of this system have an adequate financial base to support its mission. The ideal is that all injured patients reach definitive care in a time frame and at a level that are appropriate to meet their injury needs. Unfortunately, the cost of the ideal must be balanced against what is financially sustainable. The determination of need for a trauma center must first reflect its contribution to the overall capability of the trauma system to meet the population's demand. Part of this assessment must include overall taxpayer cost. As previously stated, too few trauma centers do not adequately serve the population, resulting in a more profound effect of injury on human productivity and longitudinal cost of care. Too many trauma centers produce unnecessary overhead to population health care costs, avoidable duplication of services, and potential dilution of provider skills in management of complex cases.[27] Trauma system funding parallels the challenges of providing coverage for individual patients. An unregulated "free-market" approach that enables hospitals to establish trauma programs places the burden of financial viability on the hospital. Fiscal solvency would be sensitive to payer mix, resulting in financial stress to those facilities that serve unfunded patients. Subsidizing these hospitals with public funds to cover gaps in reimbursement adds an additional financial burden to all taxpayers, since a portion of all tax dollars already pays for the medical coverage of the uninsured. Because hospitals try to cover reimbursement deficits by raising prices, the overall cost of care for all citizens increases. This cost shift creates a triple taxpayer burden of higher health insurance premiums, additional taxation to support care of those without adequate health insurance, and reallocation of existing tax revenue to provide special subsidies to many of the institutions that are the default providers of care to these underfunded patients. The provision of comprehensive trauma care is a noble cause but must be supported by a financial margin that does not undermine the fiscal solvency of the entire American health care system.

TRAUMA SYSTEM COMPONENTS

Despite the demonstrated efficacy of trauma systems, recent data show that only 60% of the United States has statewide trauma systems, and about 20% has no trauma system at all.[25,28-31] The functional elements of a trauma system are disease surveillance, system access, prehospital care, hospital inpatient management, rehabilitation, prevention, disaster medical planning, patient education, research, and accountable financial planning. Prehospital communications, a transport system, trained personnel, and qualified trauma specialists for all phases of care are essential for a system's success (Fig. 4-1).

Quality assessment and performance improvement is a vital component of the system because it guides identification of best practice and constantly evaluates the system's performance and needs.[32-35]

Based on the concept of the "inclusive system" (Fig. 4-2), trauma *centers* are identified by their ability to provide definitive care to the most critically injured, and the trauma *system* is assessed by its ability to manage all injuries.[36-38] Only about 15% of all injured patients will benefit from the resources of a Level I or II trauma center. Therefore, an inclusive system must encourage participation and enhance capabilities of the smaller hospitals. Surgical leadership is essential to development of trauma systems. In fact, trauma systems cannot develop without the commitment of the surgeons of a hospital or community. The model inclusive system is defined within a geographic area, and all health care resources are included in its planning. A centralized Level I trauma center concentrates highest risk injuries, whereas more distant, lower level centers care for less severely injured according to their capabilities and can serve as an access point for patients needing immediate care. EMS knits the system together.

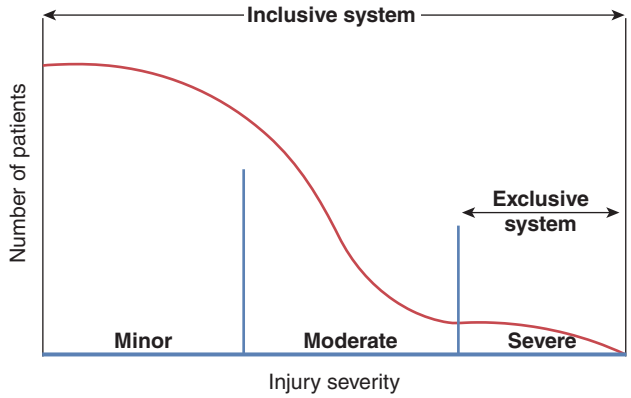

FIGURE 4-2 Diagram showing the growth of the trauma care system to become inclusive. Note that the number of injured patients is inversely proportional to the severity of their injuries.

Public Information, Education, and Injury Prevention

Death following injury occurs in a trimodal distribution defined in minutes, hours, and days. Effective trauma programs must also focus on injury prevention, since more than half of the deaths occur within minutes of injury and will never be addressed by acute care. Because trauma is not considered an important public health problem by the general population, efforts to increase awareness of the public as well as to instruct the public about how the system operates and how to access the system are important and mandatory. A Harris Poll conducted by the American Trauma Society showed that most citizens value existence of a trauma system with the same importance as fire and police services. Continuous epidemiologic surveillance to define interventions that will likely reduce both injury occurrence and severity requires trauma systems to focus on injury prevention. Identification of risk factors and high-risk groups, development of strategies to alter personal behavior through education or legislation, and other preventive measures have the greatest impact on trauma in the community and, over time, will have the greatest effect on all trauma victims.[19,22,24] If prevention is the only effective vaccine against injury, effective public education is the most critical ingredient of the vaccine.

HUMAN RESOURCES

Because the system cannot function optimally without qualified personnel, a high-quality system ensures comprehensive and continuing education to its providers. This includes all personnel along the trauma care continuum: physicians, nurses, EMTs, therapists, psychologists, and others who impact the patient and/or the patient's family. In all trauma centers, there must be a defined trauma resuscitation team consisting of predesignated personnel with specific assignments. The team's main purpose is rapid patient assessment, provision of immediately lifesaving interventions, initiation of comprehensive resuscitation, expeditious diagnostic workup, and provision of definitive care. Critical to the resuscitation team's function is linkage to EMS and timely prehospital notification. For major trauma patients identified in the field, the resuscitation team must be preassembled and

immediately available upon patient arrival. The constituents, role, and capabilities of the resuscitation team depend on the level of trauma centers.

PREHOSPITAL

Trauma care prior to hospital arrival has a direct effect on survival. The system must ensure prompt access and dispatch of qualified personnel, appropriate care at the scene, and safe and rapid transport of the patient to the closest, most appropriate facility. The primary focus is on education of paramedical personnel to provide initial resuscitation, triage, and treatment of trauma patients. Effective prehospital care requires coordination between various public safety agencies and hospitals to maximize efficiency, minimize duplication of services, and provide care at a reasonable cost. There are many comprehensive and standardized courses covering virtually every aspect of prehospital care. Most are the products of national and international organizations dedicated to emergency medical care and should be considered as the preferred alternative to "home-grown" courses or periodic symposia that provide inconsistent educational impact. Also of note is the fact that many injured patients are brought to hospitals via private vehicles. All hospitals should have a system to assess these patients and accurately triage them as appropriate.

COMMUNICATIONS SYSTEM

A reliable communications system is essential for providing optimal trauma care. Although many urban centers have used modern electronic technology to establish emergency systems, most rural communities have not. A communications system must include universal access to emergency telephone numbers (eg, 911), trained dispatch personnel who can efficiently match EMS expertise with the patient's needs, and the capability of EMS personnel at the trauma incident to communicate with prehospital dispatch, the trauma hospital, and other units. Post hoc review of many of the most recent mass casualty shootings has determined that multiple organizations responding from adjacent areas are often controlled by communication centers that cannot communicate with each other. Access also requires that all citizens know how to access and actually use the system. This can be achieved through public safety information and school educational programs designed to inform health care providers and the public about emergency medical access.

MEDICAL DIRECTION

Medical direction provides the operational matrix for care provided in the field. It grants freedom of action and limitations to EMTs who must rescue injured patients. The medical director is responsible for the design and implementation of field treatment guidelines, their timely revision, and their quality control. Medical direction can be "off-line" in the form of protocols for training, triage, treatment, transport, and technical skill operations or "online," given directly to the field provider. Simulation is an important part of ensuring appropriate training for prehospital personnel.

DEFINITIVE CARE FACILITIES

Acute care hospitals are the foundation of the regional trauma system. An inclusive trauma system integrates acute care facilities of all levels to provide the full spectrum of injury care within its region. Central to trauma system planning is the designation of definitive trauma care facilities to meet community need. The number and levels of trauma centers should reflect population distribution and the burden of injury within the region. In principle, the designating authority is responsible for determining the number and level of trauma centers needed to provide optimal care in its region. In practice, trauma centers and acute care hospitals should coexist within a region and cooperate to ensure appropriate distribution of patients based on resource needs. Every institution should contribute data to trauma system registries and participate in system performance improvement programs. Level I trauma centers should serve as the lead agency within a region to ensure that all EMS agencies, acute care hospitals, and trauma centers provide coordinated care within the region.

Trauma Center Facilities and Leadership

Hospital care of the injured patient requires commitment from specific facilities to provide administrative support, medical staff, nursing staff, and other support personnel. The network of institutions that is the core of a trauma system usually includes a variety of facilities whose capabilities reflect the local health care needs of their community. Efficient management of the system is predicated on effective communication and interaction among these participants. Part of this process is determination of level of function expected from each designated center. For most parts of the country, this is accomplished by designation of specific levels of capability based on hospital mission. Level I and Level II centers are committed to comprehensive management of all injured patients, whereas Level III and IV centers usually represent smaller community hospitals committed to optimal care of any injured patient with potential triage to a higher facility of severely injured patients with complex injury. As enhanced commitment to rural health care has evolved, many rural and critical access hospitals have become incorporated into regional trauma systems as Level IV centers. ACSCOT maintains a continuously updated compendium of qualifications and performance criteria for every component of a trauma system. In all trauma centers, there must be a defined trauma resuscitation team consisting of predesignated personnel with specific assignments. The team's main purpose is rapid patient assessment, provision of immediately lifesaving interventions, initiation of comprehensive resuscitation, expeditious diagnostic workup, and provision of definitive care. Critical to the resuscitation team's function is linkage to EMS and timely prehospital notification. For major trauma patients identified

in the field, the resuscitation team must be preassembled and immediately available upon patient arrival. The constituents, role, and capabilities of the resuscitation team depend on the level of trauma centers.

The key concepts below underscore these requirements. Regardless of level of capability, the common factors across all levels of designation include the following:

- Consistent provision of the necessary personnel and resources to deliver acute care to the injured patient
- Surgical leadership in every aspect of clinical care, including resuscitation, critical care, and definitive multisystem injury management
- A trauma medical director, trauma program manager, trauma registry managed by trained registrars, performance improvement specialist(s), and data analyst(s)
- Seamless integration within the trauma system, especially as related to EMS prehospital communication, interfacility transfer, data sharing, and system performance improvement

LEVEL I CENTER

From the perspective of clinical care to injured patients, Level I and Level II trauma centers are identical. Level I trauma centers are distinguished from Level II centers by the following characteristics:

- Admission volume requirements
- Presence of a surgically directed critical care service
- Educational leadership with graduate medical education programs in multiple specialties
- A productive program in trauma-related research

The Level I trauma center is a regional resource and tertiary care facility capable of providing immediate definitive and comprehensive care to all injured patients regardless of severity or complexity. It should function as the cornerstone of the regional trauma system. The Level I trauma center has a major responsibility for providing leadership in system planning, research, education, and training of trauma care providers. Level I trauma centers are generally located in large, population-dense areas and are typically affiliated with university teaching hospitals. They function as a regional resource center and generally serve large cities or population-dense areas, which is necessary to provide enough experience to develop clinical expertise, train new providers, and fulfill essential research and education missions. A Level I trauma center is often the lead hospital for a regional health care system. In larger urban areas, more than one Level I trauma center may be needed to ensure availability of appropriate resources and appropriate transports to the highest level of care.

LEVEL II CENTER

The Level II trauma center provides definitive care to the injured patient and functions in two distinct roles recognized by ACSCOT.

- A Level II center in a population-dense area may supplement the clinical activity and expertise of the regional Level I center, thereby augmenting capacity.
- In less populated areas distant from the regional Level I center, the Level II center may serve as the lead hospital for its region and provide support to local minor trauma centers in the same service area.

All Level II centers include the specialty services needed to provide definitive care to the severely injured, although clinical capabilities may not be as comprehensive as at Level I centers. Despite clinical capabilities similar to Level I, Level II centers may treat a lower volume of severely injured patients. Although graduate education and research are not required functions of Level II trauma centers, they are required to provide effective access to continuing medical education for all involved professional providers. The trauma medical director must have authority for determining each team member's ability to participate on the trauma panel based on an annual review. Qualified attending surgeons must be present in the emergency department for major resuscitations, to make major therapeutic decisions, and to participate in operative procedures and must be actively involved in the critical care of all seriously injured patients.

LEVEL III CENTER

The Level III center is an entry point to the regional trauma system usually in communities that are remote from major trauma centers. The presence of general surgery capability differentiates the Level III from the Level IV center, with the expectation that a general surgeon will be present in the emergency department to lead resuscitation upon arrival of every major trauma patient. The Level III center provides definitive care to the moderately injured and initial stabilization for the major trauma patient, which may include operative hemorrhage control to ensure safe transfer to a major trauma center. As with the Level IV center, predefined plans for transfer of patients to the major trauma centers are essential.

LEVEL IV CENTER

Level IV trauma centers expand the trauma system to sparsely populated, geographically isolated, and often medically underserved rural communities. These hospitals are typically the only source of medical care for many miles and function as an initial point of evaluation and treatment of injured patients. In principle, the Level IV center serves as an initial access point to the regional trauma system. The Level IV trauma center must have 24-hour emergency coverage and provide initial evaluation and stabilization of injured patients, most of whom will be transferred for definitive treatment. A defining difference between Level IV centers and higher level trauma centers is the absence of continuous surgical and/or orthopedic coverage. Thus, the Level IV trauma center must have an organized trauma resuscitation team that follows standardized protocols and predefined transfer plans for patients needing a higher level of care.

SPECIALTY TRAUMA CENTERS

Regional specialty facilities concentrate expertise in a specific discipline and serve as a valuable resource for patients with critical specialty-oriented injuries. Examples include replantation, pediatric trauma, burns, spinal cord injuries, and hand trauma. Where present, these facilities provide a valuable resource to the community and should be included in the design of the system. Most importantly, the unique capabilities of each must be seamlessly woven into the process of care so that the required specialty care is available at the appropriate time in the continuum of management of the patient. A pediatric trauma center is expected to have the same resuscitative capabilities as any center receiving acutely injured patients from the field. The most recent edition of *Resources for Optimal Care of the Injured Patient* defines pediatric criteria from the perspective of free-standing children's hospitals as well as supplemental capabilities for designated adult trauma centers.[5] A replantation or burn center, on the other hand, is usually reliant on comprehensive initial evaluation of the patient by a referring center with which it must have established transfer guidelines and protocols.

Acute Care Facilities Within the Trauma System

Many general hospitals exist within a trauma care system but are not officially designated as trauma centers. Circumstances often exist in which less severely injured patients reach these hospitals and appropriate care is provided. The trauma system should develop and manage protocols for interfacility transfer of patients whenever a major trauma patient is inappropriately triaged to an undesignated facility. Moreover, the trauma system's registry must be able to identify and track these injured patients managed at nondesignated facilities so that their care can be reviewed as part of a mature performance improvement and patient safety program.

All acute care facilities play important roles in the regional trauma system. Most patients with minor injuries receive effective and definitive care in acute care hospitals in their home communities (Fig. 4-3). This helps minimize the burden on the patient and preserves major trauma center resources for the care of the more seriously injured. Major trauma centers, especially Level I centers, are typically large tertiary referral centers located in population-dense areas and serve as the primary hospital for their communities. As such, major trauma centers also tend to attract many mildly and moderately injured patients simply because of proximity to the population and large market share.[36] Effective trauma system planning must recognize this phenomenon to ensure the proper balance of trauma center numbers and levels within a region. Sufficient minor trauma resources should be available to care for the minorly and moderately injured, and sufficient major trauma center resources should be available to not only ensure access to definitive care for the severely injured, but also concentrate severe injury volume in a limited number of major trauma centers to optimize clinical competency through experience and maximize efficiency

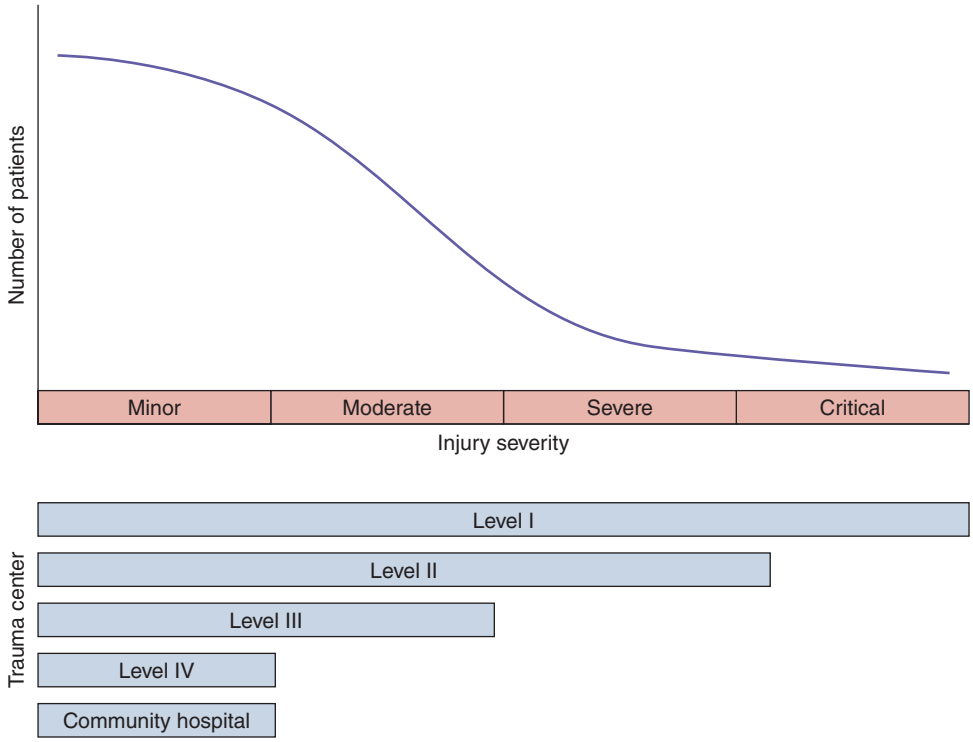

FIGURE 4-3 Distribution of trauma volume and severity within an inclusive trauma system. Proper allocation of resources should focus the bulk of the mission in the higher acuity centers and is predicated on effective communication and interfacility transfer.

through conservation of scarce, high-value human and material resources.

Rehabilitation

Effective control of injury involves a continuum of care that begins with failure of prevention and ends with complete societal reintegration of a recovered patient. In reality, injury can be an affliction that never really ends. The issues of long-term neurocognitive dysfunction and early onset of degenerative disorders are well defined in current literature. Less well understood are the impacts of chronic musculoskeletal disorders, intractable chronic pain, and numerous other impairments that undermine quality of daily living and social function. Rehabilitation is as important as prehospital and acute hospital care. Early and aggressive rehabilitation has been shown both to accelerate and enhance recovery, yet it is often least considered and incompletely available. Many insurance policies do not even cover rehabilitation, leading to a major additional burden for the patient whose coverage ends with hospital discharge. Although it is critically important to reintegrating the patient into society, only 1 of 10 trauma patients in the United States has access to an adequate rehabilitation program. Rehabilitation is often the longest and most difficult phase of care for both patient and family. It can be provided in a designated area within the trauma center or by agreement with a freestanding rehabilitation center, but it must be provided! Although it is not the purpose of this chapter to address all of the deficiencies of the health care system, it is important that trauma system planners understand this deficiency and establish processes that provide immediate involvement of rehabilitation experts as well as case managers to optimize timing and effect of patient rehabilitation. From another perspective, such service will limit excessive acute care hospitalization necessitated by lack of rehabilitation access. This latter phenomenon is detrimental to optimal recovery, adds additional financial burden to the trauma center, and denies acute care beds to other injury victims.

Psychological Services

In addition to the enormous physical burden of injury, the emotional toll can be even more debilitating. Many injured patients have preexisting mental illness, and the burden of injury adds to this toll. Inclusion of psychological services to a trauma program can help injured patients and their families manage these postinjury mental health issues in an attempt to achieve the maximum recovery and reintegration. Depression and posttraumatic stress disorder (PTSD) are prevalent problems for injured patients, especially in the year following their injury.[39] To enhance recognition of this additional threat, a simple and quick screening method for identifying injured patients at risk of developing depression and PTSD has been developed.[40] The most recent edition of *Resources for Optimal Care of the Injured Patient* recommends that trauma centers should include an effective program to screen and manage these disorders as part of their complete rehabilitation program. Support groups may be a useful adjunct as well.

TRAUMA SYSTEM FUNCTION

Emergency Response and Trauma System Access

A critical function of the regional trauma system is to ensure that all injured patients within its geographic boundaries have access to definitive care to meet their injury needs. Access to the trauma system is dependent on the availability of prehospital transport services, the proximity and availability of definitive care resources, and the processes that direct the injured patient to definitive care. Ideally, the geographic distribution of trauma centers matches that of the population, and prehospital resources are organized to assure timely access to a trauma center regardless of distance. In 2005, it was estimated that 69.2% of US residents could access a major trauma center within 45 minutes and 84.1% could access one within 60 minutes of injury.[41] The remainder lived primarily in rural areas. States with the most urban populations had the highest proportions that could access a trauma center within an hour. More current data estimate that 63.1% of the US population can reach a major trauma center within an hour by ambulance, and the inclusion of helicopter services increased this proportion to 90.4%. The University of Pennsylvania, in consort with the American Trauma Society and with support of the US Department of Health and Human Services, manages a comprehensive website (https://www.amtrauma.org/page/FindTraumaCenter) that is periodically updated and provides a continuous overview of trauma system coverage in the United States.

Triage and Transport

Access to trauma care is not only dependent on the availability of EMS and hospital physical resources, but also the processes that govern the delivery of the patient to definitive care. Triage is the process by which injured patients are sorted to ensure that each has timely access to the appropriate level of care based on medical need and availability of resources. A critical function of the regional trauma system is to triage major trauma patients to major trauma centers. This often requires bypass of a closer hospital in favor of a major trauma center for major trauma patients. Triage should be selective so that medical resources are allocated to the patients who will realize the most benefit. Triage is a dynamic process that occurs continually at every phase of patient contact. Initial triage decisions are often revised as more information becomes available. Triage priorities may also be modified based on the balance between demand and availability of medical resources, as in mass casualty scenarios.

DEFINING THE MAJOR TRAUMA PATIENT

There is no standard that defines the major trauma patient. In the prehospital setting, clinical assessment and provider experience determine which patients should be transported directly to the trauma center. This assessment process evaluates physiologic metrics, mechanism of injury, and specific

patient factors. Additional factors may include injury pattern, need for specialized resources, or standardized local criteria. Part of the process of trauma system performance improvement includes periodic retrospective analysis of triage accuracy based on mortality prediction thresholds derived from discharge diagnoses and other data sources. The major trauma patient is defined differently along the continuum of care, which can make generalizations beyond a specific context problematic. What is apparent acutely in the field and what has been determined at discharge by addition of additional factors can be very different.

PREHOSPITAL IDENTIFICATION OF THE MAJOR TRAUMA PATIENT USING LIMITED INFORMATION

The challenge of trauma triage is to anticipate definitive care needs using limited information available at the time when triage decisions must be made. Of all trauma patients, only 7% to 15% have injuries that benefit from care at a major trauma center. Although clinical recognition of the major trauma patient is usually straightforward, serious, even life-threatening, injuries are sometimes occult and not discovered until after a comprehensive workup. Because mistriage is an inherent threat, triage must be viewed as a continuous, flexible, and error-tolerant process with contingencies for mistriage.

DEFINITIONS

Primary (Field) Triage. Primary or field triage directs transport from the scene to the highest level of care within a reasonable transport distance for major trauma patients. This usually enables rapid transport directly to major trauma centers in urban and suburban environments. Because the extent of injury is not always evident in the field, prehospital triage guidelines are established to identify patients at risk for severe injury and aid prehospital decision making. These tools are designed to be simple and applied broadly; the main purpose is to determine if the patient's estimated risk warrants transport to the nearest major trauma center rather than the nearest hospital. Risk of severe injury is estimated using information based on physical examination, mechanism characteristics, preinjury patient characteristics that are easily obtained by EMS on initial patient contact, or EMS provider judgment. Criteria for field triage are ordered with physiologic derangements indicating highest risk followed by anatomic findings, energy transfer mechanisms, preinjury patient comorbidities, and EMS provider judgment, in decreasing order.

BRIEF REVIEW OF METHODS PROPOSED FOR FIELD TRIAGE SCORING

To be useful in the field, a triage protocol must meet certain criteria.[42] The components of the scoring scheme must be credible and have some correlation with the injuries being encountered. The triage scoring method must correlate with outcome, although its primary purpose is identification of immediate patient risk. A better correlation with outcome results in a lower mistriage rate within a trauma care system. Outcomes for major trauma patients are usually classified as death, need for urgent/emergent surgical intervention, length of intensive care unit (ICU) and/or hospital stay, and major single-system or multisystem organ injuries.

The scoring scheme must also have interobserver and intraobserver reliability; that is, it should be able to be consistently applied between observers and by the same observer at another point in time with the same results, recognizing that estimation of patient risk may change as more information is obtained. Finally, the scoring scheme must be practical and easily applied to trauma victims for a variety of mechanisms by a variety of personnel without the need of specialized training or equipment.

Although most of the field triage criteria are based on physiologic criteria, there are other methods for assessing the risk potential of an injured patient. As shown earlier in the chapter, mechanism of injury, anatomic region and type of injury, preexisting illnesses, and paramedic judgment are important considerations in providing additional information in the field to help determine whether a patient requires transport to a designated trauma center. Combination field triage methods make use of this additional information by including it in the initial evaluation of the injured patient. As trauma systems have evolved, the determination of which variables are most effective in attaining the accuracy required for optimal system function has resulted in numerous proposed methods. Table 4-3 lists a brief history of some of these approaches. All were designed to assist rescue personnel in determining which patient required transport to a trauma center.[43-49] The Pediatric Trauma Score (PTS) is the only approach developed specifically for assessment of children.[50] As the work detailed in Table 4-3 developed, ACSCOT, in collaboration with the CDC, compiled all of this experience into a single process and developed the ACS Field Triage System. This is a more complete, advanced triage scoring scheme that is described in the *Resources for Optimal Care of the Injured Patient* and reflects years of productive collaboration with the CDC.

CURRENT TRIAGE RECOMMENDATIONS

The first ACSCOT field triage guidelines, "Field Triage Decision Scheme," was published in 1986 and updated in 1990, 1993, and 1999. In 2005, the CDC, with financial support from the NHTSA, collaborated with ACSCOT to convene a National Expert Panel on Field Triage to revise the decision scheme, which was published in 2006 by ACSCOT as part of *Resources for Optimal Care of the Injured Patient: 2006.* In 2009, the CDC published a detailed description of the scientific rationale for revising the field triage criteria R2t. The CDC reconvened the panel in 2011 to review the 2006 guidelines in the context of recently published literature, assess the experiences of states and local communities working to implement the guidelines, and recommend any modifications to these guidelines.[51]

As has been the case from the beginning, the intent of these triage guidelines is to assist prehospital care providers in identifying individual injured patients who would benefit from specialized trauma center resources. The process is

TABLE 4-3: Review of Proposed Triage Protocols

Method	History	Components	Status	Reference
Trauma index	First reported in 1971 by Kirkpatrick and Youmans	Blood pressure, respiratory status, central nervous system (CNS) status, anatomic region, and type of injury	Some correlation with injury severity Never saw widespread use	52, 89, 90
Glasgow Coma Scale (GCS)	Teasdale and Jennett first introduced	Eye opening, motor response, verbal response	Intended as a description of the functional status of the CNS, not as a prehospital assessment tool; motor component of the GCS is almost as good as the Trauma Score and better than the Injury Severity Score in predicting mortality	91, 92
Triage index, Trauma Score, Revised Trauma Score (RTS)	Described in 1981 as index SBP, respiratory effort added 1982	Respiratory rate,[a] respiratory effort, SBP,[a] capillary refill, GCS[a]	Central idea was that the leading causes of traumatic death were related to dysfunction of the cardiovascular, respiratory, and CNS systems Revised in 1989 because of concerns about accurate assessment of capillary refill and respiratory effort	93-98
CRAMS Scale	Proposed as a simplified method of field triage	Circulation, respirations, abdomen, motor, speech	Retrospective and prospective studies indicate that CRAMS triage is accurate in identifying major trauma victims with high specificity and sensitivity Easy to use	99
Prehospital Index (PHI)	Introduced in 1986 as field triage tool	Blood pressure, pulse, respiratory status, level of consciousness	PHI is accurate in predicting the need for lifesaving surgery within 4 hours and death within 72 hours following injury	100
Trauma Triage Rule	Proposed by Baxt et al, 1990	Blood pressure, GCS motor response, anatomic region, type of injury	Major trauma victim identification sensitivity and specificity of 92% Reduced overtriage while maintaining an acceptable undertriage rate Not widely adopted	101
Pediatric Trauma Score (PTS)	Introduced in 1985, designed to follow ATLS initial assessment scheme	Patient size, level of consciousness, airway patency, SBP, long bone fracture, open wound	Still in use throughout world, frequently as risk adjuster in outcomes research	102

[a]Components of final revision (RTS).

ATLS, Advanced Trauma Life Support; SBP, systolic blood pressure.

designed to guide assessment of an individual patient and is not intended as a triage tool to be used in a situation involving mass casualties or disaster. Based on the extensive history of critical thinking, evaluation, review, and revision detailed earlier, the current recommended process of assessment proceeds in four phases as listed in Fig. 4-4. The process begins with physiologic assessment for the obvious reasons; however, it is essential to remain aware of the common presentation of "found down," which may reflect an evolving medical emergency rather than the effect of acute injury.

Step 1: Physiologic Criteria. The first step is rapid identification of critically injured patients by assessing level of consciousness (Glasgow Coma Scale [GCS]) and measuring vital signs (systolic blood pressure [SBP] and respiratory rate). Vital sign criteria have been used since the 1987 version of the ACS Field Triage Decision Protocol. These criteria demonstrate high predictive value for severe injury. Of 289 references identified from the CDC panel's structured literature review, 82 (28%) were relevant to step 1. SBP less than 90 mm Hg and respiratory rate less than 10 or greater than 29 remain significant predictors of severe injury and the need for a high level of trauma care. Multiple peer-reviewed articles published since 2006 support this threshold.

Recommended criteria for transport to the highest level of care are:

- GCS less than or equal to 13
- SBP of less than 90 mm Hg
- Respiratory rate of less than 10 or greater than 29 breaths per minute (<20 in infants age <1 year) or need for ventilatory support

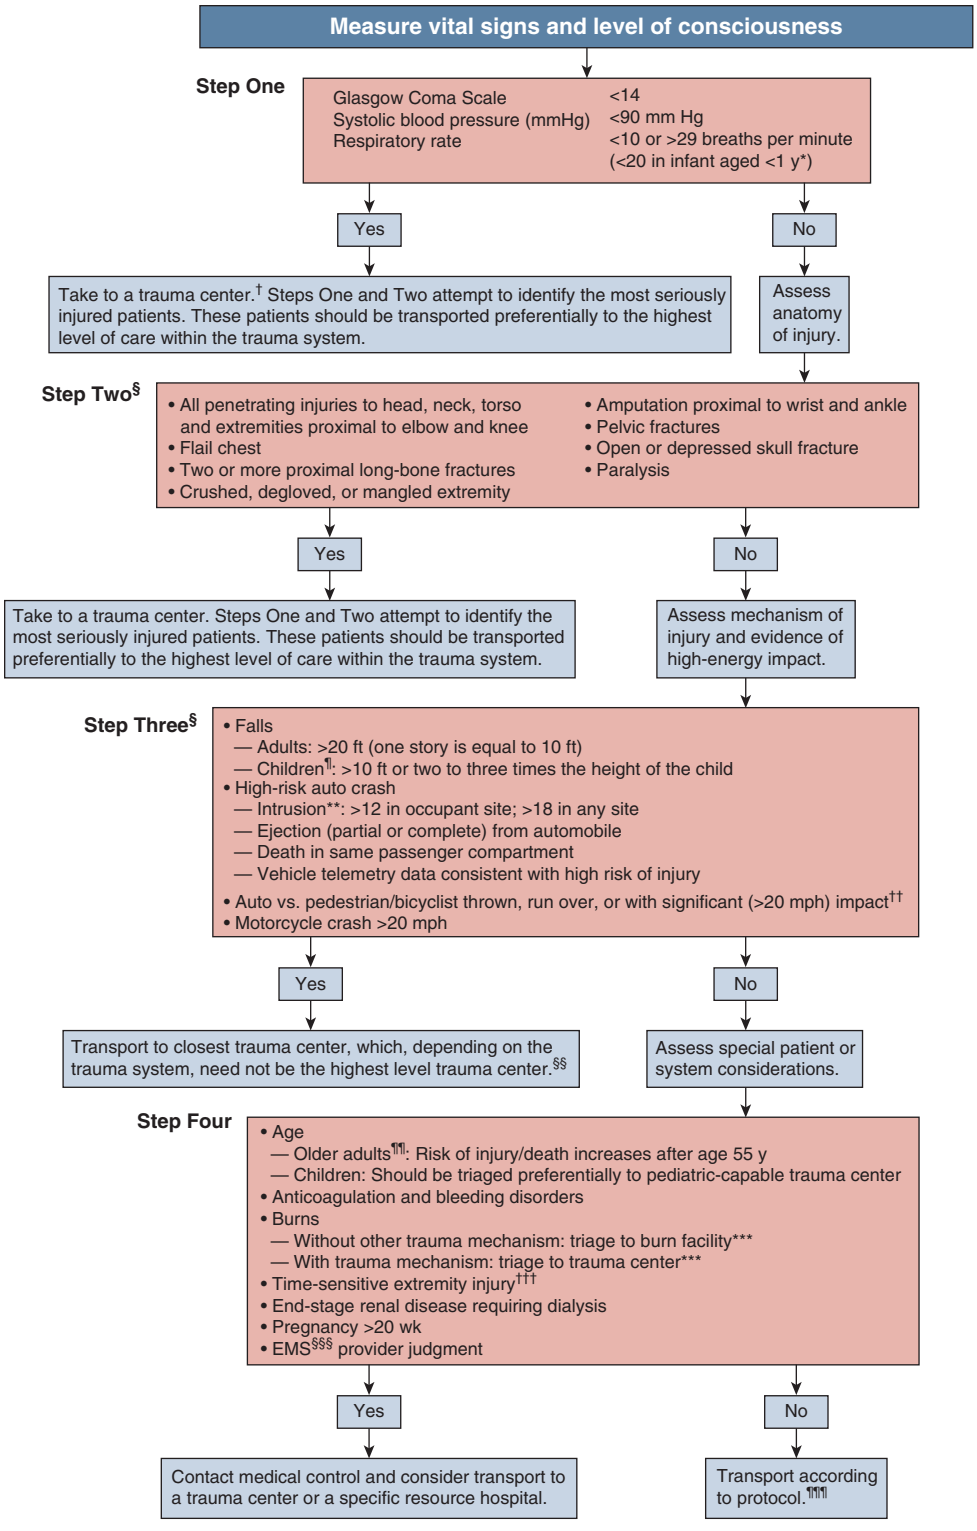

FIGURE 4-4 Centers for Disease Control and Prevention triage protocol. (Reproduced from Centers for Disease Control and Prevention. Guidelines for field triage of injured patients: recommendations of the National Expert Panel on Field Triage, 2011. *MMWR Recomm Rep*. 2012;61(RR-1):1-20. Adapted with permission from American College of Surgeons Committee on Trauma. *Resources for Optimal Care of the Injured Patient*. Chicago, IL: American College of Surgeons; 2006.)

*The upper limit of respiratory rate in infants is >29 breaths per minute to maintain a higher level of overtriage for infants.

†Trauma centers are designated Level I to IV, with Level I representing the highest level of trauma care available.

§Any injury noted in steps 2 and 3 triggers a "yes" response.

¶Age <15 years.

**Intrusion refers to interior compartment intrusion, as opposed to deformation, which refers to exterior damage.

††Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact >20 mph with a motor vehicle.

§§Local or regional protocols should be used to determine the most appropriate level of trauma center; appropriate center need not be Level I.

¶¶Age >55 years.

***Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.

†††Injuries such as an open fracture or fracture with neurovascular compromise.

§§§Emergency medical services.

¶¶¶Patients who do not meet any of the triage criteria in steps 1 through 4 should be transported to the most appropriate medical facility as outlined in local EMS protocols.

Step 2: Anatomic Criteria. The second step considers that certain patients may initially manifest normal physiology but have an anatomic injury at risk of rapid deterioration and therefore may require the highest level of care. Of the 289 references reviewed by the panel, 57 (20%) were relevant to step 2.

Current recommendations for transport to a facility that provides the highest level of care include:

- All penetrating injuries to head, neck, torso, and extremities proximal to elbow or knee
- Chest wall instability or deformity (eg, flail chest)
- Two or more proximal long-bone fractures
- Crushed, degloved, mangled, or pulseless extremity
- Amputation proximal to wrist or ankle
- Pelvic fractures
- Open or depressed skull fractures
- Paralysis

Step 3: Mechanism of Injury. Step 3 addresses mechanism of injury (MOI) from the perspective of assessment of magnitude and vectors of force. An injured patient who does not meet step 1 or step 2 criteria should be evaluated in terms of MOI to determine the potential for severe but occult injury. Evaluation of MOI will help to determine if the patient should be transported to a trauma center.

Step 4: Special Considerations. In the fourth step, EMS personnel must determine whether persons who have not met physiologic, anatomic, or mechanism steps have underlying conditions or comorbid factors that place them at higher risk of injury or that aid in identifying the seriously injured patient. Persons who meet step 4 criteria might require trauma center care. A retrospective study of approximately 1 million trauma patients indicated that using physiologic (step 1) and anatomic (step 2) criteria alone for triage of patients resulted in a high degree of undertriage, implying that using special considerations for determining trauma center need helped reduce the problem of undertriage.[52] Among 89,441 injured patients evaluated by EMS providers at 6 sites, physiologic, anatomic, and MOI criteria identified 4049 (70.8%) patients with an Injury Severity Score greater than 15; step 4 of the guidelines identified another 956 seriously injured patients (16.7%), with an increase in overtriage from 25.3% to 37.3%.[53]

"INTERNAL" TRIAGE AND THE TRAUMA RESUSCITATION TEAM

The hospital response to prehospital notification is tiered according to the initially estimated need.[54] Highest risk patients require full trauma resuscitation team activation with all members present on or within 15 minutes of arrival. Lower risk patients may need a more limited resuscitation team activation, whereas other patients who are physiologically stable may be transported to trauma center and evaluated by an emergency medicine physician, with the resuscitation team or other surgical subspecialty services consulted as needed. The overarching factor governing this process is estimated injury need at the time of evaluation. However, it must be recognized that unnecessary mobilization of expensive resources robs them from other critical missions and is often wasteful.[53] Thus, the process of internal triage is predicated on how well a trauma center can balance its extensive and expensive resources against estimated patient need and logistical reality. The process may vary among centers and reflect unique capabilities or services available at different institutions. The most recent edition of the *Resources for Optimal Care of the Injured Patient: 2014* includes ACSCOT recommendations regarding major resuscitation criteria. Regardless of how the internal triage process is developed, it must be data driven, be continuously assessed in the program's Performance Improvement and Patient Safety program, and support the overall effectiveness of the trauma system.

SECONDARY (INTERFACILITY) TRIAGE

Secondary, or interfacility, triage directs transfer of patients whose needs exceed the capabilities of the initial receiving facility to a higher level for definitive care. This commonly occurs when patients who do not meet primary triage criteria are transported to a minor trauma center or community hospital and are subsequently found to have injuries that are beyond the capabilities of that facility.[55,56] In remote or rural environments, secondary triage serves to connect minor trauma centers to the major trauma centers after providing initial evaluation and stabilization of the major trauma patient. Like the field triage guidelines, interfacility (secondary) transfer guidelines are designed to identify patients at high risk of morbidity or mortality who might benefit from early transfer to a trauma center. Occasionally, patients who meet neither field triage nor secondary transfer guidelines are found to have injuries that exceed the capabilities of the initial treating facility. The Emergency Medical Treatment and Labor Act (EMTALA) intends that such patients have access to a higher level of care and ensures transport to the nearest trauma center with capacity and capability of managing their injuries.

MEASURING TRIAGE ACCURACY

The regional trauma system's ability to deliver the right patient to the right place at the right time and make the best use of available resources is expressed as triage accuracy.[57] Mistriage (overtriage and undertriage) occurs when a patient's triage decisions are not commensurate with the patient's clinical needs. Triage accuracy is dependent on compliance with established triage tools and the ability of those tools to predict the outcome of interest. The most recent edition of the *Resources for Optimal Care of the Injured Patient: 2014* recommends an overtriage rate of 30% to 40%, whereas the undertriage rate should be less than 5%. Despite these recommendations, there is still much work to be done in this area because several authors have demonstrated undertriage rates much higher than 5% and low sensitivity and specificity of existing triage protocols.[58,59] Because triage is a continuous, dynamic process, opportunities for mistriage can occur during any phase

of injury care. Field triage destination decisions are made using the best information available at the time. In-hospital triage and trauma resuscitation team activation decisions are made using the information provided from the field. Secondary triage and interfacility transfer decisions are made with more complete information but are influenced by the availability of resources at the referring facility. At any point, early decisions may appear to have been incorrect once more information is obtained. Consequently, retrospective evaluation of early decisions, using more information than was available at the time, introduces inherent methodologic mistriage. This error is worsened when real-time identification of a major trauma patient using field triage tools is evaluated using a different retrospective definition of a major trauma patient based on another system such as Injury Severity Score or a mortality prediction model. Thus, what looks like mistriage may, in part, be the combined effects of the retrospective evaluation of real-time decisions using disparate definitions.

Overtriage is a triage decision that incorrectly classifies a patient as needing a trauma center but retrospective analysis suggests that such care was not needed, and undertriage is a triage decision that classifies a patient as not needing trauma center when, in fact, the patient does need a trauma center. Although intuitive, operationalizing these definitions into objective quality metrics is problematic. There is no retrospective standard that defines which patients need trauma centers and which do not. The term *severe injury* is commonly used to refer to patients who need trauma centers and is often applied based on meeting an Injury Severity Score or mortality prediction threshold or consuming specific hospital resources such as operative or ICU care. This assumes that all patients and only patients who meet these definitions require trauma center care. In reality, there are many patients who do not meet such definitions but need major trauma center care, typically because definitive care resources may not be available in the community. Likewise, there are many patients who meet these definitions who may receive high-quality injury care at minor trauma centers or community hospitals.

Equivocation of terms when expressing over- or undertriage as rates also complicates trauma systems research. For example, the field undertriage rate could be expressed as the number of major trauma patients who should have received, but did not receive, the highest level of trauma team activation relative to the total number of major trauma patients. It could also be expressed relative to the total number of all injured patients. Each conveys important but different information; the former reflects the proportion of major trauma patients who were undertriaged, and the latter the proportion of all patients who were undertriaged. The same issues occur with equivocation of overtriage terms. The need to differentiate field triage, which reflects primary destination decisions, and system triage, which reflects the final patient distribution within the system, further complicates terms because over- and undertriage occur at both the field and system levels.

An approach to minimize equivocation of terms is to apply standard contingency table terminology to both field and system triage (Table 4-4). Given that triage accuracy is the number of patients appropriately triaged relative to the total number of patients, then inaccuracy or mistriage is the number of inappropriately triaged patients relative to the total. Because mistriage is a reflection of both over- and undertriage, then: 1 = accuracy + overtriage + undertriage. Here, accuracy, overtriage, and undertriage have precise meanings at both the field and system levels. Sensitivity, specificity, and positive and negative predictive values convey meaningful information at the field level since field triage is expected to predict high-risk patients. At the system level, it is descriptive but less predictive because the final distribution of patients depends not only on field triage risk assessment, but also the proximity of the patient population to the major trauma center, which also serves as the community hospital for a large portion of an urban population. Utilization refers to the proportions of low- and high-risk patients discharged from major trauma centers and other hospitals.

The study of triage accuracy is conceptually, linguistically, and technically complex. Field triage, secondary transfer, EMTALA regulations, and the role of major trauma centers as large community hospitals all influence access to resources in the regional trauma system. Application of system regulations and the hospital capabilities determine the final distribution of injured patients. Inherent methodologic errors introduced by retrospective evaluation of treatment decisions, equivocation of terms, and generalizations between phases of triage must be taken into account when making conclusions on overall triage performance and setting system triage benchmarks.

TABLE 4-4: Definition of Terms for Field and System Triage

Field/System		Risk: Low	Risk: High	Total
	–	A	B	A + B
	+	C	D	C + D
	Total	A + C	B + D	A + B + C + D
Sensitivity				D/B + D
Specificity				A/A + C
Positive predictive value				D/C + D
Negative predictive value				A/A + B
Accuracy				(A + D)/(A + B + C + D)
Mistriage				(B + C)/(A + B + C + D)
Overtriage				C/(A + B + C + D)
Undertriage				B/(A + B + C + D)
Over/under				C/B
LR utilization				C/(A + C)
HR utilization				D/(B + D)

HR utilization, major trauma center utilization by high-risk patients; over/under, overtriage to undertriage ratio; LR utilization, major trauma center utilization by low-risk patients.

DISASTER MANAGEMENT

Terrorism is the emerging weapon of modern civil strife. Terrorism events now occur almost weekly in various countries around the world and are usually designed to inflict as much damage as possible to innocent bystanders and then to strike again when rescuers arrive. Manmade events such as these and natural disasters such as Hurricane Katrina (New Orleans), Hurricane Harvey (Houston), Hurricane Maria (Puerto Rico), Superstorm Sandy (New Jersey and New York), and the endless stream of floods and devastating tornadoes that seem to increase in frequency with every passing year should crystallize the resolve of all medical personnel to become educated and proficient in disaster management. The approach to disasters, whether natural or manmade, requires a coordinated relief effort of EMS, hospital, fire, police, public works personnel, and often the military. This multiorganizational operation can effectively manage a crisis only if it is well directed and controlled. The ability to assess a disaster scene and mobilize appropriate personnel to provide damage control, fire management, rescue operations, and crowd control is dependent on an organization structure that permits dynamic information processing and decision making based on adequate planning and accurate vital scene information.

The military uses the concept of command and control for its combat operations. Key personnel continually monitor and manage the battlefield situation. The Fire Service of the US Department of Forestry, in 1970, adapted command and control into an incident command structure. Within this framework, a centralized group of disaster personnel commands and controls all of resources at the disaster site. Dynamic disaster scene information is processed at a predesignated incident command center where decisions regarding deployment and mission of rescue resources are implemented.

The incident command center structure is composed of seven key groups. If the disaster is small in scope, a single person may fill all seven areas. As the scale of the disaster increases, more personnel are required to perform these functions. The incident commander is responsible for the entire rescue or recovery operation. Under the direction of the incident commander are the seven group commanders: operations, logistics, planning, finance, safety, information, and liaison. Each of these section commanders has well-defined areas of authority and responsibility. Continuous on-scene information will be communicated to the command center. This will enable the incident command center to plan and direct the rescue or recovery operation. Thus, limited resources and key personnel will be directed to produce the greatest benefit.

The disaster scene is typically divided into zones of operation. Ground zero is the inner hazard zone where the fire and rescue operations occur. EMS and other nonessential personnel are kept out of this area. Rescued victims are brought out of this area to the EMS staging area. This is the second zone, a primary casualty receiving area, and it is here that EMS personnel perform triage and initial care for the patient. Disposition directly to the hospital may occur, or the patient may be sent to a distant receiving area for care and ultimate triage and transport.

The distant casualty receiving areas provide for additional safety in the environment. This downstream movement of injured patients prevents the primary triage sites from being overrun. Transportation of the wounded from the primary receiving site is reserved for the most seriously injured patients. Thus, a tiered triage approach is developed. A temporary morgue is also set up at a distant site.

Typically, groups of patients, the walking wounded, will migrate toward the nearest medical treatment facility. This process is called convergence. Medical facilities often set up a triage area in front of the emergency department to handle these patients. Current medical philosophy and federal regulations mandate an emergency assessment and treatment for stabilization of any patient who arrives at an institution's emergency department. In mass casualty situations, however, this can quickly overwhelm facility function and actually diminish effectiveness of care for all patients. Appropriate community disaster planning must recognize this potential problem and establish processes to direct certain groups of these patients to secondary medical facilities. The use of outpatient surgery centers and freestanding emergency medical centers, which are proliferating throughout the country, may be a valuable resource for this purpose. The final operational zone of the disaster site is the outer perimeter. Police permit only essential personnel access into the disaster site. Crowd and traffic control ensure the safety and security of the disaster scene as well as provide emergency vehicles rapid transit to and from the site.

Disasters may be of a small scale such as a building fire or explosion and may remain only a local or regional problem. As was demonstrated in the wake of the World Trade Center attack and Superstorm Sandy, the magnitude of a local disaster was of such proportions that activation of the National Disaster Medical System was necessary to address the rescue and recovery efforts. Analysis of more recent natural disasters demonstrates that approximately 10% to 15% of the survivors were seriously injured. The remaining victims either were dead or had mild to moderate injuries. Thus, overall effectiveness of disaster response is predicated on rapid sorting of survivors to determine the level of care needed by each patient.

The initial scene casualties from the World Trade Center attack were the result of planes striking the building. Fire and rescue personnel could not reach these patients. With the collapse of the first tower, rescue operations were aborted and attempts to evacuate rescue personnel became paramount.[60] After the building collapsed, victims injured in the street or from the surrounding buildings required medical treatment. As rescue operations resumed, injured rescue workers began to arrive at medical treatment facilities. Unfortunately, there were only 5 survivors of the Twin Tower collapse, with over 3000 fatalities, which included civilians and rescue personnel.

Israel's experience with terrorist attacks has demonstrated that rapid and accurate triage is critical to minimize mortality. Therefore, it has been suggested that the best triage officer, at least in bombings and shooting massacres, which are the most common form of terrorist violence, is the trauma surgeon.

This is important to guarantee that those in real need of immediate surgical attention are recognized and treated in a timely fashion without inundating the hospitals with patients who can be treated at a later time or those beyond salvage.

Many critical concepts have been learned from the Israeli experience. These include rapid abbreviated care, unidirectional flow of casualties, minimization of the use of diagnostic tests, and periodic relief of medical teams to maintain quality and effectiveness in care delivery. The concepts of damage control should be liberally applied in the operating room to free up resources for the next "wave" of injured individuals.[61-64] During mass casualty events, hospitals become overwhelmed very easily. Therefore, communication between hospitals and the incident commander is critical to distribute the casualties efficiently. All surgeons should be familiar with the basic principles of mass casualty management so that they can participate in the development of mass casualty management plans. Trauma surgeons should be the leaders in this field, since trauma systems serve as a template for the triage, evacuation, and treatment of mass casualty victims.[65]

APPLICATION OF TRIAGE PRINCIPLES FOR MULTIPLE PATIENT VICTIM EVENTS

Identification of major trauma patients in need of transport to a trauma center is the core mission of every triage protocol. In mass casualty events, however, a completely different process of patient assessment must be deployed. Triaging a single trauma victim is relatively straightforward, as described previously. For multiple casualty incidents, such as seen with multiple cars involved in a large-scale crash, the same essential principles apply; however, decisions must be made in the field as to which patients have priority. A multiple casualty incident can be defined as any situation where the volume of patients with injury severity may exceed hospital resources. Patients who are identified as major trauma victims by field triage criteria have priority over those who appear less injured. All major trauma patients should be transported to a trauma center as long as the trauma center has adequate resources to manage all the patients effectively. Because this situation can stress local resources, a properly conceived regional or state disaster management plan should include provision for possible diversion of the less critically injured to another trauma center or appropriately equipped hospital. Monitoring transports with online computer assistance allows for contemporaneous determination if one trauma center is overwhelmed.

MASS CASUALTIES

Triage in this situation is unique in that priorities are different from those in the single- or multiple-victim scenarios. As described earlier, in the instance of mass casualties, the resources of the designated trauma center, as well as the regional trauma system, are overwhelmed. When resources are inadequate to meet the needs of all the victims, priority shifts from providing care to those with the most urgent need to providing care to those with the highest probability of survival. A severely injured patient, who would consume a large amount of medical resources when not part of a mass casualty event, is now a lower triage priority. Despite the potential salvageability of this patient, the medical resources are focused on other patients who would benefit from advanced medical and surgical care. This method provides the greatest good for the greatest number of people. Field triage in this situation is probably the most difficult to perform as one has to make choices of quantity over quality with very limited amounts of information. These issues are further complicated when dealing with children.[66]

The most experienced and best-trained personnel available should make these field triage decisions. Physicians may be the best qualified to make these triage decisions; however, if they are the only clinicians available, direct patient care should take precedence and triage decisions should fall to other personnel. Patients are identified according to a triage code, based on the severity of injuries and likelihood of survival, and are treated accordingly. Occasionally, there may be an indication for a specialized surgical triage team with the capability to render acute lifesaving care of an injured, trapped patient.[67] In some disaster scenarios, moving intensive care capabilities into a disaster zone may be beneficial when evacuation of patients may be unrealistic due to logistical reasons.

In order to optimize patient care in these situations, it is important for regionalized systems to stage periodic mock disaster drills. These drills allow for the proper training of all individuals who might be involved as well as the identification and correction of potential problems. With increasing terrorist activity, specific triage algorithms have been developed for specific scenarios such as biologic, chemical, radiologic, or blast attacks.[68]

DISASTER TRIAGE: SIMPLE TRIAGE AND RAPID TREATMENT

In the event of a mass casualty or disaster, EMS personnel may use the Simple Triage and Rapid Treatment (START) triage system initially developed to be used in earthquakes in California. The object of this system is to triage large numbers of patients rapidly. It is relatively simple and can be used with limited training.[69] The focus of START is to evaluate four physiologic variables: the patient's ability to ambulate, respiratory function, systemic perfusion, and level of consciousness. It can be performed by lay and emergency personnel. Victims are usually divided into one of the four groups with color codes according to the timing of care delivery based on the clinical evaluation as follows: (1) green—minor injuries (walking wounded); (2) red—immediate; (3) yellow—delayed; and (4) black—unsalvageable or deceased.

If the patient is able to walk, he or she is classified as a delayed transport, but if not, ventilation is assessed. If the respiratory rate is greater than 30, the patient is an immediate transport. If the respiratory rate is less than 30, perfusion is assessed. A capillary refill time of greater than 2 seconds will mandate an immediate transport. If the capillary refill time is less than 2 seconds, the patient's level of consciousness

is assessed. If the patient cannot follow commands, he or she is immediately transported; otherwise, he or she is a delayed transport. Although capillary refill has been considered a reliable reflection of perfusion, in fact it can vary widely in different circumstances. This is especially true for children.[70] Therefore, findings from assessment of capillary refill should be verified by palpation of pulse. If the only palpable pulse is in the neck or groin, the patient should be transported. In light of the concerns about the predictive accuracy of capillary refill, some systems link the START method with severity scores, which may add unnecessary complexity and delay to the process of assessment: a Revised Trauma Score (RTS) of 3 to 10 is categorized as immediate, RTS of 10 to 11 is considered urgent, and RTS of 12 is categorized as delayed (nonurgent). This additional assessment requires providers to be familiar with the RTS and converts a binary finding to three options. Simplicity and expediency would dictate that central versus concomitant central and peripheral pulse palpation be the validator of capillary refill.

Mass casualty triage principles are the same for children and adults. However, because of differences in physiology, response to physiologic insult, ability to talk and walk, and anatomic characteristics, disaster triage in the pediatric age group is not as straightforward. Whenever possible, decisions regarding disposition of children should include consideration of availability of parental support.

A major benefit of the START system is accurate identification of severely injured trauma patients who may be able to be transported by air or ground ambulances to more distant trauma centers where the lower number of victims will assure that resources are available to provide optimal care.

MEASURING TRAUMA SYSTEM PERFORMANCE

Overview

As stated at the beginning of this chapter, trauma system sustainability is based on accountability. Accountability is phrased first in optimal outcome for every injury victim. Concurrent with this goal is confirmation of optimally achievable cost efficiency in delivering this care and ameliorating the financial burden of injury on the population. This process of accountability must also be able to support adequate analytics to define and deploy best practice. To achieve this goal, reliable system-wide data collection and analysis is an absolute necessity. Accurate, objective, and relevant data are the glue that keeps the trauma system functioning and the fuel that drives its continuous improvement.[32-35,71,72] A statewide trauma registry is necessary to assure commonality of critical data terminology; however, as the proliferation of electronic medical records continues to transform the clinical data ecosystem, adequate connectivity and interoperability of multiple data sources will be necessary to ensure that the trauma system is a self-learning, data-driven process of continuous quality improvement. Information from each phase of care is important and must be linked with every other phase. This level of data compatibility from different phases of care is especially important to determine the effects of certain interventions on long-term outcome. Constant system evaluation is necessary to identify where the system falls short operationally and stimulate strategies for improvements in system design.[73,74] This feedback mechanism must be part of the system plan for evaluation and must include designation of the agencies that will be responsible for data system management, definition of accountability metrics, and determination of best practice. Because each of these, and many subcomponents thereof, may fall within the purview of different stakeholder groups and may require special data security arrangements, this process should be defined as part of the regional trauma system plan. ASCOT has developed multiple programs and quality assessment processes that can guide this program as well as provide objective external review.[5]

Analysis of Trauma System Performance

The data on trauma system effectiveness published in the literature are difficult to interpret due to great variability in study design, type of analysis, and definition of outcome variables. Different study designs have been used to evaluate trauma system effectiveness. The most common scientific approaches include panel review of preventable death studies, trauma registry performance comparisons, and population-based studies. Panel review studies are conducted by experts who review trauma-related deaths to determine preventability. Well-defined criteria and standardized definitions regarding preventability have been used, but significant methodologic problems can lead to inconsistencies in the results and interpretation of the data.[26,33,75] The meta-analysis of trauma system assessment by Celso et al[76] provides an extensive review of various methods applied to the processes of assessment of the function and effect of trauma systems.

In an attempt to review the existing evidence on the effectiveness of trauma systems, the Oregon Health Sciences University, with support from the NHTSA and the National Center for Injury Prevention and Control of the CDC, organized the Academic Symposium to Evaluate Evidence Regarding the Efficacy of Trauma Systems, also known as the Skamania Symposium.[25] Trauma care providers, policymakers, administrators, and researchers reviewed and discussed the available literature in an attempt to determine the impact of trauma systems on quality of patient care. The available literature on trauma system effectiveness does not contain class I (prospective, randomized controlled trials) or class II studies (well-designed, prospective or retrospective controlled cohort studies, or case-controlled studies). There are several class III (panel studies, case series, or registry based) studies that were reviewed and discussed during the symposium. According to Mann et al,[31] review of the published literature in preparation for the Skamania Symposium supported the conclusion that the implementation of trauma systems decreases hospital mortality of severely injured patients. Independent of the methodology used (panel review, registry based, or population based) and despite the previously mentioned limitations

of each study design, a decrease in mortality of 15% to 20% has been shown with the implementation of trauma systems.[30,77] This has been most recently determined in analysis of the impact of the first 5 years of function of the Arkansas trauma system. Mortality decreased, as seen in other regions, and inpatient preventable mortality decreased significantly. The leaders of the Arkansas system are currently evaluating the cost savings generated by the system's ability to triage the most severe patient to the most appropriate center.[78] The participants of the Skamania Symposium also emphasized that not only mortality but also functional outcomes, financial outcomes, patient satisfaction, and cost-effectiveness should be evaluated in future prospective, well-controlled studies.[24,25,27]

Registry studies are frequently used to compare data from an individual trauma center, a trauma system against a national reference norm, between trauma centers within the same system, or at the same trauma center during different periods. The Major Trauma Outcome Study (MTOS) was among the first used as the national reference, although several of its limitations compromise the reliability of the comparison with data from other systems or centers.[79] Currently the National Trauma Data Bank and the more rigidly controlled data sets supporting the Trauma Quality Improvement Program (TQIP) are available for benchmark analysis in both adult and pediatric trauma centers. TQIP provides for risk-adjusted analysis of outcomes. In an effort to drive performance improvement across trauma systems, TQIP collaboratives of both hospital systems and states have been developed. Participation in TQIP collaboratives has been shown to improve system performance in states such as Michigan and Tennessee.[80-83] The advantages of registry-based studies include a detailed description of injury severity and physiologic data acquired by trained registrars. The disadvantages are related to inconsistency of data submission and the need to account for missing data using imputation and often propensity scoring in many multi-institutional analyses.

Population-based studies use information obtained from death certificates, hospital discharge claim data, or the Fatality Analysis Reporting System on all injured patients in a region. These methods of data collection and analysis are important to evaluate changes in outcome before and after or at different time periods following the implementation of trauma systems in a defined region. Because this is administrative and/or claims related information, there is little or no information on physiologic data, injury severity, and treatment. The limitations of the most commonly used databases in population-based studies are described in Table 4-5.

Despite differing approaches to study design, one area of rising interest has been comparison of outcomes of inclusive and exclusive systems. As described previously, in an inclusive system, care is provided to all injured patients and involves all acute care facilities, whereas in exclusive systems specialized trauma care is provided only in high-level trauma centers that deliver definitive care. In inclusive systems, patients may be transferred to a higher level of care (trauma center) after initial stabilization based on the availability of resources and expertise in the initial treating facility. Two associated variables can affect overall inclusive trauma system performance: (1) delay in transfer and (2) dilution of trauma centers' experience. Utter et al[38] have investigated whether mortality is lower in inclusive systems compared to exclusive systems. They concluded that severely injured patients are more likely to survive in states with the most inclusive trauma system, independent of the triage system in place. A possible explanation for these findings includes better initial care in referring hospitals.[38] A more recent study confirms a mortality reduction of 25% in patients under the age of 55 years.[28]

One of the benefits of continued analysis of trauma system function has been the identification of specific areas of injury where significant improvements in care and outcomes have emerged by evaluation of similar cohorts of patients across multiple institutions. Major advances have occurred in management of traumatic brain injury, including the benefit of high-volume experience in terms of patient survival and quality of recovery.[84] Continuous analysis of trauma center data aggregated at the state level affirms the importance of adequate clinical experience to optimize chances for good outcome. Racial and social disparity studies have defined specific

TABLE 4-5: Limitations of Current Trauma System Evaluation Studies

Panel studies
Inconsistent definition of preventability
Case mix of the population
Size, composition, and expertise of the panel
Process and criteria to determine preventability
Inconsistent report of prehospital and autopsy data
Registry-based studies
Missing or incomplete data sets
Coding inconsistencies and errors
Inconsistent report of autopsy data
MTOS limitations
Outdated data set
Data are not population based
Mostly blunt trauma
Differences in trauma centers' level of care
Inconsistencies in trauma registry inclusion criteria
Lack of data on comorbid factors
Lack of data on long-term follow-up
Population-based studies
Mechanism of injury and physiologic and anatomic data usually not available
Autopsies not performed consistently in all trauma deaths
Limited number of secondary diagnoses in claims data
Autopsy findings not always included in claims data
Hospital discharge data are inaccurate in transfers and deaths in the emergency department
Inconsistencies in obtaining AIS scores
Outcome measure is in-hospital mortality
No long-term or functional outcomes data available

AIS, Abbreviated Injury Scale; MTOS, Major Trauma Outcome Study.

issues that directly impact outcomes in these populations and, more importantly, document no discriminatory barrier to trauma system access.[85] Conversely, system assessment clearly underscores the importance of accurate triage and affirms that excessive overtriage makes treatment of minor injury inappropriately expensive and potentially disruptive of the process of care for more severely injured patients.

The greatest modern challenge for which careful system performance monitoring will be critical is management of the elderly. As the American population ages, the proportion of patients over 65 years who sustain significant injury continues to increase. These individuals represent a small volume of the overall trauma patient population, yet generate a disproportionate share of the cost of care.[85,86] In addition to disproportionate cost, multiple other factors influence how an effective trauma system must adjust to optimize care for the injured elderly. Despite being more active than their predecessors, most of these patients are afflicted with the usual comorbid conditions associated with aging. The most common MOI is falls, usually in the home environment. Next most frequent are motor vehicle crashes. The desire to be treated by the physicians or health system with which they are familiar often results in inappropriate triage. Inability to determine whether the patient is at risk because of being injured and elderly versus elderly and acutely injured often results in delayed management of injuries or incomplete assessment of deteriorating chronic comorbid conditions. Of even greater importance than simple survival is quality of life after recovery. Transformation of a reasonably healthy, active senior citizen to an impaired dependent is yet another burden of the disease of injury and demands careful planning, comprehensive case management, and compassionate counseling of victims and their families.

Practical Considerations in Trauma System Performance Monitoring

As is apparent in the review of the evolution of trauma systems, the major driver of this process has been commitment to eliminate preventable death. Because any injury represents a failure of prevention, the scope of effort has broadened to the concept of an inclusive trauma system that enhances prevention education and integrates all resources into a population-based, coordinated enterprise. The milestones of this evolution have been defined by a constant focus on clinical outcomes; what works, what doesn't, and what needs to be improved. This culture of outcome-oriented performance improvement has become the model for similar efforts across all aspects of American health care. The process of quality assessment is well defined elsewhere in this text; however, from a trauma system's standpoint, the following factors represent the core of what is required for accurate assessment and accountability. As the American health care system continues its transformation and as the clinical data ecosystem evolves to a level that supports the full gamut of health care delivery, system performance and clinical outcome measurement will drive better patient care, greater efficiency, and improved population wellness. The following items are some of the major factors that will be measured and will drive continuous quality improvement for the entire trauma system.

The three major domains of trauma system function are:

- Clinical effectiveness in reduction of the burden of injury
- Efficient use of resources
- Disaster response infrastructure

Clinical effectiveness is not simply stated in terms of decreased mortality. It must reflect continued focus on elimination of preventable death and optimization of potential recovery for all injury victims. This includes effective prevention of any injury, expeditious care for those at risk, and comprehensive long-term support through full reintegration into society. Trauma system function is predicated on the availability of extensive and expensive resources. These must be used in a cost-efficient and efficacious manner. Processes to measure this and provide objective accountability to society for its investment in citizens' safety is critical to assure sustainability of the trauma system. Just as the commitment to quality and optimal patient care forged by trauma systems has become a model for clinical care in general, so also has the trauma system collaborative infrastructure that coordinates availability and deployment of critical resources from disparate sources emerged as the infrastructure that will support effective disaster response.

Critical system factors necessary to address the earlier statements in a manner that defines trends and identifies improvement opportunities can be categorized as structure, process, and outcome elements according to the Donabedian conceptual model of performance assessment.[87] Table 4-6 identifies multiple aspects of trauma system function and theoretical metrics that could be developed to generate a data-driven, objective process for continuous performance improvement. The list is by no means complete and is provided as a starting point for thought and as a framework for transformation of relevant questions into objective milestones of success.

CONCLUSION

An effectively functioning trauma system is a physiologic, sociologic, financial, political, psychological, and cultural entity that is in continuous flux. It is an identifiable social commitment by a population to the welfare of all of its citizens. It is an investment of enormous expense in talent and treasure that must be continuously monitored to ensure full accountability for every aspect of its mission.[88] This chapter has reviewed the evolution of this fascinating and critical health care phenomenon and described the features that are necessary for implementation and deployment of an effective system. The two final characteristics that define every trauma system's pathway to survival and success are sustainability and agility. A trauma system will be sustainable if it continues to preserve lives and diminish the burden of injury in terms of cost, lost productivity, and avoidable misery. A trauma system's agility in managing all of its constituent components to anticipate and preemptively adjust to new challenges in

TABLE 4-6: Potential Metrics for Continuous Trauma System Performance Surveillance

Component	Relevance	Theoretical benchmark
Structure		
EMS coverage and access	Effectiveness is predicated on adequate population coverage and access	95% of citizens are within 30 minutes of transport
Distribution of EMS resources relative to DTCs	Optimize response time against out of service during active transport time	Predicated on incident response times
Estimated time to DTC (see https://www.amtrauma.org/page/FindTraumaCenter)	By any conveyance should be within 60 minutes	Running trend below 60 minutes
Number and distribution of trauma centers	Most efficacious and cost-effective mix of complex resources and appropriately staffed system entry points	No delays in access, no delays to definitive care related to resource availability
Occupancy	Adequate bed availability for every indicated level of care	No delays along the spectrum of care related to bed or provider availability
Diversion	Trauma service must be provided continuously, and when not, appropriate alternatives identified	Facility not available <2% of time
Post-acute care facilities occupancy	Immediate and continuous bed availability within 20 miles of trauma center	Proportion of bed days spent waiting for transfer should be <5% of total trauma bed days
Process		
Triage accuracy—overtriage and undertriage	Accurate risk recognition must drive correct field triage and expeditious transfer of severely injured patients from receiving facilities to the appropriate trauma center	Overtriage rate <15% Undertriage rate <5%
Cost-effectiveness	Avoidance of unnecessary service repetition and laboratory tests/imaging that increase radiation risk, prolong resuscitation, and often spawn unnecessary follow-up exams	100% documentation of need for imaging, laboratory, or clinical service Proportion of use and violation of clinical pathways
Outcome		
Mortality	Avoidance of preventable death	Application of standardized, evidence-based process for mortality prediction to identify preventable mortality
Morbidity	Elimination of care-related adverse events associated with long-term impairment; optimal care to ameliorate impact of acute injury on functional recovery	Incidence of adverse events and failure to rescue should approach zero
Disparities	No identifiable limitation to access along any aspect of the continuum of care	No delays or barriers to indicated therapy along continuum of care
Epidemiology as a measure of prevention effectiveness	Identification of most significant threats and determination of best practice for effective control	Decrease in incidence, severity and cost over time
Burden of cost	Per-capita cost of the disease of injury in terms of expended medical resources and lost human productivity	Population-based determination of decrease over time System response to spikes in incidence or severity of specific injury patterns, especially as related to violence-related mechanisms

DTC, designated trauma center; EMS, emergency medical services.

the American economy and health care system is essential for its sustainability. Many changes are fast approaching. The aging population is changing not only patient need, but also the epidemiology of injury. Violence remains a major problem in our culture; however, the impact of effective secondary prevention by better focus on environmental safety has diminished the incidence of devastating injuries related to high-energy transfer. Finally, our population continues to shift, and with it the burden of effective disease control can quickly exceed resources available. The tax base that shifts with this migration is often inadequate to support expansion of the infrastructure required to provide increased coverage. Thus, it is imperative that a trauma system be recognized as a living human endeavor under constant scrutiny to assure

optimal return on investment by continuously responding to its population's needs. It is the quintessential example of a self-learning health system.

Injury Severity Scoring, Modeling, and Outcomes Research

Lynne Moore • Howard R. Champion

KEY POINTS

- Collecting reliable, accurate, and timely data on injury care is central to injury research and surveillance.
- Injury severity score (ISS) selection should be based on a clear sense of what one wants to measure and why and on a good understand of the score's strengths and limitations.
- Combination injury severity models attempt to combine the three concepts of risk: (1) preinjury physiologic reserve (eg, age, comorbidities); (2) physiologic status of the injured patient (eg, Glasgow Coma Scale [GCS]); and (3) anatomic injury severity (eg, ISS). The optimal injury severity model will depend on the data available, the study population, the exposure of interest, and, in particular, the outcome under evaluation.
- Injury outcomes research aims to improve our understanding of the determinants of optimal injury outcomes with the ultimate goal of reducing the societal burden of injury. Scientific ethics require a demonstration that addressing the research question will sigadvance current knowledge.
- Researchers are increasingly looking to assess outcomes that are important to patients. For hemorrhagic shock, that may be mortality, but for brain, spinal cord, and orthopedic injuries, function in daily activities and quality of life are more likely to be meaningful.
- Outcomes research must be based on a comprehensive, integrated, and end-of-grant knowledge-translation strategy. Practitioners, policymakers, decision makers, and patient/family advocates should be involved in all phases of research projects, and results should be distributed to all stakeholders, not just in the form of scientific articles but as policy briefs, clinical guides, and decision rules. We should also work to strengthen international collaborations to pool resources, avoid duplicating research projects, and generate results with maximum impact.
- To improve our understanding of the complex associations underlying the burden of injury, we need to improve the quality and coverage of injury data; employ more sophisticated analytical methods; improve the knowledge translation-to-action cycle of research results; look toward comparing outcomes across health care systems in high-, middle-, and low-income countries; and adapt our methods to the changing demographics of trauma populations.

INTRODUCTION

Injuries have long been classified in terms of severity. The world's oldest known surgical document, the Edwin Smith Surgical Papyrus (ca. 17th century BC), classified 48 traumatic injuries from ancient Egyptian battlefields and construction sites as successfully treatable, possibly curable, or untreatable.[1] Such predictions about patient outcomes, and attempts to quantify the severity of injury, are today the realm of more than 50 published injury severity scores, scales, and models.

Injury severity scoring quantifies the risk of an outcome following trauma and provides metrics based on elements of clinical acumen and statistical and mathematical modeling to describe aspects of the patient condition after injury. The primary outcome of interest is commonly survival or a measure of morbidity (eg, complications) or resource use (eg, hospital or intensive care unit [ICU] length of stay [LOS]) but may be any primary end point of interest (eg, compliance to an evidence-based clinical practice).

The injury scores and models discussed here are generally applied using retrospectively collected data. They are therefore suitable for case mix adjustment or risk prediction in groups of patients but are not appropriate for individual patient predictions to guide specific clinical management decisions. They have a host of applications including quality improvements in

patient care, trauma systems and health care delivery, injury prevention initiatives, and epidemiologic studies of injury.

DEFINITIONS

This chapter provides a concise description of injury severity scoring and modeling, with particular emphasis on application to outcomes research and quality improvement. Because there can be confusion about the precise meaning of terminologies used in this process, a few definitions are warranted to distinguish the qualitative from the quantitative.

Scales: Scales are a graduated range of values forming a standard system for measuring or grading something. Examples include the Glasgow Coma Scale (GCS), which has three components (verbal, eye, and motor) ranging from 1 (no reaction) to 5 (normal reaction), and the Abbreviated Injury Scale (AIS), which ranks severity from 1 (minor) to 6 (virtually unsurvivable, Table 5-1). Scales should be as objective as possible, and their assignment should be supported by inter- and intrarater reliability studies.

Scores: Injury severity scores place numerical values on injury descriptions, thus enabling standardized communication about the injury state. They are often generated by a standardized mathematical treatment of scales (scaled scores). Examples include the GCS score, which is the sum of the three components of the scale (ranging from 3 to 15) and the Injury Severity Score, which is the sum of squares of the AIS severity digit in the three most severely injured body regions (ranging from 1 to 75).

Scales and scores can be:

- Nominal: The values are not numerical and have no order.
- Ordinal: The values are not numerical but have an order (eg, increasing or decreasing injury severity).
- Interval: The values are numerical, and the distance between the levels is consistent both within and across the system of scoring.

Models: Modeling is defined here as the use of scoring or scaling systems to create processes for determining probabilities of risk for specific outcomes (eg, mortality, morbidity). The process of modeling is a means of combining or integrating multiple attributes, for example, multiple injuries or anatomy and physiology. Examples include generalized linear modeling with probability and link functions adapted to the outcome of interest (eg, logistic or log-binomial models for mortality and log-linear or gamma models for LOS). These models are used to formulate coefficients of risk for specific elements within a scale or risk associated with group diagnosis. Alternatives include machine-learning algorithms such as Bayesian networks[2] and neural networks.[3]

Outcomes research: Outcomes research is defined as a method of creating "empirically verified information" to better understand how variables in the real-world setting (from injury to treatment) affect a wide range of outcome variables (from mortality to satisfaction with care).[4]

Risk adjustment: Risk or case-mix adjustment entails isolation of the effects to be studied from the effects of other factors that can influence the outcome. Risk adjustment is essential for appropriate outcomes analysis. In injury outcomes research, severity scores are essential for risk adjustment because they allow accurate comparisons among disparate patient populations with varied degrees of risk. The goal is to compare populations with similar degrees of injury so that modifiable risk factors (eg, time to treatment, injury prevention interventions, mitigation equipment) may be properly isolated to examine their relationship to particular outcomes. Risk adjustment might be as simple as defining classes of a variable to stratify risk groups or as complicated as using a risk adjustor in a multivariable regression model.[5]

TABLE 5-1: Abbreviated Injury Scale (AIS)

AIS severity	Ordinal description
1	Minor injury
2	Moderate injury
3	Serious injury
4	Severe injury
5	Critical injury
6	Virtually unsurvivable injury

INJURY DATA

Collecting reliable, accurate, and timely data on injury care is central to injury research and surveillance and is the key to reducing the societal burden of injuries. Ideally, routinely collected data would be linked throughout the care continuum from prehospital care through community care. However, in most health care systems, injury data sets are limited to trauma registries and hospital discharge (administrative) databases, both based on the hospital phase of care.

Trauma Registries

One of the earliest civilian trauma registries was the Illinois Trauma Registry, which was created to benchmark and track improvements in trauma center implementation in a small geographic area.[6] However, it was preceded by an "accidental" trauma registry comprising the Wound Data and Munitions Effectiveness Team (WDMET) data collected in Vietnam from 1967 to 1969. About 15 years later, the WDMET database was rescued from destruction by a young naval officer and has provided a basis for our understanding of combat injury and future combat trauma registries.[7] The next significant step was the Major Trauma Outcome Study (MTOS),[8] which collected data from more than 100 hospitals in North America and Canada and serves as a model for all trauma registries established since the mid-1990s around the world.

Trauma registries are designed to provide information for quality improvement activities within trauma systems. They generally contain data on patient demographics, injury circumstances, prehospital care and transport (in some cases), anatomic injury, physiologic measurements on arrival,

emergency department (ED) and in-hospital interventions, comorbidities, complications, outcomes, and patient destinations. The information is generally coded from patient charts by trained data abstractors, and injuries are usually described using the AIS lexicon.

Trauma registries can be limited to a single provider but are most useful for quality improvement when they contribute to regional, state, national, and multinational registries. Trauma registries with a national reach include the US National Trauma Data Bank (NTDB), run by the American College of Surgeons (ACS), the United Kingdom (UK) Trauma Audit and Research Network (TARN), the German Trauma Register Deutsche Gesellschaft für Unfallchirurgie, and more recently, the Australian Trauma Registry and the New Zealand Trauma Registry. Because of the circumstances in Israel and the integration of military and civilian medical systems, the Israeli Defense Forces and Israeli trauma centers have a database that captures both civilian and military injuries, including those resulting from terrorist incidents. Trauma registry inclusion and exclusion criteria vary, with some registries including all injury admissions and ED fatalities and others applying inclusion criteria based on injury severity, trauma team activation, or LOS.

The main objective of most trauma registries is quality assurance or benchmarking, whereby provider performance is monitored over time or compared to an internal or external standard to identify hospital outliers. Trauma registries are also used for resource allocation planning, injury prevention, and outcomes research, to confirm specific hypotheses but also to generate them through exploratory analyses.

The major advantage of trauma registries is the fact that they include detailed clinical data that is essential for accurate benchmarking and outcomes research. Disadvantages include the facts that they are based on retrospectively collected patient chart data subject to data quality issues, they only cover the index acute-care admission for injury, and they are not usually population based. Indeed, trauma registries are generally limited to patients treated in designated trauma centers, which can represent a small proportion of regional injury admissions, particularly in exclusive trauma systems. However, trauma registries based on mandatory data collection and/or inclusive trauma systems such as the Victorian State Trauma Registry, the TARN, the Pennsylvania Trauma Registry, the Korean Emergency Medical Services Treated Severe Trauma Registry, and the Quebec Trauma Registry generally offer high population coverage.[9] Nevertheless, most trauma registries exclude a high proportion of injury-related deaths (particularly prehospital deaths) and minor injuries treated in the ED and discharged home. In addition, to maintain a focus on severe injury, many specifically exclude groups of patients, such as those with isolated hip fractures. Another important limitation of trauma registries is the investment required in terms of efforts and resources. In 2004, the Victorian State Trauma Outcomes Registry and Monitoring Group estimated the cost of the Victorian State Trauma Registry at approximately AUD$100 (US$84) per patient.[10] Despite the fact that this represents a fraction of a trauma patient's health care costs, it is usually perceived as an onerous financial burden and is a major barrier to trauma registry implementation and maintenance. Finally, most trauma registries have no data on outcomes that are important to patients such as functional capacity and quality of life and do not collect data on outcomes beyond discharge. One of the most complete trauma registries in the world is the Victorian State Trauma Registry in Australia, which provides 3-, 6-, and 12-month follow-up data on functional status and quality of life for injury patients using an opt-out consent strategy that would not be possible in most jurisdictions.[11] In summary, trauma registries present an incomplete but deliberately focused picture of injury, which may or may not even capture all severely injured admitted patients in a given geographic area.

Other Injury Databases

The US Department of Transportation National Highway Traffic Safety Agency (NHTSA) maintains two massive databases on vehicular-related injury in the United States, which are discussed in further detail later in this chapter: the Fatality Analysis Reporting System (FARS) and the National Accident Sampling System (NASS).

Military Trauma Registries

Despite the fact that military campaigns have often resulted in voluminous "after action reports" describing the type and number of injuries, systematic data collection did not occur until the Vietnam WDMET database. Seven teams of researchers were sent to Vietnam by General Creighton Abrams, then Army Chief of Staff, to comprehensively collect data on injuries for the purpose of assessing the wounding capabilities of various weapons. This database of some 8900 (an approximate 5% sample) combat injured and killed provided a useful source of data to characterize the nature and severity of modern combat injury (largely performed by Dr. Ron Bellamy). Other combat trauma databases include a complete set of data from the UK Hostile Casualty Reporting System (predominantly Northern Ireland) and databases on British casualties from the Falkland and Kosovo conflicts. Russian casualties in Chechenia were also databased. In the late 1990s, the US Special Operations Command (SOCOM) initiated efforts to database SOCOM casualties. An effort was also made to translate the injuries in the WDMET database to modern taxonomies. As Operation Enduring Freedom (OEF; Afghanistan) and Operation Iraqi Freedom (OIF) developed, the effort to database combat injuries picked up. Formats were field tested in Afghanistan. Finally, five trauma registries were in development through the early 2000s. As a result of these efforts, essentially census data were obtained on all Americans with severe combat injuries or killed in OEF/OIF. Data were generally excluded for those who returned to duty within 3 days. There have been numerous important publications from these sources of data. In addition, the information on the injured and injuries has been linked to operational data, and these classified data sets have been used to inform not only military tactics, but also body armor and vehicle design.

Hospital Discharge Data

Hospital discharge data are routinely collected in most high-income countries to meet administrative and reimbursement needs. These data sets generally include patient demographics, diagnoses, comorbidities, surgeries, and complications. Injury diagnoses and mechanisms of injury are coded using the International Classification of Diseases (ICD) lexicon. Advantages of hospital discharge data include population coverage of all hospital admissions and the fact that patients can be tracked through the system via a unique identifier, enabling researchers to obtain information on transfers, readmissions, and pre- or postinjury use of health care services. Disadvantages include the lack of clinical information, the absence of injury severity scores, and the omission of ED fatalities. In addition, discharge data are designed for administrative purposes and may not include all injury diagnoses. Hospital discharge data sets are most useful when they can be linked to trauma registry data. Systems that enter shared data simultaneously into both databases are the most efficient.

Prehospital Data

A major challenge of data acquisition in trauma systems relates to prehospital clinical data. At least half of all trauma deaths are prehospital. Few trauma registries capture these data, which, because of the emergency nature of prehospital intervention, are particularly hard to acquire and accurately record. For example, most prehospital providers do not ascertain patients' GCS scores except by gestalt. Further, although they record interventions, abstracting and converting the information into a database is particularly challenging. This is an important hurdle because at least half of all civilian trauma deaths occur in the prehospital period. This percentage is greatly increased in low- and middle-income countries. Military data reveal that at least 90% of combat deaths occur prior to reaching a medical treatment facility.[12] The 75th Ranger Regiment instituted a process of complete capture of prehospital data for the decade they were involved in Afghanistan and Iraq.[13] This is a fine example of prehospital data collection that has influenced the process of care and the speed with which care is rendered and has led to a reduction in preventable deaths. The Department of Transportation NHTSA, FARS, and NASS collect and database extensive prehospital data.

Other Data Sources

Other useful sources of injury data include police reports, road traffic or workplace injury insurance data sets, rehabilitation facility databases, physician billing records, and community care databases. Unfortunately, there are considerable barriers to linking these data sources, such as lack of unique identifiers, data-protection acts, and lack of harmonization across data sets.[14]

The US Department of Transportation NHTSA houses two large injury databases related to vehicular crashes, based on linkage of multiple data sources. FARS is a near-census population of deaths from vehicular-related injury in the United States, which contains data from police reports, emergency medical services, and EDs. NASS is a sample of vehicle crash patient data obtained from prehospital and hospital sources throughout the United States. Both of these databases, although imperfect, have been populated for decades and are a valuable resource for tracking, among other information, prehospital and in-hospital deaths from vehicle crashes (Fig. 5-1).[15]

We must continue to work toward solutions for linking routinely collected data on injury care. This would enable us to build injury life cohorts with amazing potential to inform primary, secondary, and tertiary injury prevention initiatives to alleviate the human and financial burden of injury.

Data Quality

Trauma registries generally have rigorous data quality assurance programs to ensure the accuracy and completeness of data extraction and entry. Mechanisms include initial and ongoing abstractor training, query forums, built-in electronic data error filters, retrospective data cleaning, and re-abstraction of random samples of charts. However, the quality of information in the medical charts themselves remains an important problem. Examples of common data quality issues in trauma registries include underreporting of comorbidities and complications, underestimation of injuries and their severity for early deaths, and missing data on physiologic parameters such as the GCS and respiratory rate (RR). Many clinicians ignore these data quality issues and mistakenly believe that large numbers of patients in a data set ensure quality. However, whatever the sample size, systematic variations in data quality across providers can lead to

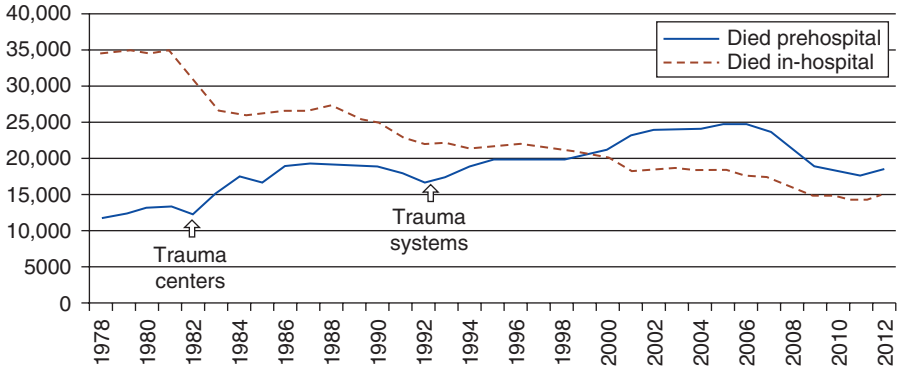

FIGURE 5-1 US vehicle crash deaths: 1978–2013.[15]

selection or information bias, whereby observed differences in performance across injury groups are due to differences in coding practices rather than quality of care. These data quality problems can be partly addressed in the analysis phase through sensitivity analyses and strategies to simulate missing data (eg, multiple imputation). However, analytical solutions will never replace high-quality data, and every effort should be made to ensure the accuracy and completeness of data collected in trauma registries.

INJURY SCORING AND MODELING

Trauma researchers must be familiar with injury scoring schemes to accurately risk-adjust injury group comparisons in an attempt to isolate the effects of an independent predictor variable on a dependent outcome variable. Four types of severity scores are typically used: (1) anatomic injury scores, (2) physiologic scores, (3) comorbidity scores, and (4) combinations of the three and other factors. The scores vary considerably in complexity of calculation and ease of use. Injury severity score selection should be based on a clear sense of what one wants to measure and why, and a good understanding of the score's strengths and limitations.

Anatomic Injury Scales, Scores, and Models

Anatomic injury scales, scores, and models describe the site of injury and extent of damage. Many anatomic scales, scores, and models have been proposed in the literature, but this review is limited to those that have gained practical acceptance. We will not review the huge number of specialty classification and grading systems such as the American Orthopaedic Foundation/Orthopaedic Trauma Association Classification of Fractures and Dislocations. Most general scoring algorithms are designed to predict mortality and are not specifically validated for other outcomes, such as resource utilization or disability, although moderate correlations may exist. The majority of scores are based on either the trauma-specific AIS coding classification or the more general ICD taxonomy.

ANATOMIC INJURY CLASSIFICATION SYSTEMS

Abbreviated Injury Scale. The AIS was first conceived as a system to define the type and severity of injuries arising from aircraft and motor vehicle crashes.[16] It began with a dictionary of 73 injuries in 1971 and now has close to 2000 injury codes, adding to its precision but also to the cost and complexity of coding.[16] Major revisions to the AIS occur infrequently; the latest revisions were in 1998 and 2005.[17,18] They aim to expand and create new codes, delete obsolete ones, and update severity scores in line with improvements in patient survival. Minor updates occur every few years with the latest ones in 2008 and 2015. To calculate AIS scores, medical records are transcribed into specific codes that capture individual injuries. The AIS is a proprietary classification system requiring specialized training for coding personnel. Because of this, AIS is not captured at every hospital.

AIS divides the body into nine regions: head, face, neck, thorax, abdomen, spine, upper extremities, lower extremities, and external. The AIS code consists of two numerical components separated by a decimal point. The first is a six-digit injury descriptor "pre-dot" code, which classifies the injury by region, type of anatomic structure and specific structure injured, and level of injury. The "post-dot" component is a severity score ranging from 1 (minor) to 6 (theoretically unsurvivable), as shown in Table 5-1. AIS severity scores are consensus-derived assessments assigned by a group of experts. The maximum AIS (MAIS), which is the highest AIS severity among all of a patient's injuries, is often used to quantify a patient's injury severity. This score is highly correlated with mortality but ignores information on concomitant injuries,[19] which may be significant in some patients and for specific outcomes.

AIS has many intrinsic shortcomings, including anatomically incorrect body regions, inability to code combat injuries,[20,21] and inconsistent scaling of severity across body regions.[22] For example, an AIS of 4 to the head and neck is associated with a higher probability of mortality than an AIS of 4 to the chest or abdomen.[23] Even when performed by experts, AIS coding has low interrater reliability, and 65% to 82% of AIS codes are not used, even in the largest registries.[24] Further, the limitations of the AIS are carried forward and multiplied when they are used as the basis for models (eg, the Injury Severity Score, discussed later).[25] A simplified version of the AIS has recently been developed for civilian injury with 450 codes, which greatly facilitates injury coding in resource-constrained environments.[26]

International Classification of Disease. Owned by the World Health Organization, the ICD is not injury specific, but is a general, all-purpose diagnosis taxonomy for all health conditions. It is well over a century old and is currently in its 11th clinical modification (ICD-11). In most countries, the 10th clinical modification, ICD-10-CM, has been used for nearly a decade.[27] In the United States, ICD-10-CM is in the process of being introduced.[28] In the ICD-10 lexicon, ICD codes exist for more than 68,000 medical conditions, and more than half of them describe physical injuries.[29,30] For trauma researchers, AIS codes are generally preferred over ICD codes because of their greater specificity of injury description (the pre-dot classification) and the availability of an injury severity classification (post-dot code).

ICD Injury Matrices. The Barell Injury Diagnosis Matrix (ICD-9) and the Injury Mortality Diagnosis Matrix (ICD-10) are matrices of ICD codes for classifying injury diagnosis by type and anatomic region into "injury profiles."[31] These matrices enable epidemiologic, management, and clinically oriented analysis by serving as a standard for case-mix comparison and characterization of injury patterns. The Barell Matrix consists of 12 columns based on ICD-9-CM sequence representing nature of injury (eg, fractures, amputations) and rows with varying levels of detail relating to body region (eg, head and neck, traumatic brain injury). Using this matrix, data can be aggregated into summary reports that indicate injury distribution, enabling descriptive comparisons.

ANATOMIC INJURY SCORING SYSTEM MODELS

Current anatomic injury models are based on the AIS or the ICD. The former has an injury scoring system derived by expert consensus (AIS injury severity score described earlier), whereas for the latter, empirically derived severity scores are available (probabilities of mortality calculated using large injury databases). AIS-based consensus models include the Injury Severity Score (ISS), the New Injury Severity Score (NISS),[32] and the Anatomic Profile (AP).[33] AIS-based empirical models include the Trauma Registry Abbreviated Injury Score (TRAIS) and the Trauma Mortality Prediction Model (TMPM). ICD-based models are all derived empirically and include the ICD Injury Severity Score (ICISS) and its derivatives.[34-37]

Injury Severity Score.

In 1974, Baker and colleagues[38] first posited a multi-injury score by introducing the ISS. Injuries in each AIS region are given an AIS score, and the highest AIS scores in the three most severely injured regions are squared and summed to form the ISS. The ISS range is an ascending scale of severity from 1 (least severe) to 75 (originally designated as unsurvivable). An AIS of 6 automatically translates to an ISS of 75.

ISS correlates with mortality, but the association is neither smooth nor monotonic.[39] Further, it only considers one injury in each body region and thus ignores important injury information, especially in penetrating and ballistic injury.[21,40] It also carries over the problem of nonuniform severity across body regions described earlier for the AIS. The ISS is probably most well known for its use in the definition of major trauma. Traditionally in the United States, an ISS of greater than 15 has been used to define major trauma. However, the major revision of the AIS in 2005 led to a reduction in severity for many injuries, in line with improved survival since the 1998 version. Consequently, it has been suggested that the definition of major trauma should be changed to an ISS of greater than 12.[41,42]

New Injury Severity Score.

The NISS was formulated to address ISS shortcomings in quantifying multiple occurrences of serious injuries within the same body region.[32] NISS is the sum of the squares of the three most severe AIS injuries, regardless of body region and, as with the ISS, an AIS of 6 automatically translates to an NISS of 75. This permutation offers a slight predictive advantage but has several of the same shortcomings as the ISS.

Anatomic Profile.

The AP, developed by Sacco and colleagues, uses AIS severity scores with an adjustment for differences across body regions.[21] Three modified components are weighted to form a single scalar based on anatomic location of all serious injuries (AIS >3). The AP overcomes many modeling defects inherent in ISS and NISS and avoids the excessive complexity and nontransportability in scores such as the TMPM.[33] The fact that the AP has not supplanted the ISS, however, is probably a reflection of the general lack of understanding of injury severity modeling in the injury research community.

ICD Injury Severity Score.

The ICISS took an empirical estimation approach to injury severity scoring with the formulation of ICD-9 survival probability (P_s).[34] P_s is an ICD code-specific estimate of the survival probability associated with that particular injury. The traditional ICISS is calculated as the product of P_s for as many as 10 injuries and ranges from 0 (unsurvivable) to 1 (null probability of death). Other versions of the ICISS include P_s of the worst injury and independent P_s calculated on patients with isolated injuries. A similar approach was used in the 1970s, with each ICD code being given a conditional and definitive P_s related to the presence of other injuries.[35]

The ICISS offers several advantages over other anatomic scores. First, because it is based on the ICD coding lexicon, it can be used in any clinical setting, including smaller centers that typically do not perform AIS coding. Second, unlike the consensus-derived AIS severity scores, the ICISS empirical approach enables powerful statistical estimates of injury-specific survival if the patient population used to derive them is large enough. Consequently, unlike the ISS and NISS, the ICISS is a smooth, if nonlinear, function of mortality.

The ICISS does, however, have limitations. First, although it resembles an overall probability, the ICISS can only be considered a scalar because P_s is often "contaminated" by patients with multiple injuries. Independent P_s can be calculated as mentioned earlier, but these are not available for all codes because many injuries rarely occur in isolation.[40] Second, P_s is database specific, and the degree to which it is applicable in injury populations with different patient characteristics remains uncertain.[41] Third, because empirically based injury severity scores are based on observed all-cause mortality, the ICISS is not an independent measure of anatomic injury but inherently incorporates physiologic reserve and physiologic reaction to injury, which vary across injury diagnoses. Finally, the ICISS has been validated for ICD-10 in a large aggregation of seven countries (Australia, Argentina, Austria, Canada, Denmark, New Zealand, and Sweden; 4 million observations) but will not be available for US data for several years.[43]

Trauma Registry Abbreviated Injury Score.

ICD codes are nominal, meaning they are unordered, qualitative categories not ranked by severity. If one ignores the AIS severity score, AIS codes can also be treated nominally, taking advantage of their specificity in injury classification. As such, AIS injury descriptor codes can be used to calculate P_s, similar to the ICISS. The TRAIS is the product of AIS-derived P_s. Kilgo and colleagues showed that ICISS and TRAIS behave similarly in a large group of patients coded both ways and that TRAIS predicts mortality more accurately than its AIS counterparts ISS, NISS, and AP.[44] Although ICISS and TRAIS are derived from two different coding systems, they behave similarly in terms of their association with mortality. This suggests that empirical approaches might obviate the inherent structure of the coding systems.

Trauma Mortality Prediction Model. The TMPM is also based on P_s associated with AIS codes, generated using NTDB data. It adds a level of complexity because it is calculated as a weighted sum of coefficients from two probit models of mortality: one based on AIS pre-dot codes and one on body region injured.

ICD-MAP. To address the lack of an injury severity scoring mechanism in the ICD classification system, MacKenzie and colleagues developed an algorithm to convert ICD-9-CM codes to AIS90 codes.[45] The algorithm has more recently been updated to map ICD-9 or ICD-10 codes to AIS05 (update 2008) codes.[46-48] Mapped AIS codes can be used to calculate AIS consensus-based severity scores including the ISS, NISS, and AP. This algorithm has proven useful for quantifying injury severity in administrative databases, but mapping is not achieved for all ICD codes, and the performance of mapped AIS injury severity scores for predicting mortality is significantly inferior to directly coded AIS severity scores and ICD-based scores (eg, ICISS).[19,49]

Trauma clinicians, outcomes researchers, and hospital administrators may ask which of these approaches is best. There is no consensus, and many publications every year continue to debate this question. Several large studies, including ones by Sacco[49] and colleagues and Meredith and colleagues,[19] compared these anatomic scores in terms of their ability to predict mortality. Both studies found that AP and ICISS better discriminate survivors from nonsurvivors than ISS, NISS, and the ICD-MAP versions of ISS, NISS, and AP. A surprising finding was that MAIS performed better than its multi-injury counterparts ISS and NISS. Based on this result, Kilgo and colleagues[44] showed that the patient's worst injury, regardless of coding lexicon (ICD-9 or AIS) or estimation approach (AIS severity consensus or empirical P_s), was a better predictor of mortality than multi-injury scores. Harwood and colleagues[50] reported that the NISS was better than the ISS and equivalent to the MAIS in the prediction of mortality in blunt trauma patients.

However, many of these studies have not accounted for other risk factors inherently incorporated into empirical scores (eg, age, comorbidities, physiologic reaction). Studies that do not account for these risk factors when comparing consensus-based and empirical scores unfairly disadvantage the former.[51] As mentioned earlier, through the large body of research on injury scoring systems, we have learned that each of these scores has strengths and limitations, and the choice of score should be adapted to the outcome, data, and study population at hand.

Physiologic Scoring Systems and Models

Anatomic injury unleashes a set of physiologic and biochemical consequences that require modulation and mitigation as part of the patient's treatment. The concept of integrating physiology into injury severity modeling recognizes the dynamic and time-dependent changes to physiologic status following injury. A patient with a ruptured spleen who is seen within 1 hour of injury might be normotensive and, when appropriately and promptly treated at a trauma center, will have a very low risk of dying. A patient with the identical anatomic injury who is seen 4 hours later, for whatever reason, may present with a systolic blood pressure (SBP) of 60 mm Hg and a significant risk of death, despite availability of the same system of in-hospital care. The hospital should not be penalized if the patient dies (but perhaps the trauma system should). Integration of physiologic parameters on arrival with other data is therefore essential for accurate case-mix adjustment and outcome prediction in injury research.

Early death following injury occurs as a result of central nervous system (CNS) impairment, hemorrhage, respiratory causes, or a combination of these. Clinical markers, including RR, SBP, base deficit, and reaction to stimuli/state of consciousness, are important prognosticators of outcome and are routinely used in clinical management. However, unlike anatomic injuries and preexisting comorbidities, which are fixed at the time of hospital admission, physiologic parameters are ever-changing, both spontaneously and in response to therapy. Thus, it is necessary to obtain a "snapshot" of physiologic status at one point in time, usually immediately upon ED or trauma center arrival. The main physiologic scores currently in use in injury research include the GCS and the Revised Trauma Score (RTS), which is a composite of the GCS, RR, and SBP.

GLASGOW COMA SCALE

The GCS was first proposed by Teasdale and Jennett as a means to directly triage brain-injured patients and to monitor postoperative craniotomy patients.[52,53] The GCS was subsequently integrated into the Trauma Score/RTS to describe level of consciousness without using subjective terms such as *semicomatose* and *lethargic* to classify head injury following trauma.[54] GCS measures brain function via three components: (1) motor (GCS-M), (2) verbal (GCS-V), and (3) eye opening (GCS-E), each with ordinal characterizations of severity (Table 5-2). The sum of scale components ranges

TABLE 5-2: Descriptors of Glasgow Coma Scale (GCS) Components

Function	Description	GCS scaled value
Eye	Spontaneous	4
	To voice	3
	To pain	2
	None	1
Verbal response	Oriented	5
	Confused	4
	Inappropriate	3
	Incomprehensible	2
	None	1
Motor response	Obeys commands	6
	Localizes pain	5
	Withdraw (pain)	4
	Flexion	3
	Extension (pain)	2
	None	1

from 3 (completely unresponsive) to 15 (fully conscious), and the GCS score has been shown to be strongly correlated with survival.[55] The motor component alone has been shown to be almost as powerful as the full GCS score for predicting mortality[56] and can be evaluated even when the patient is sedated and/or intubated. However, the verbal and eye components discriminate noncomatose patients and are thus valuable for predicting nonfatal outcomes.[55]

REVISED TRAUMA SCORE

The Trauma Score, later updated to the RTS, was designed by Champion and colleagues as an approach to combining clinical and observational physiologic data into one score.[57,58]

Two forms of the RTS exist, one for triage (Triage-RTS) and one for outcomes evaluation and risk adjustment (RTS). Both are based on the GCS, SBP, and RR (Table 5-3). The Triage-RTS is calculated by summing the coded values for each of the three variables and ranges between 0 and 12. The RTS equation for outcomes evaluation computes indexed values of GCS, SBP, and RR by weighting their coded value with logistic regression coefficients and summing them.

The RTS ranges from 0 to 7.84, with lower scores translating into more physiologic derangement. RTS correlates strongly with mortality[55] and remains important in injury scoring through its contribution to the Trauma Injury Severity Score (TRISS) model (discussed later in this chapter). Studies have also shown that the combined use of SBP and GCS-M is just as effective at predicting patient survival as the RTS.[59] Disadvantages of the RTS include the fact that coefficients are based on MTOS data and have not been updated and that categories of the GCS, SBP, and RR used to calculate the RTS often have very sparse data.[55] The 2009 version of the TRISS did not use the RTS but modeled the GCS, SBP, and RR separately.[60]

Comorbidity Scoring Systems

Injury outcomes research has long recognized the importance of comorbidities in outcome prediction models. For that reason, comorbidities were integrated into the ACS Committee on Trauma (ACSCOT) field triage decision scheme developed by Champion.[61] Morris and colleagues,[62] among others, identified several preexisting conditions that worsen prognosis following trauma, most notably liver cirrhosis, chronic obstructive pulmonary disease, congenital coagulopathy, diabetes, and congenital heart disease. Morbid obesity has now been added to this list.[63] The incorporation of preexisting conditions into injury severity models is difficult because so many potential comorbidities exist, each of which may occur with variable severity. Further, many are relatively rare and may be inconsistently recorded.

Specific comorbidity adjustments, such as the Charlson Comorbidity Index (CCI) or the Elixhauser Comorbidity Index, which are widely used in other disciplines,[64] are frequently used in injury severity models in an attempt to enhance their predictive abilities. Results, however, have been poor.[65,66] This may be because such scores are not adapted to acute injury populations.[66] Indeed, the CCI, a weighted sum of 17 preexisting conditions, is based on coefficients derived in a population of general admissions (mostly chronic diseases) using a Cox proportional hazards model in 1994 (updated in 2004)[67] and is therefore suboptimal for injury research. The number of Charlson comorbidities has been shown to predict injury mortality as well as the CCI.[66] The Elixhauser Comorbidity Index is based on 30 preexisting conditions, including hypertension, obesity, weight loss, and psychiatric disorders that are not included in the CCI. Other approaches include using the presence of individual comorbidities or classes of conditions (ICD ranges) or simply using patient age as a surrogate for comorbidities. Injury-specific comorbidity indices include the Mortality Risk for Trauma Comorbidity Index,[68] which achieves predictive accuracy for mortality equivalent to the CCI with just six items. With the aging of trauma populations, comorbidity and multimorbidity will increase, and accounting for these factors in injury research will become increasingly important. Further efforts should therefore be made to develop injury comorbidity indices for mortality but also for nonfatal outcomes, including complications, functional capacity, quality of life, and resource utilization.

TABLE 5-3: Revised Trauma Score (RTS)

Coded value	GCS	SBP (mm Hg)	RR (breaths/min)
0	3	0	0
1	4–5	1–49	1–5
2	6–8	50–75	6–9
3	9–12	76–89	>29
4	13–15	>89	10–29

GCS, Glasgow Coma Scale; RR, respiratory rate; SBP, systolic blood pressure.

Injury Outcome Scales

Outcomes following injury are widely measured in terms of mortality, complications, and resource utilization. However, there are several scales that can be used to measure functional outcomes and quality of life.

The Glasgow Outcome Scale is designed to provide an objective measure of recovery following brain injury.[69] The extended version ranges from 1 (death) to 8 (upper good recovery), and scores of 5 or more (lower moderate disability to upper good recovery) are considered to be consistent with a favorable outcome.

The Functional Independence Measure aims to assess functional status through the rehabilitation phase of care. It is a propriety scale that scores motor and cognitive function in 18 categories to assess independence in activities of daily living.[70]

Quality of life following injury in adults is often assessed with the Short Form Health Survey (SF-36 or SF-12)[71] or the EuroQol instrument EQ-5D.[72]

Combat Injury: A Special Case

Since the addition of descriptors for coding penetrating injuries with the AIS 1985 edition, researchers have had a tool for evaluating both blunt and penetrating injuries. The descriptors of penetrating injuries included in AIS versions since 1985 describe low-kinetic-energy injuries treated in civilian trauma centers and hospitals. Subsequent iterations have been used to code military combat injuries as well.[73] These codes, however, did not adequately describe commonly seen penetrating combat injuries such as multiple and massive soft tissue fragment wounds, high-velocity penetration, blast overpressure injuries (mutilating or nonmutilating), and/or bilateral and multiple injuries[20,21] that result from explosive devices, including improvised explosive devices, which account for 55% to 75% of combat injuries.[12] They also did not account for, nor were they designed to, some of the injury phenomena associated with mass casualty incidents, for example, crush injuries in earthquake disasters.

ABBREVIATED INJURY SCALE–MILITARY EDITION

To address these issues, a committee of military physicians was formed to work with the International Injury Scaling Committee of the Association for the Advancement of Automotive Medicine to propose guidelines for developing a version of the AIS specifically for coding combat injuries. These physicians represented all three services of the US military (Army, Navy/Marines, Air Force) as well as a spectrum of medical specialties relevant to combat casualty care including emergency medicine and trauma, orthopedic, neurosurgery, and general surgery. AIS 2005-Military is used for coding of all injuries in the three combat trauma registries: (1) the Department of Defense Trauma Registry (formerly the Joint Theatre Trauma Registry) based in San Antonio, Texas; (2) the Navy/Marine Combat Trauma Registry Expeditionary Medical Encounter Database based in San Diego, California; and (3) the Mortality Trauma Registry based at the Office of the Armed Forces Medical Examiner. These registries also code in AIS 2005 (civilian version) and AIS 1998 for future comparisons with civilian trauma registry data.

Development of AIS 2005-Military coincided with the revision efforts that would culminate in publication of the civilian AIS 2005, which included additional expanded descriptors for orthopedic trauma based on the Orthopaedic Trauma Association scale and expanded bilateral injury codes, particularly for vessel injuries. The same consensus model used in determining changes to each injury description by the International Injury Scaling Committee was used to determine AIS 2005-Military scores.

MILITARY COMBAT INJURY SCALE

Despite revisions that culminated in the AIS-Military, numerous combat injuries, such as those caused by explosive devices, still could not be coded or adequately described. Trying to adapt AIS was only moderately successful. Therefore, the Military Combat Injury Scale (MCIS)[24] was drafted by a large panel of military and civilian experts. First, a more anatomically correct and militarily relevant set of body regions was developed (head and neck, torso, arms, legs, multiple), five combat severity levels were determined (minor through likely lethal), and combat-relevant injury descriptions were tabulated.

Using these new body regions, severity levels, and injury descriptors, a five-digit MCIS coding scheme was developed, and 269 codes were assigned. Digit 1 indicates injury severity; digit 2 indicates body region; digit 3 indicates the type of tissue involved; and digits 4 and 5 together indicate the specific injury when combined with digits 1, 2, and 3. This coding scheme allows for injuries to the skull and brain to be identified separately from injuries to the face or neck and for injuries to the chest, abdomen, and pelvis to be separately identified despite being assigned to the same body region. It also allows for identification of unilateral or bilateral injuries, right or left for specific injuries, and easy identification of junctional area vascular injuries.

MILITARY FUNCTIONAL INCAPACITY SCALE

The Military Functional Incapacity Scale (MFIS) was developed at the request of military personnel to correlate immediate functional impairment with MCIS injury severity for ground troops and later for shipboard environments.[24] The ground operational requirement is based on the ability of an injured combatant to (1) communicate, (2) move, and (3) fire a weapon. The MFIS was developed as an ascending scale of functional impairment with four levels, as follows: (1) able to continue mission, (2) able to contribute to sustaining mission, (3) lost to mission, and (4) lost to military.

MFIS levels of incapacity were linked directly to MCIS injury severity. MCIS Severity 1 injuries are not associated with immediate functional incapacity, and casualties are able to continue with the mission; MCIS Severity 2 injuries usually result in immediate functional impairment with the potential for the casualty to contribute to the mission; and MCIS Severity 3, 4, or 5 injuries require medical treatment—casualties who sustain one or more of these injuries are lost to the mission or to the military. Specific Army and Navy scales have been developed.

Combination Injury Severity Models

Combination injury severity models attempt to combine some or all of the three concepts of risk described by MacKenzie[74]: (1) preinjury physiologic reserve (eg, age, comorbidities), (2) physiologic status of the injured patient (eg, GCS, RR, SBP), and (3) anatomic injury severity (eg, ISS, NISS, MAIS, ICISS).

Injury severity models are generally used to quantify patient case mix or to perform adjusted comparisons across injury groups. To date, most injury severity models have been based on mortality, but models based on nonfatal outcomes (eg, complications, readmissions, resource use) have more recently been proposed.[75-77] The most common use is probably for institutional benchmarking.

The most well-known injury severity model is the TRISS.[78] Documented limitations of TRISS include the fact that age is modeled in just two categories (equivalent mortality risk is assumed in all patients 55 years of age or older) and it does not account for comorbidities; in addition, it has other limitations inherent to the ISS and RTS (discussed earlier).[79] Further, the original coefficients are more than 20 years old, although they were updated in 2009 using NTDB data.[60]

In an attempt to address these limitations, many other injury mortality prediction models have been proposed. A Severity Characterization of Trauma (ASCOT) includes age modeled in five categories and uses the AP instead of the ISS.[80] The Harborview Assessment for Risk of Mortality (HARM) is based uniquely on hospital discharge data and includes anatomic injury descriptors (ICD), mechanism, comorbidities, and injury intent.[81] The Revised Injury Severity Classification (RISC) II model uses the AIS severity score of the two worst injuries, head injury, age, sex, pupil reactivity and size, preinjury health status, blood pressure, base deficit, coagulation, hemoglobin, and cardiopulmonary resuscitation.[26] The Trauma Risk Adjustment Model (TRAM) includes comorbidities and transfer status and employs flexible modeling techniques to use all information on continuous covariates (ie, age, GCS, RR, SBP) and to preserve their nonlinear associations with mortality.[82] Several studies have compared the predictive accuracy of injury severity models, and results indicate that the most complex models offer significantly better predictive accuracy and change the results of trauma center benchmarking analyses.[19,49,51] However, these more complex models have trouble supplanting the TRISS.

To address the problem of limited injury data available in low- and middle-income countries, the Kampala Trauma Score (KTS) has also been proposed. Originating in Uganda, the KTS is a "simplified composite of the RTS and the ISS, closely resembling TRISS,"[83] and is calculated along a descending scale of severity (ie, 5–10 = severe; 11–13 = moderate; and 14–16 = mild). Importantly, the KTS does not include anatomic injury description (AIS or ICD) because this would be unfeasible in a low-income setting.

Development of Injury Severity Models

Development of an injury severity model implies rigorous statistical methods in line with guidelines proposed for prediction models.[84,85] The purpose of the model must be clearly defined, the model should be derived on a large sample of (representative) patients subject to the highest standards of care, the choice of potential risk factors should be based on literature review and expert opinion in line with a conceptual model, and the model should allow for nonlinear associations with the outcome (eg, the probability of mortality does not increase linearly with age or the ISS, and associations with SBP and RR are nonmonotonic). The internal, temporal, and external validity of the model should be evaluated. Some injury severity models published to date have been evaluated in terms of apparent performance (discrimination and calibration on the sample used for derivation), but relatively few have been subject to rigorous internal and external validation.

Evaluating Predictive Models

The performance of models is evaluated according to their capacity to accurately predict the outcome of interest. Injury severity models based on binary outcomes (eg, mortality, readmission, complications) are generally based on the logistic regression model. The predictive accuracy of logistic models is evaluated by calculating measures of discrimination and calibration.

MODEL DISCRIMINATION

Model discrimination describes the accuracy of the model for distinguishing between survivors and nonsurvivors and is generally measured using the area under the receiver operating characteristic curve (AUC). This area varies between 0 and 1, where 0.5 indicates a model that discriminates no better than chance alone (noninformative) and 1 indicates a model that discriminates perfectly. Discrimination depends on the frequency of the outcome but, unlike calibration, tends to be relatively stable across similar populations. For example, injury severity models generally have excellent discrimination for predicting mortality (AUC >0.9)[82,86] and good discrimination for complications (AUC = 0.81),[77] but poor discrimination for unplanned readmission (AUC = 0.65).[75] This indicates that baseline risk (physiologic reserve, physiologic parameters on arrival, and anatomic injury severity) explains mortality well but that complications and unplanned readmissions are explained to a greater extent by other factors, such as quality of care. Discrimination is usually considered to be more important than calibration because it cannot generally be improved by modeling strategies.

MODEL CALIBRATION

Model calibration (or goodness of fit) indicates how well the model fits the data or how closely model risk estimates approximate observed event rates across different levels of risk. Good model calibration is dependent on the data at hand and can, to a large extent, be ensured by appropriate model specification, respecting clinically plausible associations between each independent variable and the outcome of interest.

Calibration is often quantified using the Hosmer-Lemeshow (HL) statistic,[87] based on the difference between observed and predicted probabilities of the outcome of interest in prespecified risk groups. The HL statistic has several limitations, including the fact that it is sensitive to sample size (a large, statistically significant value does not necessarily indicate poor model fit), is dependent on the risk groups used (deciles or other), and cannot be compared over different patient samples.[84,88-90]

Calibration should therefore also be evaluated using other strategies, the most useful of which is Cox's calibration curve. This curve is based on plotting predicted against observed probabilities of the outcome, thus providing a global

impression as to how the model fits the data, and enabling the analyst to identify areas where the fit is problematic. The intercept α and slope β of the calibration curve, which should be as close to $\alpha = 0$ and $\beta = 1$ as possible, are useful summary indicators of calibration.[91]

Models can also be evaluated in terms of explanatory power using, among others, *r*-squared adapted to binary outcomes, the Akaike information criterion,[92] and the Brier score.[93]

MODEL VALIDATION

Because the performance of predictive models tends to be overoptimistic in the sample used to derive them, predictive models should be validated in a sample of the study population from which they were derived (internal validation or temporal validation) and in a completely independent sample (external validation).

The internal validity of a model may be evaluated using split-sampling, cross-validation, or bootstrapping. In split-sampling, the model is derived on a random sample of the study population (eg, two-thirds), and it is validated by fitting the same model to remaining observations and calculating metrics of discrimination and calibration. In cross-validation, the sample is split in *k* samples of equal size. The model is repeatedly derived on one or several subsamples and its predictive accuracy evaluated on the remaining subsamples. In bootstrapping, the whole sample is used to derive the model, and it is validated on repeated random samples drawn from the original sample with replacement. The advantage of split sampling is that the validation sample is theoretically independent from the derivation sample (although in practice it has the same characteristics, as it is a random sample). However, bootstrapping has been found to be equivalent to split-sampling and is generally preferred because it uses all observations to derive the model, thereby increasing model precision.[94] The temporal validity of the model can then be evaluated by fitting the model to data collected in the same population at a different time. If the model has acceptable internal and temporal validity, model performance should then be evaluated on a completely independent sample (external validity).

SUMMARY

Current documented limitations do not invalidate the available injury severity models. Indeed, empirical validation studies provide strong evidence that all available models yield risk estimates of acceptable accuracy for groups of patients. The ongoing concerns are how to determine which model is best and how to improve available models. Several trends in recent modeling efforts provide initial answers to both questions. Models that reduce the weight given to secondary injuries relative to primary injuries,[95] incorporate interactions between injuries, and utilize better body region information are examples of promising directions for improving the accuracy of outcome predictions.[96-98] Multilevel modeling and methods that smooth the risk function (eg, spline regression, fractional polynomials) demonstrate directions for analytic refinement.[44,56,99,100] Data simulation techniques such as multiple imputation improve the feasibility of adding physiologic variables to the current anatomic/demographic models without excluding observations.[101] The growing access to extensive databases, improvements in analytic tools, and increased sophistication of substantive models lead to a straightforward conclusion: Today's models are good; tomorrow's will be better. However, analogous to severity scoring systems, the optimal injury severity model will depend on the data available, the study population, the exposure of interest, and, in particular, the outcome under evaluation.

INJURY OUTCOMES RESEARCH

Injury outcomes research aims to improve our understanding of the determinants of optimal injury outcomes with the ultimate goal of reducing the societal burden of injury. Patient outcomes were at one point focused solely on survival, but contemporary injury outcomes research has integrated nonfatal outcomes, including measures of morbidity and resource use. We are also gradually moving away from a predominant focus on intrahospital objective outcome measures toward patient-reported outcome measures,[102] such as health-related quality of life and function in daily activities, in line with patient-oriented research. These changes reflect a trauma community that has begun to embrace the World Health Organization's definition of health as a "state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity."[103] The objective of this section is to provide an overview of the basic elements of injury outcomes research.

Basics of Outcomes Research

A comprehensive programmatic approach is essential to answering the complex research questions that arise in injury research. Such an approach should include a systematic review of the literature with or without meta-analysis (scoping or rapid reviews may also be appropriate), analysis of retrospective cohort data, pilot data collection, and progression to a randomized controlled trial (RCT) or a well-designed prospective cohort study when an RCT is not possible. The first step in successful research is the rigorous elaboration of a strong research protocol in collaboration with methodologic experts and key stakeholders. There is an increasing trend toward registering and publishing study protocols.[104] One example of injury research that demonstrates the challenges of conducting studies in injury populations and has defeated many over the past decades is acute resuscitation. Significant challenges include obtaining sufficient sample sizes (participation from multiple institutions is often required), randomizing patients in the acute care phase, and defining appropriate end points. The insistence on 30-day end points by the US Food and Drug Administration when the vast majority of deaths occur within the first 3 to 12 hours following injury represents a significant barrier to interpretable research results and increases cost and risk of confounders.

According to Kane,[4] outcomes research comprises the following five essential steps:

1. Define a research question.
2. Develop a conceptual model.
3. Identify the critical dependent and independent variables.
4. Identify appropriate measures for each.
5. Develop an analysis plan.

RESEARCH QUESTION

Central to the success of a research project is the translation of a research question into carefully thought out research objectives and hypotheses. Rigorous research requires significant financial and human resources. Scientific ethics therefore require a demonstration that addressing the research question will significantly advance current knowledge. To do so, the researcher must be able to show, usually through a systematic literature review, that the question has not been adequately addressed in the past and that the research has the potential to have a positive direct or indirect impact on patient outcome. One important aspect in defining the research question is to establish whether the intention is to predict an outcome from a series of independent variables or to explain the association between one or more exposures and the outcome of interest. The injury severity models mentioned earlier (eg, TRISS, ASCOT) were derived to calculate predicted probabilities of mortality for benchmarking purposes, but injury outcomes research often aims to explain the association between an exposure variable (eg, intervention) and an outcome by estimating a measure of association (eg, odds ratio). Predictive and explicative research goals require very different analysis plans. The derivation and validation of predictive models has been covered earlier in this chapter. In this section, we will concentrate on explicative modeling of injury data in observational studies.

CONCEPTUAL MODEL

Each step of outcomes research is critical, although none more so than refining a research question through the elaboration of a conceptual model. Prior to building the conceptual model, investigators should carefully define the target population for the study, that is, the population to which they wish to generalize results. For example, in the study of the effect of surgical delay on complications for long-bone fracture fixation, the target population may be all patients 16 to 64 years of age admitted to a not-for-profit acute care center in a high-income country and requiring long-bone fracture fixation. The conceptual model should be elaborated as a causal diagram using directed acyclic graphs[105] (DAGs) and based on information from literature review and expert opinion. DAGs will provide the foundation for understanding how the association of interest between exposure variable(s) and outcome(s) is influenced by confounding, mediating, and moderating variables. In the example shown in Fig. 5-2, the association between trauma center care (exposure) and mortality (outcome) is of primary interest. Physiologic reserve, physiologic reaction, and anatomic injury severity are confounders, and interventions are mediators.

Study Sample. Prior to collecting information on the variables of interest, one must identify the study sample that will be used to address the research question. Careful choice of the study sample with clear inclusion and exclusion criteria in line with the target population is important for the external validity of a study. Ideally, the study population would be a random sample of the target population, but this is rarely possible. A convenience sample is therefore often used. For example, when studying the association between surgical delay for long-bone fracture fixation and complications, data availability may lead us to include only patients eligible for participation in the trauma registry when, ideally, we would include all admissions for long-bone fracture fixation within a health system. The consequences of the choice of study sample on the generalizability of results should be carefully thought out and discussed.

OUTCOME/DEPENDENT VARIABLES

The dependent variable represents the outcome of interest that we want to predict or explain with independent variables in the model under study. According to the quality of health care model proposed by Donabedian,[106] outcomes that should be evaluated to improve patient care include mortality, adverse events, unplanned readmission, resource use,

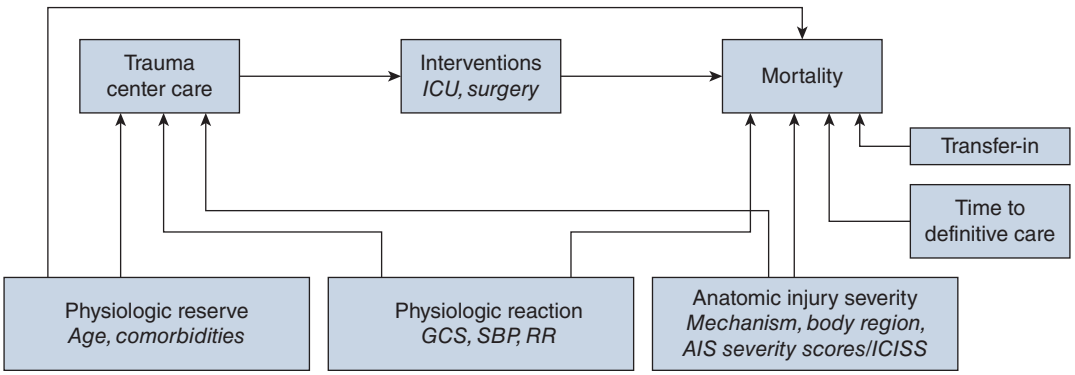

FIGURE 5-2 Causal diagram of the association between trauma center (vs nondesignated center) care and injury mortality. AIS, Abbreviated Injury Scale; GCS, Glasgow coma scale; ICISS, International Classification of Diseases Injury Severity Score; ICU, intensive care unit; RR, respiratory rate; SBP, systolic blood pressure.

quality of life, and ability to function in daily activities. A 2013 systematic review identified 14 nonfatal outcomes that have been used to evaluate injury care quality.[107] The most common were complications (35 of 40 studies) and hospital/ICU LOS (34 studies). Only three studies evaluated ability to function in daily activities, four evaluated unplanned readmission, and none used quality of life.

Outcome variables are frequently dichotomous in injury research because they represent the presence or absence of a health state (eg, mortality, complications). Depending on the design of the study, the outcome may be measured in terms of prevalence, incidence proportion, or incidence rate. For example, in a transversal study on community-acquired infection, the outcome may be measured as a prevalence (eg, presence or absence of infection on arrival). In a longitudinal study on hospital-acquired infection, the outcome may be measured as an incidence proportion or incidence rate (development of the infection over the hospital stay). In injury research based on trauma registry/hospital discharge data, retrospective cohort studies are common, and hospital outcomes are generally measured in terms of incidence proportions because events of interest often occur shortly after injury and time to event is of little interest. Incidence rates are common in chronic disease populations and may be more appropriate than incidence proportions for longer-term injury outcomes where loss to follow-up is an issue. Incidence proportions should be based on evaluation of outcome over a fixed period of time (eg, 30-day mortality), but information on postdischarge events is rarely available. Previous research has shown that hospital mortality, 30-day in-hospital mortality, and 30-day in-hospital and postdischarge mortality agree well, at least for patients less than 65 years of age.[108] However, the same is unlikely to be true for complications, which are a common reason for unplanned hospital readmission.[109]

The choice of outcome variable and the timing of outcome evaluation should be carefully adapted to the research question and target population. Hemorrhagic shock and/or brain injury are responsible for 90% of deaths following injury, and 80% of these deaths occur on the scene or in the hospital within 4 hours.[110,111] Therefore, as mentioned earlier, in resuscitation research, 4- or 24-hour mortality may be a more appropriate primary end point than 30-day mortality (Fig. 5-3).[112] The latter includes deaths due to comorbidities and late effects of injury (eg, complications), which may confound intervention evaluations. As mentioned earlier, the inclusion of prehospital deaths, which compose more than 50% of all injury deaths,[113] represents a significant advantage when systems of care or prehospital interventions are being evaluated.[114-116] Researchers are increasingly looking to assess outcomes that are important to patients.[117] For hemorrhagic shock, that may be mortality, but for brain, spinal cord, and orthopedic injuries, function in daily activities and quality of life are more likely to be meaningful.

INDEPENDENT VARIABLES

If the goal is to predict outcome, independent variables will be risk factors of the outcome, with consideration for the availability of information in populations intended for the prediction model. If the goal is to explain the association between an exposure(s) and outcome, independent variables will include the exposure variables of interest and covariates that influence the exposure(s)-outcome association(s).

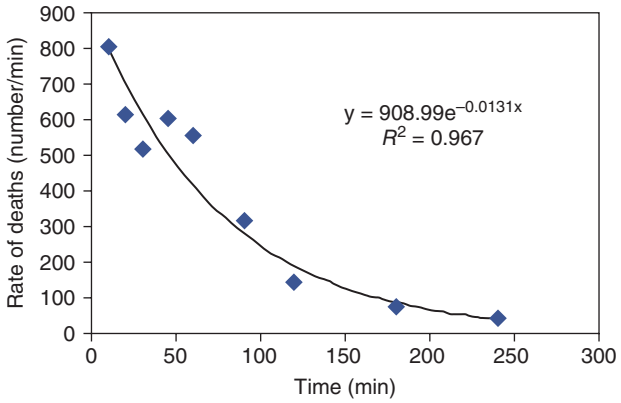

FIGURE 5-3 US vehicle-related deaths 5 minutes to 4 hours after injury, 2003–2005.[112]

COVARIATES

In an explicative design, covariates are independent variables that are known to influence the exposure-outcome association but whose relationship to the outcome is not of primary interest. They may be confounders, mediators, or modifiers and will be identified by the conceptual model (Fig. 5-2) and confirmed empirically during the analysis stage.

Confounders. Confounding variables are risk factors of the outcome that are also associated with the exposure (Fig. 5-2). Not adjusting for confounder variables in the statistical model will lead to a biased estimate of the exposure-outcome association. For example, if we evaluate the association between treatment in a designated trauma center (exposure) and mortality (outcome) and patients treated in a trauma center are sicker than patients treated in nondesignated hospitals, not accounting for injury severity would lead to an underestimation of the beneficial effect of trauma centers on injury mortality. The measure of association between trauma center designation and mortality (eg, odds ratios or relative risks) would thus suffer from confounding bias. In injury research, potential confounders are often identified among risk factors of the outcome that commonly cover physiologic reserve (eg, age, gender, comorbidities), physiologic reaction to injury (eg, GCS, SBP, RR), and anatomic injury severity (mechanism of injury, body regions injured, AIS- or ICD-based severity scores).[74] Randomized, double-blinded, controlled clinical trials should not suffer from confounding bias because risk factors are evenly distributed across exposure groups so the confounder-exposure association in the study sample is null.

Mediators. Mediator variables are caused by exposure and in turn cause the outcome. For example, in the association

between trauma center care and mortality, acute care (in-hospital) interventions would act as mediators. Some or all of the effect of the exposure on the outcome may pass by the mediator. In outcomes research, we usually aim to evaluate the total effect of exposure on outcome. It is therefore important not to adjust for mediator variables; otherwise, we will obtain an estimate of the direct effect only, which is an underestimation of the total effect. In the example, if we adjusted for in-hospital interventions, we would underestimate the effect of trauma center care on mortality. The distinction between mediator and confounding variables is critical to valid injury research.

Modifiers. Effect modifiers are variables that modify the association of interest. For example, we may expect trauma center care to reduce mortality for major trauma but to have no effect for minor trauma. If this is the case, injury severity would be said to modify the trauma center–mortality association. In outcomes research, potential effect modifiers are identified a priori, and usually, only one or two are specified because effect modification implies estimating the exposure-outcome association for each category of the modifying variable, thus increasing necessary sample size and the probability of a type I error due to multiple comparisons. Note that effect modification is not a bias but rather a natural phenomenon, which is present even under randomization. Global estimates of the exposure-outcome association are valid even under effect modification. Frequent effect modifiers in injury research are age (pediatric, adult, geriatric), injury severity, and type of injury (eg, TBI, blunt multisystem, penetrating). Stratifying analyses by injury type is particularly informative due to the heterogeneous nature of injury. For example, the pathophysiologic sequence to death in patients with isolated head injury is completely different from that for hemorrhagic shock; estimating a global exposure-mortality association for both patient populations may therefore be less meaningful.

ANALYSIS PLAN

Injury outcomes research is widely based on generalized linear models. The scale of measurement for the outcome variable will determine which model should be used. For outcomes measured on a continuous scale (eg, LOS, costs), a linear model will generally be appropriate. However, variables such as LOS or costs are right-skewed (many patients have an LOS <7 days and a few have LOS >90 days), so when sample sizes are small (ie, <100 observations per independent variable), log-linear models or gamma models may be more appropriate.[118] Sensitivity analyses should be conducted to evaluate the influence of outliers (eg, truncate LOS at the 95% percentile) and model specification on study results. Another issue with nonfatal outcomes such as LOS and costs is the competing risks of death, particularly in populations with high mortality (eg, severe TBI). This may need to be addressed with competitive risk models to avoid survival bias (discussed in the later section "Common Pitfalls and Mitigation Strategies in Injury Outcomes Research"). For ease of interpretation, results from simpler models should be preferred over those from more complex models when similar results are obtained.

For injury outcomes measured on a dichotomous scale (eg, mortality, readmission, complications), logistic or log-binomial models are commonly used. Logistic models are easier to use because convergence is rarely a problem (the logit of a proportion is not bounded, whereas the log of a proportion has a maximum of 0). However, odds ratios (logistic model) overestimate relative risks (log-binomial model), and this overestimation increases as the outcome becomes more common. For this reason, log-binomial models are generally preferred when the outcome occurs in more than 10% of patients.[119] The convergence problems encountered in log-binomial models can generally be overcome by using a Poisson model with robust variance estimates.[119] Finally, if long-term outcomes are of interest (eg, mortality up to 12 months after injury), incidence rates may be more appropriate than incidence proportions, in which case the Cox proportional hazards model is usually the model of choice.

Once the analysis model has been chosen, particular attention should be paid to the specification of independent variables. This should be based on a priori hypotheses about the functional relationship between each independent variable and the outcome using literature review and expert opinion. This stage is essential if we are to build a model with good face validity and to respect the postulate of a linear relationship between the independent and dependent variables, required for most parametric regression models. If this postulate is not respected for exposure variables, associations may be underestimated or missed, and for confounding variables, the exposure-outcome association may be subject to residual confounding, which can lead to over- or underestimation of the association(s) of interest. In injury research, most continuous independent variables do not have a linear relationship with mortality. For example, for general injury admissions, mortality risk is stable for patients 16 to 54 years of age and increases exponentially thereafter.[86] For SBP and RR, the change in mortality risk is not monotonic because risk increases both for patients who are hypotensive/hypoventilate and for those who are hypertensive/hyperventilate. These variables can therefore not be modeled using simple linear terms but should be specified using dummy variables on categories or more complex functions such as fractional polynomials or splines.[120]

All of these modeling strategies have advantages and disadvantages. Dummy variables on categories are easy to understand, operationalize, and present. However, disadvantages include difficulty identifying appropriate cut points, categories with small sample sizes, and nonintuitive step changes in risk. Fractional polynomials or splines offer more flexibility and therefore better model fit, but are complex and difficult to present. Simulations suggest that covariables modeled with dummy variables on at least four categories offer equivalent confounding control to fractional polynomials or splines.[121] However, the latter are interesting tools for graphically describing the functional relationship between the exposure variable(s) and the outcome. One often overlooked point is

that when scores based on probabilities (eg, ICISS) are modeled as independent variables in a logistic (log-binomial) model, they should be logit (log)-transformed to preserve the linearity assumption.[122]

As discussed earlier, an explanatory model contains exposure variable(s) and all potential confounders of the exposure-outcome association, commonly risk factors of the outcome. However, when sample size is an issue, a more parsimonious model may be required. This may involve a manual backward model selection approach, whereby potential confounders are removed from the model one at a time, starting with those that have the weakest association with the outcome (highest *P* value). Covariables are reintroduced into the model if their removal leads to a change of more than 10% in the exposure-outcome association estimate (eg, odds ratio, relative risk).[123]

MULTILEVEL MODELS

The generalized linear models described earlier are only valid under the assumption that outcome probabilities are independent. In many injury research contexts, this assumption is not respected. Common examples include study samples in which the same patient can be counted more than once for different injury events, samples that include several hospitals or trauma systems (cluster design), or studies in which the outcome variable is measured repeatedly over time on each patient (repeated measures design). If traditional methods are used to analyze such study samples, effect estimates (eg, odds ratio, relative risk) will be accurate, but variance estimates will generally be too low (increased chance of rejecting the null hypothesis when it is true).

The first example is not generally a problem in injury research because repeat visits for different injury events usually represent less than 10% of injury populations. Cluster samples are problematic, however, and generally require multilevel modeling techniques to correctly estimate variance.[109,124,125] Multilevel models are a simple extension of the traditional models described earlier, which allow for estimation of different intercepts and/or slopes for different clusters (eg, hospitals). These models can be useful for simultaneously modeling patient-level effects, such as age or injury severity, and hospital-level effects, such as volume or designation level. Generalized estimating equations are commonly used to account for intraindividual dependence in outcomes in repeated measures designs.[126]

OTHER STATISTICAL MODELS FOR INJURY RESEARCH

The traditional explicative models described earlier may not control well for confounding, especially with small sample sizes. Several new methods have been proposed to address this problem, including propensity scores and instrumental variables.

Propensity scores are obtained by modeling the exposure variable on all confounding variables and obtaining a score that is the probability of being exposed given confounders.[127] This score can then be used for matching, or simply included in the exposure-outcome model as a covariate to control for confounding. Propensity scores have been used to evaluate the hypothesis that intracranial pressure monitoring leads to a reduction in mortality in severe TBI patients[128] and to evaluate the advantage of helicopter transport over ground emergency medical services in the same patient population.[129] The propensity scores approach is based on the same confounder information as a traditional model so cannot theoretically reduce residual confounding. However, it does offer an advantage in terms of statistical power, particularly when the exposure is common and the outcome is rare.

Instrumental variables are intended to act as a proxy for unmeasured confounders.[130] Including them in the analysis model should therefore reduce residual confounding if they are chosen carefully. For example, Prada and colleagues[131] used the proportion of resident population served by helicopter ambulance services (at the state level) as an instrumental variable for evaluating the influence of Level I trauma center treatment on return to work, and Haas and colleagues[132] used county-level trauma center transport rate to evaluate the benefit of direct trauma center transport in a regional trauma system. However, choosing appropriate instrumental variables is not a simple task because they should be highly correlated with exposure but only associated with the outcome through the exposure variable.

The major problem with the methods described so far is that they are based on simple unidirectional associations with a single outcome. To improve our understanding of the influence of trauma systems and their components on multiple short- and long-term outcomes, more sophisticated statistical models are required. Examples of statistical methods that can better account for the multidimensional time-varying associations in injury research include marginal structural models,[133] structural equational models,[134] and microsimulation models.[135] These models are promising for gaining a better understanding of complex causal patterns and for evaluating the potential impact of modifying interventions on outcomes. However, all of these methods rely on the availability of high-quality, multidimensional data.

SAMPLE SIZE GUIDELINES

Sample size and power analysis can quickly become extremely complex with many hypothetical parameters to estimate, particularly for multivariable models and further still for multilevel models. However, accurate sample size calculations are essential to ensure studies have sufficient power to detect clinically meaningful associations. Several rules of thumb based on simulations are available to simplify the sample size estimation process. In general, for logistic, log-binomial, or Cox models, 10 outcome events per independent variable are necessary to obtain estimates with acceptable bias and precision.[136] For example, in a study sample of 1000 patients with 10% mortality, no more than 10 independent variables should be included in the model (dummy variables on categories count!). More recent research has suggested that five outcome events per independent variable are sufficient.[137] For

linear models, suggested sample size requirements are 10 to 25 observations per independent variable.[138] In injury outcomes research based on specific pathologies (eg, patients in hemorrhagic shock), studies based on single institutions will never reach sufficient statistical power to be meaningful and current. Collaborative multicenter research is thus essential to achieving sufficient sample size and representivity to confirm research hypotheses (explanatory analysis), rather than simply generate them (exploratory analyses). Researchers should also bear in mind that very large sample sizes like those seen in national or international trauma registries may lead to statistically significant associations that are not clinically important or even relevant.

COMMON PITFALLS AND MITIGATION STRATEGIES IN INJURY OUTCOMES RESEARCH

As in any research domain, injury research is vulnerable to bias, which should be considered in study design, analytical approaches, and interpretation of results. The following are some of the more common challenges of injury outcomes research:

- *Evaluating long-term outcomes*. Studies based on injury cohorts are often subject to high loss to follow-up over time as patients are more exposed to precarious living conditions than in chronic disease populations. They are also less likely to comply with treatment instructions or follow-up visits.
- *Obtaining patient consent*. Obtaining consent from the patient or family in a critical care situation is often very difficult. Ways to circumvent this problem include deferred and community consent.
- *Multiple admissions due to transfer*. Acute injury care often implies multiple hospital admissions due to transfer, particularly in an inclusive trauma system. Trauma registries and hospital-based cohort studies often fail to incorporate information on multiple admissions. This can lead to an underestimation of mortality and complication rates and resource use, including interventions. In many systems, linkage between registry- or hospital-specific databases and hospital administrative data enables investigators to track patients through multiple admissions.[139]
- *Survivor bias*. Injury research based on nonfatal outcomes is complicated by survivor bias.[140,141] For example, LOS is not fully observed (right censored) in fatalities. Therefore, if deaths are included in group comparisons of mean LOS, the latter will be underestimated in groups with higher mortality. If deaths are excluded from analyses, groups with lower mortality will have a high proportion of critically injured patients (those who did not die) and, therefore, higher mean LOS. In both scenarios, analysis will unfairly favor groups with higher mortality rates. Survivor bias may lead to biased measures of associations between interventions and outcomes, as fatalities may die before they can receive the intervention. It also leads to the detection of more injuries, comorbidities, and complications in survivors than in fatalities. Survival bias can be addressed with competitive risks models such as the subdistribution hazards model, introduced by Fine and Gray (more appropriate for predictive modeling), and the cause-specific hazards model (more appropriate for explicative modeling).[142] The former is mathematically equivalent to attributing the worse outcome (eg, longest LOS or highest cost) to deaths in a proportional hazards model. However, measures of association are difficult to interpret; the Fine and Gray model of LOS generates hazard ratios of hospital discharge.
- *Heterogeneity in injury coding*. The validity of intergroup comparisons in injury research is dependent on homogeneous injury coding across groups. Injury coding is particularly susceptible to heterogeneity across data collection sites, due to local coding conventions, and over time, due to changes in coding conventions. More obvious examples of the latter include changes in AIS versions; injury severity scores calculated with AIS 2008 are lower on average than injury scores calculated with AIS 1990, as discussed earlier.[143] AIS 2005/2008 to AIS 1990 conversions are available but are imprecise. In such a situation, analyses should be stratified by time period, and temporal comparisons should be conducted with caution. For comparisons between trauma centers or systems, analysts should be aware of intersite or intersystem differences in coding conventions and perform appropriate sensitivity analyses.
- *Missing data on physiologic parameters*. The GCS and RR are frequently used as covariates for risk adjustment in injury research. However, they are missing in 15% to 50% of patient files (and thus in trauma registries) due to prehospital sedation and/or intubation or lack of evaluation in patients with minor extracranial injury.[103,144] Excluding these variables from analysis may lead to confounding bias, whereas excluding patients with missing physiologic data may lead to selection bias and reduced statistical power. Possible solutions to this problem that have been proposed include using just the motor component of the GCS (can be evaluated in sedated/intubated patients) and simulating missing data using imputation techniques.[145] Perhaps the most promising technique proposed to date is multiple imputation (MI), whereby multiple plausible values are generated by simulation for each missing data value based on an imputation model that includes all independent and dependent variables to be used in the analysis model.[145] This technique takes account of the uncertainty surrounding the real data value in subsequent variance estimates. Much work has been done to evaluate the validity of MI for missing physiologic data in injury research, and simulations suggest that when the MI model is specified correctly, MI leads to valid effect estimates.[146,147] However, these solutions will never be as good as complete data and should not be used as a replacement for efforts to improve data quality.
- *Missing anatomic data*. Without autopsy records, anatomic data for early deaths are not fully available, and in many jurisdictions, autopsies are not frequently performed.[147] This results in an underestimation of injury severity in

early deaths, which leads to information bias in the evaluation of associations between exposure(s) and mortality.

SENSITIVITY ANALYSES

Since no observational study is exempt from selection, information, or confounding bias, sensitivity analyses should be used to evaluate the extent of the influence of these biases and any other analytical assumptions on study results. Robust sensitivity analyses plans should be developed a priori and integrated into the study protocol. For example, in evaluating the influence of trauma center care on mortality, sensitivity analyses may consist of (1) excluding deaths within 6 hours of arrival to account for underestimation of injury severity in early deaths and survival bias, (2) restricting analysis to patients age less than 55 years to assess the potential influence of underreporting comorbidities, (3) excluding deaths transferred in with GCS of 3 on arrival to address the problem of interfacility transfer for organ donation, (4) excluding patients age 85 or over to assess the potential influence of do-not-resuscitate orders, and (5) excluding patients transferred out to another acute care center to address varying rates of repatriation across hospitals. These sensitivity analyses will not provide definitive answers but will give an idea of the potential influence of bias on study results that can be used in formulating study conclusions.

BENCHMARKING

Comparing quality metrics within or across trauma centers or systems is central to the process of quality improvement. Benchmarking in injury care was initiated with the TRISS model, which has been used for decades to inform trauma care quality improvement activities worldwide. As mentioned earlier, despite its important contribution to trauma care quality, the TRISS has several documented limitations, including lack of adjustment for comorbidities and transfer status, consideration of age in just two categories, and the fact that performance statistics (W, Z, or standardized mortality ratios) cannot be used for interhospital comparisons.[148] Perhaps the most important limitation is the standard used for comparison. The MTOS cohort is now outdated, and the NTDB cohort used to generate the most recent published coefficients (2009) was based on voluntary participation with nonuniform inclusion criteria and nonstandardized coding practices. These limitations have been addressed in more recent benchmarking models.

Injury benchmarking has now moved beyond TRISS mortality calculations, and the injury research community has embraced the quality of care model introduced in 1966 by Donabedian.[106] Donabedian's model is based on the evaluation of structure, process, and outcome (Fig. 5-4),[149] where structure refers to physical characteristics of the health care provider (eg, presence of closed ICU), process refers to the use of evidence-based clinical interventions (eg, antibiotic prophylaxis for open fractures within 1 hour of presentation), and outcome refers to the result at the end of the care process (eg, mortality, morbidity, resource use). According to this model, improvements in structure lead to improvements in compliance with evidence-based processes, which in turn have a positive impact on patient outcomes.

Benchmarking under Donabedian's model implies the derivation and validation of a series of quality indicators (QIs) that cover the three quality domains. The American College of Physicians Performance Measurement Committee recently developed criteria to evaluate performance measures.[150] According to these criteria, QIs should be important (have a meaningful clinical impact), measure appropriate care (overuse, underuse, and appropriate timing), have a clinical evidence base, be clearly defined with good validity and reliability and appropriate risk adjustment, and be feasible and applicable. QIs should be developed in close collaboration with clinical and methodologic experts, knowledge users, and stakeholders according to the following steps: (1) identify structures, processes, and patient outcomes on which health care providers should be evaluated; (2) develop a risk-adjustment strategy, when appropriate; (3) establish a benchmark to which providers can be compared; and (4) evaluate the internal and external validity of QIs.

Step 1. The goal is to identify structures and processes of care that have a positive impact on patient outcome and measures of outcome that appropriately represent the burden of injury in terms of mortality, morbidity, and resource utilization. These should be supported by the best available evidence (identified using a systematic literature review) and expert opinion (expert consensus process involving clinicians, health care administrators, measurement experts, and patient-partners). This step is crucial if benchmarking results are to be used to improve care; previous research has provided evidence that there is little correlation between certain quality metrics and actual quality of care.[151]

Step 2. Structure or process QIs rarely require case-mix adjustment because they are based on the careful definition of providers/patients eligible for each structure/process (eg,

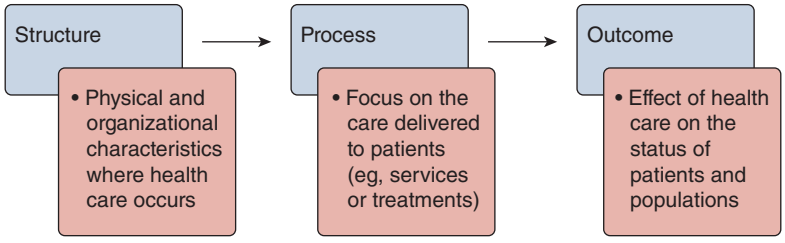

FIGURE 5-4 Donabedian's quality of care model.[149]

all Level I trauma centers should have closed ICUs, and all patients with GCS <9 on arrival should be intubated in the ED). However, appropriate risk adjustment is central to the process of benchmarking outcomes. Development of outcome QIs therefore implies the additional step of deriving and validating a risk adjustment model, as discussed earlier.

Step 3. The benchmark can be based on (1) a consensus-based standard (eg, all patients with major trauma should have an ED stay <1 hour); (2) an empirical, internal standard (eg, global mean in the system under evaluation); or (3) an empirical, external standard (global mean in an external population, such as the NTDB used for the TRISS model). The external standard has the potential to provide valuable information for quality control programs but should be based on an injury population with similar characteristics, subject to exemplary quality of care and high-quality data.

Step 4. The evaluation of QI validity implies providing evidence of face validity, content validity, criterion validity, discriminant validity, and predictive validity (Table 5-4).[152]

The selection of QIs through literature review and expert consensus should ensure both face and content validity. Criterion validity can be evaluated by assessing the correlation between QIs measuring the same quality construct (structure, process, outcome). Discriminant validity can be evaluated by assessing whether a QI detects statistically significant variation in performance across providers. Finally, predictive validity can be evaluated by assessing the correlation between structure-process QIs and process-outcome QIs (under Donabedian's model, structure influences process, which, in turn, influences outcome). Predictive validity should also be verified by assessing forecasting properties (ie, care provider results on QIs in one time period correlated with those in a following period). Once the internal validity of QIs has been demonstrated using all these metrics, their external validity should be evaluated in a new, independent patient sample.

TABLE 5-4: Measures of Validity[152]

Type of validity	Definition	How to measure
Face	On the face of it, do the metrics seem to be credible measures of the construct in question?	Expert consensus
Content	Does the metric evaluate the appropriate content and breadth of content?	Literature review and clinical peer review
Criterion	How well do the test scores reflect performance as measured by other accepted or widely used measures of the same concept?	Correlation with other quality indicators
Discriminant	To what extent do the inferences from a test's score accurately reflect the construct the test claimed to measure?	Discrimination between providers
Predictive	How well do the test scores predict the properties that they are designed to measure?	Correlation with outcomes
External	To what extent can the results of a research study be generalized to individuals and situations beyond those involved?	Validity in a completely independent sample

Several research groups have proposed QIs to evaluate injury care. In 1993, the ACSCOT introduced 22 audit filters to evaluate trauma care in terms of clinical processes.[153] More recently, Stelfox and colleagues[154] performed a systematic review to identify evidence-based QIs followed by an international expert consensus study according to University of California at Los Angeles (UCLA)/RAND guidelines. They generated a list of 31 QIs that experts consider should be used to evaluate the quality of injury care.[154,155] Inspired by this work, Moore, Stelfox, and colleagues derived and validated a comprehensive tool to evaluate the quality of acute injury care. The tool includes (1) a composite QI for evaluating trauma center structure including elements of commitment, trauma program, and procedural protocols based on ACS verification criteria[156]; (2) 15 clinical process QIs as well as composite process QIs based on compliance with best practice guidelines[157,158]; and (3) outcome QIs to evaluate mortality, complications, unplanned readmission, and hospital LOS.[75,76,159] The face, content, criterion, discriminant, and predictive validities of these QIs have been demonstrated, but their external validity has yet to be evaluated. Investigators have provided evidence that their injury care quality evaluation tool reproduces the structure-process-outcome associations of Donabedian's conceptual model.[160] In a mature, inclusive trauma system, trauma centers with higher scores on the composite structure QI also had higher scores on the composite process QIs, and centers with high scores on the process QIs also had lower risk-adjusted incidence of mortality, complications and unplanned readmission, and mean LOS. In addition, a significant positive correlation was observed among all QIs on outcomes; hospitals with lower risk-adjusted mortality also tended to have lower rates of readmission and complications and lower mean LOS.

Perhaps the most widely used QIs are those proposed under the Trauma Quality Improvement Program (TQIP) model. Many trauma centers/systems have subscribed to the TQIP benchmarking system, a for-profit organization that receives and processes institutional data to produce benchmarking results for hospital mortality, LOS, major complications, and selected clinical processes against the national average using the NTDB.[161] TQIP is based on standardized inclusion criteria, rigorous initial and ongoing training of data coders at participating sites, and extensive data quality-control mechanisms. Collaboratives allowing comparisons within hospitals of the same region have been formed, and drill-down tools to help identify root causes of quality problems are available.

Details on how TQIP models were derived have been published,[162] but information on model coefficients and validation of risk adjustment models is currently not available.

QIs are largely disseminated as part of an audit-feedback intervention, whereby providers (usually hospitals) receive a quality report, identify root causes of any quality problems (by discussions with stakeholders or drilling down data), propose quality improvement strategies, and are reevaluated. An approach based on feedback reports, educational material, local quality improvement teams, and quality improvement plans is associated with higher success rates than other audit-feedback approaches.[163-165]

International Injury Care Comparison

Benchmarking within a trauma system is an essential part of quality improvement activities, but international comparisons across health care systems provide a much greater opportunity to improve injury care and reduce the global burden of injury. There is clear evidence that trauma systems improve mortality, morbidity, and functional outcome following injury,[140,166-168] but it is unclear which aspects of trauma systems lead to optimal patient outcomes.[169] Many countries have or are in the process of adopting a trauma system model, but trauma systems worldwide have very different structures and levels of integration. International comparisons of injury care and injury outcomes therefore provide a unique opportunity to identify which components of trauma systems improve patient outcomes and which offer no advantage. Gabbe and colleagues have made considerable progress in international comparisons of trauma systems by comparing mortality and functional injury outcomes in Victoria, Australia, to those in the United Kingdom[170] and Hong Kong.[171] In addition, using the Utstein template to develop a pan-European trauma registry, Ringdal and colleagues[172] now have tools to compare injury outcomes across Europe. However, to truly improve our understanding of how differences in structures and processes of care across systems influence patient outcomes, efforts should be made to build an international injury data set including high-, middle-, and low-income countries. We also need to develop a standardized methodology to benchmark injury structures, processes, and outcomes on an international scale. A group of international injury researchers is currently working toward this goal. The first steps are to conduct a systematic review of international injury comparisons, to compare population-based injury outcomes using World Health Organization data, and to establish a framework for an international trauma registry.[169]

Challenges of Benchmarking

Many health care administrators and policymakers are moving toward making providers accountable for their performance by publishing benchmarking results (eg, health care report cards) or linking them to financial incentives such as pay for performance. However, rather than stimulating performance improvement, research has shown that the threat of institutional stigmatization or losing resources often leads to data gaming (eg, overestimation of injury severity, underreporting of complications), refusal of high-risk patients, and concentration on quality elements that are measured to the detriment of those that are not.[164,173] In addition, systematic variation in results across providers may be due to provider-level quality of care that can be modified by the provider, but may also be due to system-level problems or poor data quality. Therefore, it has been suggested that benchmarking activities should be used on an informative basis to identify potential problems and implement solutions as part of a quality loop (plan-implement-evaluate).[174]

FUTURE DIRECTIONS

We have made giant steps in injury severity scoring and outcomes research over the past three decades. The MTOS of the late 1980s[8] was the first to compare institutional outcomes of trauma patients while controlling for case mix. This process is now instantiated in trauma systems throughout the world and, despite some hiccups, has resulted in the NTDB, which contains data on more than 7 million patients, and the ACS TQIP, which has more than 200 subscriber institutions. However, there are more challenges to be faced in the future to address the growing global burden of injury.[156] To improve our understanding of the complex associations underlying the burden of injury, we need to improve the quality and coverage of injury data; employ more sophisticated analytical methods; improve the knowledge translation-to-action cycle of research results; look toward comparing outcomes across health care systems in high-, middle-, and low-income countries; and adapt our methods to the changing demographics of trauma populations.

Injury research is currently based largely on the acute (hospital) phase of care in trauma centers. Research has shown that the introduction of trauma systems within a public health care model leads to better short-term patient outcomes. However, we need to improve our understanding of which components of trauma systems drive optimal patient outcomes. To do so, population-based data from all components of the care continuum including prevention, prehospital, emergency, acute care, rehabilitation, and community care are needed. Some of these data are already available in many systems, but data protection acts and lack of unique identifiers often prevent database merging. Fortunately, fast progress is being made in methodology related to the acquisition, linkage, and treatment of big data, which should lead to breakthroughs in injury data coverage in the near future.[175-177] The ultimate goal may be to build injury life cohorts, which would have amazing potential to improve our understanding of the short-, medium-, and long-term consequences of injury. The immediate consequences of injury are the tip of the iceberg. To advance knowledge on the significant long-term burden of injury, we need to obtain information on long-term outcomes including quality of life and functional status.

Obtaining high-quality, high-coverage injury data represents a much greater challenge than employing appropriate analytical techniques, yet injury outcomes research is fraught with inappropriate statistical models. Despite our preference for simpler statistical models, traditional regression analysis is unlikely to be sufficient to fully understand the complex nature of trauma systems. Therefore, future research needs to look toward more sophisticated analytical methods such as causal inference and microsimulation models to better understand the determinants of optimal injury outcomes. In addition, whereas data coverage and quality may be improved, no observational study is exempt from selection, information, and confounding bias. We thus need to develop methods to evaluate the influence of such biases on observational injury data.

Efforts should be made to improve translation of research results into quality-of-care improvements as part of the quality loop. This is the essence of the public health model. Outcomes research must therefore be based on a comprehensive, integrated, and end-of-grant knowledge-translation strategy.[178] Practitioners, policymakers, decision makers, and patient/family advocates should be involved in all phases of research projects, and results should be distributed to all stakeholders, not just in the form of scientific articles but as policy briefs, clinical guides, and decision rules. We should also work to strengthen international collaborations to pool resources, avoid duplicating research projects, and generate results with maximum impact.

Injury severity scoring and biometric modeling remain fertile research fields. These include biometric markers and models for head injury and impending shock states, as well as a variety of biochemical markers being considered to augment models for identifying at-risk patients, including lactate, bicarbonate, and tissue oxygenation. Ultimately, these processes of risk evaluation of trauma patients will improve the general strategy and link in with therapeutic innovations, which include improved resuscitation therapies and energy-directed cellular-level therapies of the future.

Measuring and comparing structures, processes, and outcomes across health care systems is key to identifying areas for improving injury outcomes on a global scale. Despite challenges in terms of obtaining comparable data, an international repository for injury data would have the potential to greatly improve our understanding of the drivers of optimal injury care.

Finally, the demographics of injuries are changing rapidly. Traditionally designed to manage major blunt multisystem trauma and penetrating wounds, trauma systems must now adapt to trauma populations dominated by low-kinetic, isolated injuries in the elderly. We will therefore need to work toward adapting injury severity scoring systems, outcome measurement, and analytical strategies to these changes.

Fundamental to the process of evaluating innovation and the inexorable progress toward improving quality of care is a firm foundation of understanding of the power and limitations of injury severity scoring systems and biological, biometric models and an ability to adapt them to changing realities.

Coding and Billing

R. Lawrence Reed II

KEY POINTS

- Medicare (established in 1965) provides health care benefits to Social Security beneficiaries (ie, previously employed individuals over age 65).
- Medicare hospital payments are payments based on the patient's admitting diagnosis in diagnosis-related groups that may be affected by documented comorbidities and quality metrics.
- Medicare physician payments: For each *Current Procedural Terminology* (CPT) code, a previously determined assessment is made of the amount of physician work (~50%), practice expense (~40%), and malpractice costs (~10%) associated with that service or procedure. The amount of work is assessed in comparison to the work already assigned to other similar procedures.
- The Relative Value Scale Update Committee (RUC) is a committee of the American Medical Association that assesses physician work for procedures and services and provides recommended relative value unit (RVU) valuations to the Centers for Medicare and Medicaid Services (CMS). Although the RUC provides recommendations, CMS makes all final decisions about what the Medicare payments will be.
- Conversion factor = Dollars paid/RVU.
- Billing Concept 1: Identify why physician does something for a patient by using codes for diagnoses from the International Classification of Diseases, 10th edition, Clinical Modification.
- Billing Concept 2: Identify what the physician does for the patient by using codes for services or procedures from CPT (updated annually).
- The provision of critical care services is specifically *excluded* from a global surgical package in the setting of trauma and burns.

INTRODUCTION

Although most physicians know that payment for their services must usually be coded and billed for monetary reimbursement to occur, their traditional medical education and training have not explained how this actually is accomplished. And, although it is true that most physician practice groups have employed personnel trained in medical professional coding and billing, those personnel are completely dependent on the quality of physician documentation in the medical record. The rules for coding personnel usually dictate the specific requirements that must be in the medical record to enable them to code appropriately for any given service. Therefore, physicians who are knowledgeable regarding documentation requirements will make it easier for their coders to apply the correct codes and then see better reimbursement. The purpose of this chapter is to provide the information and guidance for trauma and acute care surgeons to optimize their professional reimbursement due to a better understanding of the documentation, coding, and billing rules.

HISTORICAL BACKGROUND

Prior to the 20th century, physicians in the United States were paid for their services directly by the patient. Because of new developments and discoveries, the ability to provide life-saving remedies became increasingly available but was accompanied by increasing costs. The concept of using an insurance model (designed to pay for catastrophic events that were unlikely to occur) first evolved in the private sector in the late 1920s.[1] Initially limited to few people, private health care insurance received a significant boost during World War II, when a restrictive wage freeze forced industries to compete with other options for the few able-bodied men who were present stateside. Since they were prohibited from

boosting wages, employers were forced to compete by offering employee health care as a benefit of their employment. Employer-based health care insurance ultimately became the norm in American society with few exceptions.

Upon retirement, however, such employer-based health care insurance was no longer available to retirees, who were now forced to pay for their increasingly expensive health care needs out of their fixed Social Security income. Throughout the 20th century, there was a progressive movement to socialize American medicine and provide health care benefits for all citizens. A major milestone in this effort was the implementation of Medicare in 1965, which provided health care benefits to Social Security beneficiaries (ie, previously employed individuals over the age of 65).

Initially, patients submitted health care claims to Medicare and then received payments from Medicare to turn over to their physicians. Because many patients did not transfer their claim payments to their physicians, however, Medicare began to offer physicians the option of accepting "assignment," meaning that physicians would accept payment directly from Medicare instead of directly from the patient. With this benefit came the requirement that the physician would agree to accept Medicare's allowed amount as payment in full. Ultimately, private insurers followed suit, with actual payments by patients becoming minimized to the level of deductibles and copays, which were designed to prevent excessive or unnecessary use of health care resources by patients. Current-day health savings accounts seek to provide patients with the same disincentives toward needless health care expenses while simultaneously providing them the potential for additional financial support during retirement.

MEDICARE ADOPTION OF THE RESOURCE-BASED RELATIVE VALUE SCALE

The modern era of payments to physicians began in the 1980s, when assessments of the financial health of the Medicare program indicated that it was on course to bankrupt the Social Security system. Consequently, cost-cutting measures were instituted over several years, primarily aimed at lessening payments to physicians and hospitals.

For hospital payments, the Medicare program switched from a fee-for-service system to a "prospective" payment system. Realistically, this system is only prospective in that the payment that is ultimately provided is based upon the standard payment for the patient's admitting diagnosis, grouped into diagnosis-related groups (DRGs). The payment to the hospital, however, is not actually made prospectively (ie, at the time of admission), but is only paid after the patient is discharged. This system had the potential to reduce unnecessary tests and treatments that would not be paid separately as had previously been the case.

On the physician side, the concept of a Resource-Based Relative Value Scale (RBRVS) was developed as a means to quantify physician services on a relatively objective basis.[2] The American Medical Association's *Current Procedural Terminology* (CPT), an annually produced catalog of services and procedures performed by physicians, served as the structural basis for the RBRVS. For each CPT code, a previously determined assessment is made of the amount of physician work, practice expense, and malpractice costs associated with that service or procedure. These assessments are summed for each CPT code, and the resulting totals are ranked in a standardized scale to produce relative value units (RVUs).

RELATIVE VALUE UNITS DEFINED

RVUs serve as the fundamental currency for physician services. The entire concept and structure for physician RVUs under Medicare is defined in the US Code of Federal Regulations.[3] Although the valuation of the amount of physician work, practice expense, and malpractice costs varies slightly for each CPT code, physician work valuation composes about 50% of the total RVU payment, with practice expense averaging roughly 40% and malpractice expense averaging about 10%.

Physician work, in turn, is determined based on assessments of the time spent, the technical skill and/or physical effort required, the amount of mental effort and judgment required, and the stress arising from any potential risk to the patient from performing the procedure or service. These assessments are developed by the Relative Value Scale Update Committee (RUC), which is composed of representatives from physician specialty societies and the American Medical Association. The RVU valuations are recommended to the Centers for Medicare and Medicaid Services (CMS), which in turn produces a quarterly update of RVU valuations on its website.[4]

Physician reimbursement is directly tied to RVUs through the *conversion factor*, which specifies the number of dollars paid for each RVU. Unfortunately for physicians, the conversion factor has not kept pace with inflation. In 1999, the conversion factor was $34.73/RVU, whereas in 2018, the conversion factor was $35.9996/RVU. If the conversion factor had kept pace with inflation, it would now be $48.93/RVU. Although the difference of $13.18 may seem trivial, a general surgeon with an average production of 7000 RVUs annually now only earns $250,250, instead of the $342,510 he or she would have earned if the conversion factor had kept pace with inflation, representing an annual loss of $92,260.

Payments to physicians are made for two types of care: services and procedures. *Services* represent patient interactions such as clinic visits, emergency department visits, consultations, inpatient admissions, daily rounds, critical care services, and others. Although there may be some procedures bundled into these services (such as is the case with critical care services), the majority of this work on the physician's part involves evaluation and management (E&M) of the patient's condition, which are primarily cognitive in nature. As opposed to E&M services, *procedures* include surgical operations, bedside procedures, anesthesia services, radiologic interpretations and procedures, and performance

or supervision of laboratory procedures. In addition, in contrast with cognitive-only E&M services, procedures involve actual physical work by the physician in addition to cognition.

FUNDAMENTAL BILLING CONCEPTS

Most patients do not pay their health care bills directly out of their checking account or credit card, as they do with other purchases. Instead, health care services are usually paid by third parties, usually an insurance company or a government entity such as Medicare or Medicaid. These entities seek to ensure that they are paying for actual and appropriate services. Therefore, they demand to know *what* was done for the patient and *why* it was done before they will process a payment to the physician.

The "why" takes the form of one or more coded diagnoses, currently using the diagnoses enumerated by the World Health Organization in the International Classification of Diseases (ICD). Since the early 1980s, CMS and other third parties have required the use of a clinical modification (CM) of version 10, ICD-10-CM, for this purpose. Previously, ICD-9-CM had been in use since 1979 but was transitioned to ICD-10-CM on October 1, 2015.

The "what" is contained in one or more CPT codes, which are revised and produced annually by the American Medical Association. CPT provides a system that lists and codes the majority of procedures and services provided by physicians. CMS has established the CPT system as level I of the Healthcare Common Procedure Coding System (HCPCS). Level II HCPCS codes apply to nonphysician services that are billed to CMS, such as ambulance services, prosthetic devices, and rehabilitative services. In addition to identifying the procedure or service performed, the CPT code is the entity to which RVUs are assigned.

It is not uncommon for multiple procedures to be performed during the same operation, and in many cases, they can all be reimbursed. In an effort to counteract procedural "unbundling," however, the Health Care Financing Administration (HCFA)—CMS's previous name—established the Correct Coding Initiative (CCI) in the early 1980s. The CCI defines those procedures that cannot be billed simultaneously.[5] For example, the higher paying splenorrhaphy (CPT 38115, 21.88 work RVUs) cannot be reported at the same time as a splenectomy (CPT 38100, 19.55 work RVUs). Reporting both as having been performed during the same operation will result in payment for the lower-paying splenectomy alone. While seemingly reasonable, there have been several instances where the prohibition of simultaneous billing makes little sense.[6] In such cases, appeals can be made with proper documentation and, often, with modifiers.

Modifiers indicate that there is a change in the fundamental assumption about the service or procedure represented by the CPT code. To ensure appropriate reimbursement, CPT codes may need to be reported with one or more modifiers. As will become apparent, modifiers play an important role for trauma surgeons because of the multiple conditions being managed during surgical global periods. For example, most procedure codes are considered to have some degree of E&M services incorporated into the payment for the code. Therefore, payment for any additional E&M services that are unrelated to the procedure must be justified by the addition of a modifier.

DOCUMENTATION REQUIREMENTS

Appropriate and thorough documentation in the medical record is necessary for effective coding and billing. As previously noted, professional coding and billing personnel are completely dependent upon appropriate and specific physician documentation. The coders simply cannot generate any ICD-10 or CPT codes unless the basis for those code assignments exists in the physician documentation. The documentation must provide information regarding the condition(s) or disease(s) being treated and the procedures or services used in the treatments. Coders translate the documentation into ICD-10 codes for the diagnosis and into CPT codes for the procedures or services. In addition, the procedures or services must be appropriate for the conditions being treated. For example, if a patient admitted with a sacral fracture (ICD-10 code S32.1) requires insertion of a central venous catheter (CPT code 36556 for a nontunneled catheter in an individual >5 years old), there will need to be a separate diagnostic code to justify reimbursement for the central venous catheter because a sacral fracture by itself will not provide that justification. Thus, conditions such as hypovolemia (ICD-10 code E86) or traumatic shock (ICD-10 code T79.4) should be identified as the reason for the central venous catheter. Many of the coding software programs used by billing personnel have cross-coding applications that alert coders when a procedure may not be appropriate for a specific diagnosis, or vice versa. Fortunately, or unfortunately, there are no universal standards for these code pairs. Therefore, there have been situations in which the coding office is telling the physician they have identified an inappropriate diagnosis for a particular procedure and yet the physician knows that his or her diagnosis and procedure code pairing is clinically appropriate. In such circumstances, the physician will need to provide the appropriate clinical guideline, policy, or medical literature to educate the coding staff and provide effective clinical feedback to the cross-coding information provider.

Again, although professional coders can find the proper codes to apply, it is the physician's responsibility to provide adequate documentation for the coders to do their job well. The physician must realize that his or her note provides the information for invoicing the third-party payers. The documentation requirements under ICD-10 are significantly greater than under ICD-9 due to the need to describe conditions and injuries with greater specificity. Thus, it will no longer be adequate to identify an open fracture of the femoral shaft; rather, the fracture must be identified as to the body side (right or left), whether it is displaced or nondisplaced, the type of open fracture, whether the patient encounter for this problem is the initial or subsequent encounter, and, if

the latter, whether the healing has been routine, delayed, or complicated by malunion or nonunion.

SPECIAL CONCERNS FOR PHYSICIAN CODING AND BILLING IN TRAUMA CARE: SURGICAL GLOBAL PACKAGE

In the 1980s, Medicare adopted the concept of a global surgical period to enable a single payment for all services inherent to a procedure. Thus, when a surgeon sees a patient preoperatively on the day of surgery, operates on the patient, and provides routine postoperative wound and other care in the hospital and in the clinic, there are no separate payments for the admission history and physical examination, daily hospital visits, and postoperative clinic visits, nor are there separate payments for dressing changes, suture removal, or other routine postoperative care. The global package applies not only to the surgeon who did the procedure, but also to his or her colleagues in the same specialty from the same billing group, because CMS considers them to be the same individual. Physicians from other specialties or physicians from the same specialty but other billing groups are not considered to be the same individual.

Initially, there was a great deal of variability among Medicare carriers (private health care insurers contracted by Medicare to process claims) with respect to what services were included in the global surgical package and the duration of the global surgical period for each procedure. On January 1, 1992, HCFA established a national global surgery policy, standardizing the included services and durations of each procedural CPT code's global package. E&M services that are included in the global package are considered to have been paid by the global package payment and, therefore, cannot be billed for separately (Table 6-1), although there is evidence that such payments lack equivalence to actual E&M payments for similar services.[7] However, there are many other professional services and procedures performed on surgical patients for which separate billing and payment is appropriate (Table 6-2).

These billable encounters during global periods are common in the practice of trauma surgery as well as in surgical critical care. Unfortunately, many surgeons fail to realize this and consequently lose significant amounts of revenue. The reality is that trauma surgeons currently operate on a small percentage of the patients they manage, so there are often no global package concerns.[8-11] If a trauma surgeon is providing overall management for a multiply-injured patient on whom an orthopedist has operated, the global surgical package for the orthopedic surgeon does not apply to the general (trauma) surgeon because these individuals have two different specialty codes (specialty codes identify the physician's specialty in the bills submitted to third parties).[12] Thus, a general trauma surgeon can bill a daily visit (ie, CPT code 99231, 99232, or 99233, depending on the extensiveness of the note) for nonoperatively managing four rib fractures (ICD-10 S22.4), a grade II splenic injury (ICD-10 S36.0), and acute anemia (ICD-10 D62) on a patient for whom an orthopedic surgeon has performed an open reduction and internal fixation (CPT 27506) on a mid-shaft femur fracture (ICD-10 S72.3).

TABLE 6-1: Components of the Global Surgical Package (cannot be separately billed)[15]

1. Preoperative visits after the decision is made to operate beginning with the day before the day of surgery for major procedures and the day of surgery for minor procedures *(Note that this usually applies to elective surgical cases where the decision to operate was made in the clinic days or weeks prior to the scheduled operative date. Emergency surgical cases are handled differently because the initial evaluation and management [E&M] service in the emergency department can be separately paid for if the -57 modifier is applied, thereby identifying the emergency E&M service itself as the source for the decision to operate. Similarly, a daily E&M progress note can serve as a decision to operate service for an existing inpatient whose condition has changed and now requires an operation; the -57 modifier on that daily progress note will ensure the note is paid.)*
2. Intraoperative services that are normally a usual and necessary part of a surgical procedure (eg, dissection services, exposure services, wound closure, dressing applications, local anesthesia provided by the surgeon)
3. Complications following surgery that do not require additional trips to the operating room (eg, opening a wound at bedside)
4. Postoperative visits related to recovery from the surgery
5. Postsurgical pain management by the surgeon
6. Supplies
7. Miscellaneous services (dressing changes; local incisional care; removal of operative pack; removal of cutaneous sutures and staples, lines, wires, tubes, drains, casts, and splints; insertion, irrigation, and removal of urinary catheters, routine peripheral intravenous lines, nasogastric and rectal tubes; and changes and removal of tracheostomy tubes)

Moreover, many trauma patients have multiple conditions that require the trauma surgeon's attention, over and above those conditions for which this individual has operated, and this management is also reimbursable. It is in these situations where use of a modifier is critical. As previously stated, modifiers indicate that the fundamental assumption about a CPT code is altered for the CPT code being submitted. If, in the previous example, the trauma surgeon performed a splenectomy (CPT 38101), the fundamental assumption about the CPT code is that the daily visit E&M service is bundled into the payment for the splenectomy. Yet, the management of the rib fractures and the anemia is not a usual, customary, and reasonable experience in postsplenectomy care. Applying the -24 modifier to the 99231/99232/99233 daily visit code during the postoperative visit indicates that the E&M service is separately payable because of the management of conditions unrelated to the splenectomy. The modifiers relevant to procedures and services performed during global surgical packages are listed in Table 6-3.

TABLE 6-2: Services and Procedures *Not* Included in the Global Surgical Package (ie, separate billing and payment are appropriate)[15]

1. The initial consultation or evaluation of the problem by the surgeon to determine the need for major (ie, 90-day global package period) surgery. This is a separate evaluation and management (E&M) service (with a -57 modifier). The initial evaluation is always included in the allowance for a minor surgical procedure.
2. Services of other physicians except where the surgeon and the other physician(s) agree on the transfer of care.
3. Visits unrelated to the diagnosis for which the surgical procedure is performed, unless the visits occur due to complications of the surgery.
4. Treatment for the underlying condition for which the surgery was performed or an added course of treatment that is not part of normal recovery from the procedure.
5. Diagnostic tests and procedures, including diagnostic radiologic procedures.
6. Clearly distinct surgical procedures during the postoperative period that are not reoperations or treatment for complications (except for those complications that require a return trip to the operating room [OR]; see 7 below). Note that a new postoperative global period begins with the subsequent procedure.
7. Treatment for postoperative complications that require a return trip to the OR.
8. If a less extensive procedure fails and a more extensive procedure is required, the second procedure is payable separately.
9. Splints and casting supplies are payable separately.
10. Immunosuppressive therapy for organ transplants.
11. Critical care services (codes 99291 and 99292) unrelated to the surgery where a seriously injured or burned patient is critically ill and requires constant attendance of the physician.

TABLE 6-3: Modifiers That Enable Appropriate Billing During Surgical Global Periods

Time point of the CPT code being modified	Type of CPT code that is modified: Evaluation & management (E&M)	Type of CPT code that is modified: Procedure
Same day as global procedure	-25: E&M service unrelated to the procedure performed on the same day. This is used when the procedure carries a 0- or 10-day global period. -57: E&M service involves the decision to operate. This is used when the procedure carries a 90-day global period.	-51: Applied to procedures that are performed on the same day through the same incision as the primary (ie, highest RVU) procedure. -59: Applied to procedures performed on the same day as the primary (ie, highest RVU) procedure but performed at a different time or through a separate incision.
Any day during global period after the day of the procedure	-24: Postoperative E&M service managing conditions unrelated to the procedure whose global period is still present.	-79: Applied to procedures performed for unrelated conditions after the procedure whose global period is still present. -78: Applied to unplanned procedures performed for conditions related to and after a procedure whose global period is still present. -58: Applied to staged or planned procedures performed after a procedure whose global period is still present.

CPT, *Current Procedural Terminology*; RVU, relative value unit.

SPECIAL CONCERNS FOR PHYSICIAN CODING AND BILLING IN TRAUMA CARE: SURGICAL CRITICAL CARE

Critical care E&M services for adult patients are time-based codes, with 99291 being applied for the first 30 to 74 minutes (the first "hour") and 99292 being applied for any subsequent 15- to 30-minute periods during a calendar day. The following two documentation requirements justify the higher E&M payments provided for critical care services: (1) the clinical documentation must support the premise that the patient meets the definition of critical illness; and (2) the physician (and his or her partners within the same specialty) must document the total time spent that day in the critical care of the patient, exclusive of the time spent performing procedures (as they are billed separately). Critical illness or injury is defined by CMS as an acute impairment of "one or more vital organ systems such that there is a high probability of imminent or life threatening deterioration in the patient's condition."[13] Therefore, in addition to documenting the total time spent, the physician's note should also focus on the nature of the organ system impairment(s), the potential consequences (eg, organ failure or death) if untreated, and what the physician has done to manage those impairments.

Despite what many physicians believe to the contrary, the provision of critical care services is specifically excluded from a global surgical package in the setting of trauma and burns[14]; in other words, critical care is not considered part of an operative procedure for trauma patients. Nevertheless, if a trauma surgeon has performed an operative procedure on a critically

ill patient, it is best to identify the clinical condition(s) requiring critical care for the ICD-10 code(s), instead of the diagnosis used for the operation. This would be essential anyway, because a ruptured spleen, for example, does not routinely justify critical care. Trauma patients who are truly critically ill, however, usually have multiple conditions that must be assessed and managed. These all have ICD-10-CM codes, such as respiratory failure (ICD-10 J96.00), traumatic shock (ICD-10 T79.4XXA), post-hemorrhagic anemia (ICD-10 D62), oliguria (ICD-10 R34), and many others. A postoperative (-24) or same-day (-25) modifier should be applied to the critical care E&M code as appropriate. The critical care note should also attest that the time spent performing critical care E&M was independent of time spent on any procedures on the patient.

EXAMPLE: TRAUMA ACTIVATION RESPONSE, OPERATIVE, AND CRITICAL CARE BILLING

You respond to a trauma activation, identifying a 26-year-old male ejected during a high-speed motor vehicle collision. His breathing is shallow, and he is hypoxic on pulse oximetry. The anesthesiologist intubates the patient, and you note decreased breath sounds on the left. A chest radiograph confirms a left hemothorax. You place a left chest tube, which drains 750 mL of gross blood. He is hypotensive and tachycardic, and you perform a focused assessment with sonography in trauma (FAST) exam, which is positive. You take him emergently to the operating room, removing a ruptured spleen. You also debride, cauterize, suture, and pack a grade IV liver laceration. The anesthesiologist places a central venous catheter and an arterial line. The patient begins to stabilize, and you perform a temporary abdominal closure.

You complete your examination of the patient and perform computed tomographic imaging of his head, neck, and pelvis. A small subarachnoid hemorrhage is identified, and you consult neurosurgery. You take him back to the intensive care unit, continue the resuscitation, and note that his vital signs have normalized. You adjust his ventilator settings, order a number of laboratory studies, and discuss his situation and your plans with his family. You have spent a total of 115 minutes in his critical care management (including writing the note).

The next day, you assess his respiratory, cardiovascular, renal, coagulation, and nutritional status, noting some oliguria and anemia. You order infusions of crystalloids and transfuse red blood cells. Also, you pass a gastric feeding tube and trickle in some enteral feedings slowly. You speak again with his family. After writing the daily note, you have spent a total of 75 minutes performing critical care.

On the third day, you perform critical care services as on the previous day, although it only takes you 45 minutes. The patient's oliguria, hypovolemia, and anemia have improved, but they require continued monitoring. You also take him back to the operating room, remove the temporary abdominal closure, and close his abdominal midline incision.

A billing summary for these 3 days of this patient's case is provided in Table 6-4. In the setting of a trauma activation, the comprehensive history, comprehensive physical examination, and high-complexity medical decision making usually qualify for a high-level E&M service, such as an admission note (CPT 99223) if the note appropriately documents those components. If the patient meets the definition of critical illness, as in this case, however, billing for critical care services will pay more. The injuries should be identified and coded as the diagnoses being managed if you are billing a 99223; however, if you are billing a 99291 with or without additional 99292 codes, the abnormal physiologic conditions making the patient critically ill should also be coded as the diagnoses being managed. If a decision is made to take the patient to the operating room, a -57 modifier should be applied to the E&M service on the first day. Other minor bedside procedures, such as the chest tube insertion, can also be billed, but will require that a -25 modifier be applied to the E&M service also. Without the -57 and/or the -25 modifiers being applied to the E&M CPT code (either 99223 or 99291/99292), you will not be paid for the E&M service. The underlying assumption is that the patient came to have the procedures performed, and all procedures are considered to have some E&M care included in their payments. Given that there are conditions requiring E&M other than those E&M services related specifically to the procedures performed, it is essential to provide appropriate modifiers to ensure that the additional E&M services are legitimately paid.

BACK-OFFICE ISSUES

Because of the complexity of the documentation, coding, and billing process for acute care surgeons, it is essential that physicians maintain a healthy and collegial relationship with their billing and coding personnel. Both groups share the common goal of ensuring that the organization receives the maximal legitimate reimbursement possible. Coding and billing personnel need to understand what conditions physicians are treating and how they are treating them so that the appropriate codes can be submitted for third-party payments. They should be able to capture this from the clinical documentation, but whenever doubt exists, they should feel absolutely free to contact the physicians for clarification. They should also feel comfortable in suggesting clarification of documentation by the physician when necessary should there be documentation deficiencies that could be challenged in an audit.

Physicians, in turn, should learn as much as they can about the coding and documentation issues pertinent to their field. There are several opportunities to acquire such knowledge, which can often include discussions with their coding and billing personnel regarding specific services. In addition, there are various books and subscriptions available, including online software and subscriptions. For example, software such as HCPro's EncoderPro Professional provides a comprehensive catalog of ICD-10, CPT, DRG, Ambulatory Payment Classification, and HCPCS codes, as well as a great deal of other information. Although modestly

TABLE 6-4: Summary of Billing Potential for Example Case

Day	Diagnoses (ICD-10-CM)	Description	Procedure or service (CPT)	Description	wRVUs
First day	J96.00	Respiratory failure	99291-57-25	2 hours of critical care with decision to operate modifier and same-day minor procedure for the E&M service	9.00
	T79.4XXA	Traumatic shock	99292-57-25x2		
	S06.6X9A	Subarachnoid hemorrhage (SAH) with loss of consciousness (LOC) of unspecified duration			
	S27.1XXA	Traumatic hemothorax (closed)	32551-59	Chest tube insertion with modifier for distinct procedure (from liver packing)	3.04
	S36.81XA	Hemoperitoneum	76700-59	Abdominal ultrasound with modifier for distinct procedure	0.81
	S36.116A	Major liver laceration	47361	Exploration of hepatic wound, extensive debridement, coagulation, suture, with packing of liver	52.60
	S36.032A	Major splenic laceration	38100-51	Splenectomy with modifier for multiple procedures: 50% payment[a]	9.78
	Total first day wRVUs				**75.23**
Second day	J96.00	Respiratory failure	99291-24	90 minutes of critical care with modifier for postoperative unrelated E&M services. (Note that gastric intubation is included in 99291.99292.)	6.75
	S06.6X9A	SAH with LOC of unspecified duration	99292-24		
	R34	Oliguria			
	E86.1	Hypovolemia			
	D62	Post-hemorrhagic anemia			
	Total second day wRVUs				**6.75**
Third day	J96.00	Respiratory failure	99291-24-57	60 minutes of critical care with modifier for postoperative unrelated E&M services as well as modifier for decision to operate on day of surgery	4.50
	S06.6X9A	SAH with LOC of unspecified duration			
	R34	Oliguria			
	E86.1	Hypovolemia			
	D62	Post-hemorrhagic anemia			
	S31.619A	Open wound of abdomen	49002-58	Relaparotomy for closure with modifier for staged procedure	17.63
	Total third day wRVUs				**22.13**

[a]Because of the E&M services purportedly included in operative procedures, the second procedure's RVU valuation is halved to avoid "overpayment" of duplicate included E&M services.

CPT, *Current Procedural Terminology*; E&M, evaluation and management; wRVU, work relative value unit.

expensive, these programs will pay for themselves if conscientiously used to improve the quality of documentation, coding, and billing, which will result in enhanced professional revenue.

Critical Appraisal of Trauma Research

Angela Sauaia • Ernest E. Moore

KEY POINTS

- By randomly distributing patients to the study groups, the potential risk factors in randomized clinical trials are likely to be evenly dispersed.
- Bayesian statistics are an approach for learning from evidence as it accumulates; that is, the Bayes theorem is applied to combine prior information with current information on an outcome of interest and derive a probability.
- The propensity score is the probability of treatment assignment conditional on observed baseline characteristics; that is, each treated patient is matched to one or more control patients with similar propensity scores.
- Relative risk or risk ratio (RR) compares the outcome probability in two groups (ie, with and without an intervention, or with and without a risk factor). When the RR is equal to 1, there is no evidence of effect.
- Odds ratios are good estimates of the RR when the outcome is relatively rare (<20%); however, this is not true when the outcome is more common.
- *P* value is the probability of obtaining the observed effect (or larger) under the null hypothesis that there is no effect; that is, the *P* value can be interpreted colloquially as the probability that the finding was the result of chance.
- Bias is the deviation of results due to systematic errors in the research methods and includes selection bias (study groups differ systematically) or observer/information bias (systematic differences in the way information is collected).

Good doctors use both individual clinical expertise and the best available external evidence, and neither alone is enough. Without clinical expertise, practice risks becoming tyrannized by evidence, for even excellent external evidence may be inapplicable to or inappropriate for an individual patient. Without current best evidence, practice risks becoming rapidly out of date, to the detriment of patients.

Sacket et al, 1996

WHAT IS EVIDENCE-BASED TRAUMA CARE?

Evidence-based medicine (EBM) is "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients."[1] The term *evidence-based medicine* was coined by a group of physicians at McMaster University in Hamilton, Ontario, in the early 1990s.[1,2] EBM is a combination of clinical expertise and best evidence, as eloquently stated by Sacket and colleagues in the quotation at the beginning of this chapter.[1] The definition of EBM has two basic components: the first is "the conscientious, explicit, and judicious use," which, in trauma, applies to split-second decisions in the face of an immense variety of unexpected clinical scenarios. The time pressure and the irreversibility of many surgical procedures enhance the anxiety of decision making. The second component of the EBM definition is "best evidence." What constitutes "best evidence"? Best evidence is "clinically relevant research,"[1] which can both invalidate previously accepted procedures or replace them with new methods that are more powerful, efficacious, safe, and cost containing. In simple words, it comes down to "How does the article I read today change (or not) how I treat my patients tomorrow?"[3]

Searching for evidence usually starts with the formulation of a searchable clinical question. For this purpose, experts recommend the use of the PICO framework,[4] which stands for population (P), interventions (I), comparators (C), and outcome(s) (O). When searching for evidence on a specific topic or simply determining whether the most recent article

applies to the patient currently being seen, one must define whether the PICO in the study(ies) is (are) similar enough to the individual patients in your practice to allow application of the evidence. For example, in the 1990s, randomized clinical trials showed the benefits of treating *Helicobacter pylori* in patients with peptic ulcer disease; thus, guidelines recommended this practice in all patients with peptic ulcer disease.[5] Yet subsequent evidence showed that, among elderly patients, *H pylori* treatment did not have as much of an impact as anticipated based on this evidence. Application of the PICO framework to the initial randomized clinical trials unveiled that many trials excluded elderly patients, who often have comorbidities and take nonsteroidal anti-inflammatory drugs (population); thus, their findings did not necessarily apply to elderly patients. Indeed, among this advanced age group, counseling for appropriate use of nonsteroidal anti-inflammatory drugs had a greater effect.[6]

Once you determine that a published report applies to your practice, critical appraisal is the next step. Critical appraisal ascertains the level of uncertainty of the study's findings through the assessment of its internal and external validity. This step is essential to filter the information that can improve individual patient care as well as contribute to an efficient, high-quality health care system. Critical appraisal of an article requires an inquisitive and skeptical mindset combined with a basic understanding of scientific and statistical methods.[7] Many would say that scientific and statistical methods are only for researchers, but actually they are essential in becoming effective consumers of research and EBM practitioners. This chapter will provide a basic review of methods for searching for, critically appraising, and applying evidence, including an introduction to statistical topics essential to a reliable interpretation of trauma literature.

DEFINING THE LEVEL OF EVIDENCE

Best evidence rarely comes from a single study; more often, it is the final step of a long scientific journey, in which experts collect, appraise, and summarize the findings of several individual studies using standard methods.[1] Systematic reviews, as detailed later in this chapter, are excellent starting points to distill the daunting amount of information available. Indeed, when first learning about a topic, a systematic review is a good start. These reviews are commonly assigned a level of evidence, which gauges the confidence of the summative collection of research on a specific topic.

When a systematic review is not available, how should busy health care providers manage the formidable volume of information that becomes available every day, much of which is contradictory? Appraisal is the answer. There are several systems to appraise and grade the level of evidence. For example, the Grading of Recommendations Assessment, Development and Evaluation (GRADE)[8] system follows a detailed stepwise process to rate evidence (http://www.gradeworkinggroup.org/; accessed September 9, 2018). The *Journal of Trauma and Acute Care Surgery* recently adapted the GRADE system to classify the level of evidence of individual articles (Table 7-1). The study design (ie, randomized study, observational prospective or retrospective, case-control, case series) is a major factor in the classification, because a randomized trial produces more certainty than a case series. Yet we must recognize that different clinical questions (ie, whether the question relates to a therapeutic procedure, diagnostic test, prognostic factors, epidemiologic description, etc) demand different types of study designs and tolerate different levels of uncertainty.[9,10] In other words, potentially harmful therapeutic approaches demand a higher level of certainty (thus a higher evidence level) than the validation of a new score to gauge injury severity.

The determination of the level of evidence of a study involves four steps.

Step 1: Define the Type of Clinical Topic Addressed by the Study

1. Therapeutic and care management studies evaluate a treatment's efficacy, effectiveness, and/or potential harm; also included in this category are comparative effectiveness research, investigations of adherence to standard protocols, clinical recommendations, guidelines, and/or algorithms.
2. Prognostic and epidemiologic studies[11] assess the influence of predictors or risk factors of a condition and/or its outcome. Epidemiologic investigations describe the incidence or prevalence of a disease and its risk factors, diagnosis, morbidity, and prognosis; also included are new or revised scores to gauge disease severity (eg, Injury Severity Score [ISS]).
3. Diagnostic test or criteria[12] studies describe the validity and applicability of diagnostic tests or procedures; also included are assessments of diagnostic criteria to define certain conditions (eg, definition of adult respiratory distress syndrome, multiple organ failure, trauma-induced coagulopathy).
4. Economic and value-based evaluations focus on the value, quality, and cost of specific care management strategies. They include cost-benefit, cost-effectiveness, and cost-utility analyses. More recently, Porter[13,14] proposed the concept of value-based health care evaluations, in which value was defined as the health outcomes achieved per dollar spent.
5. Systematic reviews and meta-analyses evaluate the body of evidence on a topic through comprehensive, systematic search and appraisal; meta-analyses specifically include the quantitative pooling of data across different studies addressing a single topic.
6. Guidelines are statements developed by reputable groups of experts to assist practitioners and patients with decisions about the appropriate health care for the specific clinical circumstances, based on the appraisal of existing evidence.[15]

Step 2: Define the Research Questions, the Hypothesis(es), and the Study Design Chosen to Address Them

The study design is the plan used by the investigators to test a hypothesis related to a research question as unambiguously as possible given practical and ethical constraints. Even

TABLE 7-1: Evidence Level of Individual Studies

Types of studies

Level	Therapeutic/care management	Prognostic and epidemiologic	Diagnostic tests or criteria	Economic and value-based evaluations	Systematic reviews and meta-analyses	Guidelines
Level I	• Randomized controlled trial (RCT) with no negative criteria[a] and with a significant difference • RCT with no negative criteria[a] without significant difference and adequate statistical power[b]	• Prospective[c] study with large effect[d] and no negative criteria[a]	Testing of previously developed diagnostic criteria in consecutive patients (all compared to "gold" standard)	Sensible costs and alternatives; values obtained from many sources; multiway sensitivity analyses	Systematic review (SR) or meta-analysis (MA) of predominantly level I studies and no SR/MA negative criteria[e]	GRADE system
Level II	• RCT with significant difference and only 1 negative criterion[a] • Prospective[c] comparative study with no negative criteria[a]	• Prospective[c] study with less than large effect[d] and no negative criteria[a] • Untreated controls from RCT • Prospective/retrospective[c] study with large effect[d] and only 1 negative criterion[a]	Development of diagnostic criteria on consecutive patients (all compared to "gold" standard)	Sensible costs and alternatives; values obtained from limited sources; multiway sensitivity analyses	SR/MA of predominantly level II studies with no SR/MA negative criteria[e]	
Level III	• Case-control study with no negative criteria[a] • Prospective[c] comparative study with only 1 negative criterion[a] • Retrospective[c] comparative study with no negative criteria[a]	• Case-control study with no negative criteria[a] • Prospective or retrospective[c] study with up to 2 negative criteria[a]	Nonconsecutive patients (without consistently applied "gold" standard)	Analyses based on limited alternatives and costs; poor estimates	SR/MA with up to 2 negative criteria[e]	
Level IV	Prospective or retrospective[c] study using historical controls or having more than 1 negative criterion[a]	• Prospective or retrospective[c] study with up to 3 negative criteria[a]	Case-control study with no negative criteria[a]	No sensitivity analyses	SR/MA with more than 2 negative criteria[e]	
Level V	• Case series • Studies with quality worse than level IV	• Case series • Studies with quality worse than level IV	No or poor "gold" standard			

[a]Negative criteria (decreases level of evidence):
1. <80% follow-up
2. >20% missing data or missing data not at random without proper use of missing data statistical techniques
3. Limited control of confounding (eg, mortality comparisons with inadequate risk adjustment)
4. More than minimal bias (selection bias, publication bias, report bias, etc)
5. Heterogeneous populations (eg, institutions with distinct protocols/patient volume; conditions caused by distinct pathogenic mechanisms)
6. For RCT only: no blinding or improper randomization

[b]Adequate statistical power: this only applies to studies *not* finding statistical differences, and it is defined as power >80% for declaring "failure to detect a significant difference" or power >90% for declaring "bio-equivalence or noninferiority or comparative effectiveness" of a *predefined* difference based on previous evidence.

[c]Prospective versus retrospective: studies with data collected to answer predefined questions are prospective; studies with data collected for questions unrelated to the original question for which the data were gathered are retrospective.

[d]Large effect:
- Study with large relative risk (RR; >5 or <0.2) about condition of low to moderate morbidity/mortality
- Study with moderate to large RR (2–5 or 0.2–0.5) about condition of high morbidity/mortality

[e]Negative criteria for systematic reviews and meta-analyses (decreases level of evidence):
1. No or inadequate standard search protocol
2. More than minor chance of publication bias or publication bias nonassessed
3. Moderate heterogeneity of included studies and/or populations (eg, elective surgery and acute surgery)
4. Predominance of level III or lower studies
5. No measures or inappropriate measures of pooled risk (for meta-analysis only)

Modified with permission from Sauaia A, Moore EE, Crebs JL, Maier RV, Hoyt DB, Shackford SR. Evidence level of individual studies: a proposed framework for surgical research. *J Trauma Acute Care Surg*. 2012;72(6):1484-1490.

descriptive and exploratory studies should have research questions and, most of the time, a testable hypothesis. This step is where you assess whether the research design was appropriate to address the research question and test the hypothesis. Certain designs are better than others; randomized clinical trials (RCTs) remain the paragon of biomedical research, followed by cohort comparative studies, case-control studies, and case series, in that order. In RCTs, by randomly distributing patients to the study groups, potential risk factors are likely to be evenly dispersed. When blinding of patients and investigators is added to the design, bias is further minimized. These processes diminish the risk of confounding factors influencing the results. Therefore, the findings generated by RCTs are likely to be closer to the true effect than the findings generated by other research designs.

Although RCTs provide the best evidence due to unparalleled control of confounding, they have weaknesses, such as limited generalizability/external validity due to strict enrollment criteria (ie, they may not reflect the intended population). In addition, study settings and procedures may not mirror real-life practices. Indeed, as Archie Cochrane, the creator of the Cochrane Collaboration (the most important collection of systematic reviews), himself noted, randomization does not, of itself, promote external validity; that is, the applicability of a trial's results to situations other than the precise one in which the trial was done. Recognizing that RCTs do not always have great generalizability, funding and regulatory agencies, such as the US Food and Drug Administration (FDA), have started to rely also on what is called real-world data (RWD; the data relating to patient health status and/or the delivery of health care routinely collected from a variety of sources) and real-world evidence (RWE; clinical evidence regarding the usage and potential benefits or risks of a medical product derived from analysis of RWD) in addition to RCTs (see https://www.fda.gov/scienceresearch/specialtopics/realworldevidence/default.htm; accessed October 18, 2018).

Also in response to these valid concerns, RCTs labeled as pragmatic have been designed, in which the context and the included subjects reflect more accurately the environment and population to which the findings should be applied.[16] For example, the COMBAT[17] and the PROPPR trials,[18] which assess blood transfusions in the resuscitation process, were both pragmatic trials, with limited exclusion criteria and conducted with minimal interference to the standard of care other than the tested intervention. More recently, stepped-wedge RCTs have been proposed.[19,20] The stepped-wedge pragmatic design is different than the usual parallel RCTs, in which the intervention and control groups run, as the name suggests, in parallel. The stepped-wedged approach involves a sequential rollout of an intervention to participants (individuals or clusters) over a number of time periods, such that at the end of the study, all participants will have received the intervention. The name of the design (stepped-wedged) comes from the schematic illustration of the design. The order in which participants receive the intervention is assigned at random. The design is particularly relevant when the intervention is likely to have a benefit, thus making a control group possibly unethical. For example, the 1987 Gambia hepatitis intervention study,[21] the likely pioneer stepped-wedge trial, tested the effectiveness of a hepatitis B vaccine. Because the vaccine had established effectiveness at preventing hepatitis B (although no definitive evidence showing protection for chronic liver disease existed), it would be unethical to have a simultaneous control group receiving placebo. Thus, in order to obtain evidence on long-term benefit, a sequential but random rollout of the hepatitis B vaccination was implemented; geographic areas were randomly allocated to incorporate the vaccine into the existing childhood vaccination schedule. A new region was randomly allocated at 10- to 12-week intervals, such that complete national coverage was obtained after a few years. The stepped-wedge design is also useful when it is difficult to deliver the intervention simultaneously to all participants (or hospitals) for logistical, practical, or financial reasons (eg, use of whole blood in postinjury resuscitation).

We should also mention Bayesian trials, which are starting to gain popularity with the availability of computational algorithms and computing speed making it possible to carry out calculations for the very complex Bayesian models.[22] Because these trials are much more complex than traditional frequentist approaches, a full description of this type of trial is beyond the scope of this chapter. In brief, Bayesian statistics are an approach for learning from evidence as it accumulates; it applies the Bayes theorem to combine prior information (the prior probability, ideally based on pilot data or literature) with current information on an outcome of interest and derive a posterior probability (revised/updated probability of an event occurring after taking into consideration new information). In a Bayesian trial, the inferences are updated each time new data become available. Bayesian trials can be advantageous to reduce sample size, make modifications to the randomization ratio mid-study, deal with missing data, and in trials with multiple outcomes. However, the complexities of Bayesian trials should not be underestimated.[22] For an example in trauma, Jansen et al[23] provided a didactic description of a Bayesian trial, the UK-REBOA trial, designed to compare standard major trauma center treatment plus resuscitative endovascular balloon occlusion of the aorta (REBOA) with standard-of-care treatment alone for trauma patients with life-threatening torso hemorrhage.

When controlled experimentation is not possible or ethical, other research models must be considered.[24] Cohort comparative and case-control studies include a comparison group (ie, a group of patients who received a different type of care, procedure, or test). Alternatively, the investigator can compare the same group of patients before and after an intervention, using historical controls. The fundamental difference between cohort and case-control studies resides on where we start (ie, the outcome or the intervention/risk factor). In case-control studies, investigators find a group of patients with a specific outcome (eg, patients with severe torso trauma and coagulopathy) and a comparable group of patients without the outcome (eg, patients with severe torso trauma but no coagulopathy); the investigator then compares the incidence

of a risk factor (eg, hemodynamic instability in the field) or whether a particular intervention was instituted (eg, plasma in the field). For example, Wu et al[25] used a case-control design to compare the bone mineral density (BMD) of 87 elderly patients with hip fractures to 87 elderly patients without hip fractures and found BMD to be significantly lower among patients with the outcome (ie, hip fracture). In contrast, for cohort studies, investigators find a group of patients with the risk factor or intervention (eg, severe torso trauma patients who received plasma in the field) and a comparable group without the risk factor or intervention (eg, severe torso trauma patients who did not receive plasma in the field); then the outcome (eg, coagulopathy) rates of these groups are compared.

To make things more confusing, a case-control study is sometimes a later offspring of a well-planned cohort study, as in the case-control study by Shaz et al[26] on postinjury coagulopathy, which was nested within the ETIC (Early Trauma-Induced Coagulopathy) Prospective Study. Of the 383 ETIC patients, the authors selected 38 patients with prolonged prothrombin time (study cohort) and compared them with 53 age- and sex-matched controls with normal prothrombin time (control cohort). The authors reported decreased factor activities without significant differences in thrombin and fibrin generation between these two groups. Although important medical discoveries have been made through case-control studies, such as the association between smoking and lung cancer,[27] this design has several limitations that place it lower on the evidence hierarchy. These include, but are not limited to, potential for bias in the selection of the control group and uncontrolled confounding in the assessment of the risk factor or intervention.

Case series rank the lowest in the evidence hierarchy. They describe a group of patients with a certain condition or patients who were submitted to a specific care, procedure, or test, but without a comparison group. Case series have a role in rare conditions and in describing the preliminary experience with a new intervention. These studies generate hypotheses and motivate larger studies with more powerful designs. The lack of a comparator, however, lowers the confidence in the findings; thus, this type of study is less likely to change current practice. Of course, if this is an innovative treatment for a currently incurable, lethal disease, we may adopt it despite the low confidence for lack of better options. The urgency to adopt the new treatment, however, does not change the fact that the confidence generated by this design is low and that further research is crucial to decrease the uncertainty.

Matching is a procedure employed to decrease confounding in nonrandomized studies. Specifically, propensity score matching (PSM) has gained increased popularity in clinical research as an alternative design when RCTs are not possible.[28-32] In brief, the propensity score is the probability of treatment assignment conditional on observed (emphasis on *observed*) baseline characteristics. Each treated patient is matched to one or more control patients with similar propensity scores (ie, similar propensity to receive the treatment) but who did not receive the intervention. For example, patients treated with REBOA can be matched to patients with similar clinical *propensity* to require REBOA (ie, similar propensity scores) but who did not receive the procedure for some nonclinical reason (eg, physicians not trained on the procedure); the outcomes of these two groups are then compared. In traditional matching, REBOA-treated patients are matched on specific variables (eg, injury mechanism, age, cardiac arrest), whereas in PSM, they are matched on a combination of these variables (the propensity score). PSM works well when the intervention is relatively new and there is variation in its adoption by health care professionals for patients with the same set of clinical indications. There is controversy regarding how well PSM studies reflect the results of correspondent RCTs. Lonjon et al[33] reported no significant differences in effect estimates between RCTs and PSM observational studies regarding surgical procedures. Conversely, Zhang et al[34,35] reported that PSM studies tended to report larger treatment effects than RCTs in the field of sepsis, but the opposite was true for studies in critical care medicine. It is likely that differences in studied populations and confounders play a role in the disparities between PSM and RCTs. We must always keep in mind that RCTs control for both measured and unmeasured confounders, whereas PSM is only as good as the measured confounders included in the propensity score model. While appraising a PSM study, we must make sure to inspect the model used to generate the propensity score: Were all important confounders included in the model? More on the PSM approach will be presented in subsequent sections of this chapter.

Step 3: Define Effect Size

Effect size represents the magnitude and the direction of the difference in the outcomes between studied groups.[36,37] There are several measures of effect size, and some of the most commonly reported are as follows:

1. *Relative risk or risk ratio (RR):* RR compares the outcome probability in two groups (eg, with and without an intervention, or with and without a risk factor). When equal to 1, there is no evidence of effect.
2. *Odds ratio (OR):* This index compares the odds of the outcome in two groups. Unless the reader is a gambler, the concept of odds is not intuitive, yet because the highly popular logistic regression (discussed later in this chapter) produces ORs, this measure is often reported in the literature. Thus, it is important we understand it. For example, in a group of pediatric severe trauma admissions:
    - Odds of death in the group receiving antifibrinolytic: number of deaths/number of survivors
    - Odds of death in the group *not* receiving antifibrinolytic: number of deaths/number of survivors
    - OR: odds of death in the antifibrinolytic group/odds of death in the non-antifibrinolytic group

ORs are good estimates of the RR when the outcome is relatively rare (<20%); however, this is not true when the

outcome is more common. In studies with high prevalence of the outcome, OR may exaggerate the effect and should be interpreted with caution.[38] To illustrate the dangers of misinterpretation of OR, consider the study by Schulman and colleagues[39] titled "The Effect of Race and Sex on Physicians' Recommendations for Cardiac Catheterization" published in the *New England Journal of Medicine* (*NEJM*) in 1999. In this experiment, physicians were asked to predict compliance and potential benefit from revascularization for cases portrayed by actors of different races and sex. A logistic regression model showed that black race was associated with a lower likelihood of receiving a referral to cardiac catheterization, with an OR of 0.4. The authors concluded that the "race and sex of a patient independently influence how physicians manage chest pain."[39] Their study received extensive coverage in the news media, including a feature story on ABC's *Nightline*, with Surgeon General David Satcher providing commentary.[40] For the most part, the media interpreted the findings as "blacks were 40% less likely to be referred for cardiac testing than whites." In a subsequent *NEJM* Sounding Board article, Schwartz and colleagues[40] called attention to the dangers of using the OR as an effect size measure when the outcome was very common; in the Schulman et al[39] study, greater than 80% of patients had the outcome (referral for cardiac catheterization). The OR, in this case, led to a gross exaggeration of the actual RR: the reported OR of 0.6 [(blacks referred/blacks not referred)/(white referred/whites not referred)] actually corresponded to an RR of 0.93. In other words, blacks were 7% less likely than whites to receive the referral for further cardiac testing. Quite a difference! When faced with the report of OR in studies with outcomes more frequent than 20%, one can use the formula proposed by Zhang and Yu[38] to obtain an estimate of the RR, as follows:

$$RR = OR/[(1 - Po) + (Po \times OR)]$$

where Po is the probability of the outcome in the control (or reference) group.

Although this formula has been criticized for still overestimating the RR (although less than the OR) and not accounting for confounders,[41] it is a simple calculation that can assist the reader in obtaining a more realistic estimate of the effect size when the OR was inappropriately used. One may ask why researchers are still using OR instead of RR; the answer is that logistic regression, one of the most popular statistical methods, deploys ORs. Until recently, models that derived RR were more difficult to use, and software was not as widely available as that for logistic regression. This has now changed with a myriad of user-friendly models that estimate RR; thus, there is little (no) excuse for reporting OR when the outcome is common.

Large RRs and ORs tend to strengthen the evidence. Although there is no strict definition of a large effect, effects greater than 5 (or smaller than 0.2, when the desired direction is to decrease the outcome) in a condition of low to moderate morbidity or mortality (eg, stable femur fracture in a young person) are considered large effects.[3] In highly morbid or lethal conditions (eg, penetrating chest wounds), an effect size greater than 2 (or <0.5) may be considered large enough.

Two other measures of effect size are also reported in publications:

1. *Cohen's d:* This measurement is the standardized mean difference; it is not commonly reported but can be easily calculated as: (mean 1 – mean 2)/(pooled standard deviation).[42] Cohen's d values around 0.2 are considered small; 0.5, medium; and 0.8 or greater, large.
2. *Correlation:* Pearson's correlation coefficient *r* (and its nonparametric equivalent, the Spearman's rho) measures the correlation between two continuous outcomes (eg, volume transfused and systolic blood pressure) and ranges from –1 to 1. Cohen (the same statistician who proposed the Cohen's d) suggested the following rule of thumb for correlations: small = |0.10|, medium = |0.30|, and large = |0.50|.[43]

Step 4: Assess the Limitations of the Study

The next step recognizes that all research designs, even RCTs, are more or less limited by confounding, bias (especially selection bias), inadequate sample size and statistical power, heterogeneity of included subjects, missing data, loss to follow-up, lack of generalizability, and other factors. These factors increase the uncertainty surrounding the research findings and, consequently, decrease its level of evidence. These factors will be explored in detail in the next sections of the chapter.

A FEW STATISTICAL CONCEPTS

Study Designs

In previous sections, we briefly defined study designs. The classic hierarchy ranks designs based on their ability to decrease bias and confounding. It is usually illustrated by a pyramid, with designs in the following order (from the top of the pyramid to the bottom): (1) systematic reviews and meta-analyses (of high-quality RCTs with little heterogeneity); (2) RCTs with confidence intervals (CIs) that do not overlap the threshold of clinically significant effect; (3) RCTs with point estimates that suggest clinically significant effects but with overlapping CIs; (4) cohort studies; (5) case-control studies; (6) cross-sectional surveys; and (7) case reports.[44] More recently, it has been proposed that systematic reviews are not at the top of the pyramid; rather, they correspond to the lens through which we examine the available evidence.[45] Currently, however, several investigators and organizations recognize that most clinical trials, despite the best designs, fail to provide the evidence needed to inform medical decision making.[46] Thus, such strict ordering has been criticized; a more flexible rule is that we must use the best research design available to define the best evidence.[47]

RCTs are considered the best design because the randomization provides an unbiased group allocation and often (but not always) results in similar distribution of both observed and nonobserved confounders across study arms. Ultimately, the goal of randomization is "to ensure that all patients have the same opportunity or equal probability of being allocated to a treatment group."[48] In random allocation, the assignment cannot be predicted for any individual patient.[49] If effective, randomization creates at the start of the study (before the intervention) groups of patients with similar prognoses; therefore, the trial results can be attributed to the interventions being evaluated.[50]

In emergency research trials, the patients are not recruited; instead, they are enrolled as they suffer an injury, in a completely random fashion. This is an advantage, as the subjects enrolled may more closely resemble the target population. However, emergency trauma research imposes challenges to the randomization as the interventions must be made available without any delay.[51,52] Conventional randomization schemes (eg, sealed envelope with computer-generated random assignment, calling a randomization center) may impose unethical delays in providing treatment. Other major challenges of sophisticated randomization schemes are adherence to protocol and rapid, inclusive enrollment. Thus, alternative schemes (eg, prerandomization in alternate weeks) have been proposed.[53] In a recent trial, we randomized severely injured patients for whom a massive transfusion protocol was activated to two groups: (1) viscoelastic (thromboelastography)-guided, goal-directed massive transfusion or (2) conventional coagulation assays (eg, prothrombin time) and balanced blood product ratios on predefined alternating weeks.[54] The system was formidably successful in producing comparable groups at baseline and minimized interference in the resuscitation. Another example is the Prehospital Acute Neurological Treatment and Optimization of Medical Care in Stroke Study (PHANTOM-S), published in 2014, in which patients were randomly assigned weeks with and without availability of a stroke emergency mobile unit.[55] These alternative randomization approaches are recognized as appropriate in emergency research.[51]

Adaptive designs, including adaptive randomization, have been proposed to make trials more efficient.[56,57] A 2015 draft guidance document from the FDA defines an adaptive design clinical study as "a study that includes a prospectively planned opportunity for modification of one or more specified aspects of the study design and hypotheses based on analysis of data (usually interim data) from subjects in the study."[58] Just as an example, the 2015 PROPPR trial used an adaptive design to grant their Data and Safety Monitoring Board (DSMB) authority to increase the sample size and reach adequate power during interim analyses.[59] The trial assessed effectiveness and safety of transfusing severely injured patients with major bleeding using plasma, platelets, and red blood cells in a 1:1:1 ratio compared with a 1:1:2 ratio. Their initial sample size (n = 580) was planned to detect a clinically meaningful 10% difference in 24-hour mortality based on previous evidence. Based on the results of an interim analysis, their DSMB recommended increasing the sample size to 680, which would allow the trial to have 95% power to detect the prespecified 10% difference at 24 hours and 92% power to detect the prespecified 12% difference at 30 days, if such differences existed. Interestingly, however, the trial did not show a significant difference in mortality at 24 hours (12.7% in 1:1:1 group vs 17.0% in 1:1:2 group; $P = .12$) or 30 days (22.4% vs 26.1%; $P = .26$). The study was not powered to detect the observed differences of 4.3% and 3.7% (much smaller than the prespecified differences) in the two mortality outcomes.

In sum, the research design must be appropriate to the research question, ethical, and valid, both internally and externally. Internal validity refers to the extent to which the results of the study are biased or confounded. In the next sections, we will discuss bias and confounding in more detail, but basically this comes down to one question: Is the association between outcome and effect reported in the study real? How much of it may be due to bias and/or confounders? External validity, on the other hand, reflects the extent to which the study is generalizable.

Primary and Secondary Data

When researchers use data collected for the specific, preplanned purpose of addressing a research question, they are using primary data. However, in the era of "big data," it is common to see the use of secondary data, collected for purposes unrelated to the specific research question. Secondary data sets have advantages, as they are usually large and inexpensive. Yet, they have had mixed results when used for such tasks as risk adjustment.[60] Administrative data sets collected for billing purposes, for example, are often influenced as a result of financial reasons, which can favor over- or undercoding, and the number of diagnoses may be capped or deincentivized due to declining marginal returns in billing.

In addition, medical coding and clinical practices are subject to change over time due to a variety of reasons; thus, longitudinal studies need to make sure to account for changes. For example, the coding of "illegal drugs" upon trauma admission is likely to change in unpredictable ways in states where cannabis became a legal recreational drug. Another glaring example relates to collection and coding of the social construct variable race and ethnicity, which has changed dramatically over the past few decades.[61] In addition, comorbidities may be misdiagnosed as complications and vice versa. To address this problem, since 2008, most hospitals now report a "present on admission" (POA) for each diagnosis in its administrative data as a means to distinguish hospital-acquired conditions from comorbidities. Of course, using data from before and after modifications were implemented, such as the inclusion of a POA code, affects the quality of the data. Whenever longitudinal data are used in a study, especially if covering long periods of time, it is important to verify whether there were changes in data collection, health policies, or regulations that could potentially affect the data.

Sometimes the distinction between primary and secondary data becomes blurry, as happens in registries such as state-mandated and hospital-based trauma registries or the National Trauma Data Bank (NTDB), a voluntary national trauma data set maintained by the American College of Surgeons. These data sets were developed to provide a comprehensive epidemiologic characterization of trauma; thus, one can assume that when the research question is related to frequency, risk factors, treatments, and prognosis of trauma, these represent legitimate primary data. However, registries may lack the granularity to address study hypotheses (eg, analyzing the effects of early transfusions of blood components on coagulation-related deaths). In the end, the discussion of whether registries represent primary or secondary data is probably irrelevant; what matters is whether the data are appropriate to address the research question and whether bias and confounding, variability, and inconsistencies are taken into account during data analysis and research appraisal. For example, low-volume hospitals may not contribute enough to aggregate estimates, biasing mortality toward high-volume facilities. The Center for Surgical Trials and Outcomes Research (Department of Surgery, Johns Hopkins School of Medicine) in Baltimore has done a commendable job of documenting differences in risk adjustment and, more important, providing standardized analytic tools to improve risk adjustment and decrease low-volume bias in studies using the NTDB.[62-64]

Hypothesis, Significance, and Power

All studies that use a statistical test, even purely descriptive studies, have a hypothesis. That is because a statistical test is based on a hypothesis. Every hypothesis can be placed in the following format:

Variable X distribution in Group A
is different (or not different) from
Variable X distribution in Group B

Despite its simplicity, this is a widely applicable model for constructing hypotheses. It sets the stage for elements that must be included in the methods section. The authors must define what characterizes Group A and Group B and what makes them comparable (aside from Variable X). Variable X, which is the variable of interest, must be defined in a way that allows the reader to completely understand how the variable is measured. The hypotheses should be further defined using the previously mentioned PICO framework. For example, "We hypothesize that adult trauma patients (P) receiving pharmacoprophylaxis for venous thromboembolism (I) will have fewer venous thromboembolisms (O) than patients not receiving pharmacoprophylaxis (C)."

The commonly reported *P* value is the probability of obtaining the observed effect (or larger) under the null hypothesis that there is no effect. Colloquially, we can interpret the *P* value as the probability that the finding was the result of chance.[65] The *P* value is the chance of committing what is called a type I error, that is, wrongfully rejecting the null hypothesis (ie, accepting a difference when in reality there is none). More important, the *P* value is *not* how sure one can be that the difference found is the correct difference.

Significance is the level of the *P* value below which we consider a result statistically significant. It has become a worldwide convention to use the $P = .05$ level, although this value is completely arbitrary, not based on any objective data, and, in fact, inadequate in several instances. This level was suggested by the famous statistician Ronald Fisher, who rejected it later and proposed that researchers report the exact level of significance.[66]

In research articles, readers will often see that *P* values were "adjusted for multiple comparisons," with significance set at *P* values smaller than the traditional $P = .05$ threshold. This is a controversial issue in biostatistics, with experts debating the need for such adjustment.[67-69] Those who defend the use of multiple comparisons adjustments claim that multiple comparisons increase the chances of finding a $P < .05$ and inflate the likelihood of a type I error.[68] Those who criticize its use argue that this leads to type II errors (ie, the chance of not finding a difference when indeed there is one).[67,69] One of the authors of this chapter (A.S.) recalls her biostatistics professor claiming that if multiple comparisons indeed increased type I error, then biostatisticians should stop working at the age of 40, as any differences after then would be significant just by chance. Our recommendation is that if the hypotheses being tested are predefined (ie, before seeing the data), then multiple comparisons adjustment is probably unnecessary; however, if hypothesis testing was motivated by trends in the data, then it is possible that even the most restrictive multiple comparisons adjustment will not be able to account for the immense potential for investigator bias. In the end, the readers should check the exact *P* values and make their own judgment about a significance threshold based on the impact of the condition under study. Lethal conditions for which there are few or no treatment options may require looser significance cutoffs, whereas benign diseases with many treatment options may demand stricter significance values.

A special case of multiple comparisons is the interim analysis, which is a preplanned, sequential analysis conducted during a clinical trial. These analyses are almost obligatory in contemporary trials due to cost and ethical factors. The major rationale for interim analyses relies on the ethics of holding subjects hostage of a fixed sample size, when a new therapy is potentially harmful, overwhelmingly beneficial, or futile. Interim analyses allow investigators, upon the DSMB independent advice, to stop a trial early due to efficacy (the tested treatment has already proven to be of benefit), futility (the treatment-control difference is smaller than predicted, and continuing the trial is not likely to result in a significant difference), or harm (treatment resulted in some harmful effect).[70] For example, Bulger et al,[71] in their RCT testing the effect of prehospital hypertonic resuscitation after traumatic hypovolemic shock, reported that the DSMB stopped the study based on the potential harm in a preplanned subgroup analysis of nontransfused subjects. The COMBAT study,[17]

published in 2018, was stopped after the second interim analysis because the absence of differences in the primary outcome of mortality persisted during all analyses, thus strongly suggesting that continuing the trial was unlikely to result in a change in the observed lack of differences.

The 95% CI is a concept related to significance. Its interpretation is as follows: if we were to repeat the experiment infinite times and, at each time, calculate a 95% CI, 95% of these intervals would contain the true effect. A more informal interpretation is that the 95% CI represents the range within which we can be 95% certain that the true effect lies. Although the calculation of 95% CI is highly related to the process to obtain the *P* value, the CIs provide more information on the degree of uncertainty surrounding the study findings. There have been initiatives to replace the *P* value with 95% CI, but these have been met with much resistance. Most journals now require that both be reported. For example, in the CRASH-2 trial, a randomized controlled study on the effects of tranexamic acid (TXA) in bleeding trauma patients, the TXA group showed a lower death rate (14.5%) than the placebo group (16.0%), with $P = .0035$.[72] We can interpret this *P* value as follows: "There is 0.35% chance that the difference in mortality rates was found by chance." The CRASH-2 authors reported the effect size as an RR of 0.91, with a 95% CI of 0.85 to 0.97. This means, in a simplified interpretation, that we can be 95% certain that the true RR lies between 0.85 and 0.97.

The CRASH-2 example reminds us that it is important to keep in mind that statistical significance does not necessarily mean practical or clinical significance. Even very small effect sizes can be statistically significant if the sample size is very large. The CRASH-2 trial, for example, enrolled 20,211 patients to obtain a 1.5% absolute difference and a 9% relative difference in mortality.[72] *P* values are related to many factors other than chance, including the sample size (larger samples sizes often result in significant *P* values), the effect size (larger effect sizes usually produce smaller *P* values), and multiple unplanned comparisons.[73]

We must make sure that the study used appropriate statistical tests. Statistical tests are based on assumptions, and if these assumptions are violated, the tests may not produce reliable *P* values. Many parametric tests (eg, t-test, analysis of variance, Pearson correlation) rely on the normality assumption. The parametric test is a test that relies on a known distribution (eg, the normal distribution), whereas nonparametric tests (eg, Wilcoxon-Mann-Whitney test, Kruskal-Wallis test) do not rely on any distribution. One may ask: Why not always use nonparametric tests? The answer is because they are usually less powerful in detecting differences than parametric tests. When the sample is large (n >30), parametric tests are robust against violations of the normal distribution, because of the Central Limit Theorem (the distribution of the mean of a large number of independent, identically distributed variables will be approximately normal, regardless of the underlying distribution) and the law of large numbers (the sample mean converges to the distribution mean as the sample size increases). However, gross skewness and small sample sizes (n <30) will render parametric tests inappropriate. Thus, if the data are very skewed, as is often the case with number of blood units transfused, length of hospital stay, and viscoelastic measurements of fibrinolysis (eg, clot lysis in 30 minutes), or the sample size is small (as is often the case in basic science experiments), nonparametric tests (eg, Wilcoxon rank sum, Kruskal-Wallis, Spearman correlation) or appropriate transformations (eg, log, Box-Cox power transformation) to approximate normality are more appropriate. More on this topic is in the section on sample descriptors later in this chapter.

Statistical power is the counterpart to the *P* value. It is highly related to the sample size (ie, the larger the sample, the greater the statistical power). It relates to type II error, or the failure to reject a false null hypothesis (a false negative). Statistical power is the probability of accepting the null hypothesis (there is no difference) when there is actually a difference. The most basic formula to calculate power is shown below:

$$N = \frac{2\sigma(Z_{\beta} + Z_{\alpha/2})}{\text{Difference}^2}$$

where N is the sample size in each group (assuming equal sizes), σ is the standard deviation of the outcome variable, Z_{β} represents the desired power (0.84 for power = 80%), $Z_{\alpha/2}$ represents the desired level of statistical significance (1.96 for α = 5%), and "Difference" is the proposed, clinically meaningful difference between means.

Despite its importance, power is one of the most neglected aspects of research articles. In most studies, the researchers are searching for a significant difference; that is, they conducted superiority studies, where one group is hypothesized to have a condition (or intervention) that is superior compared to the other. When a difference is found to not be significant in a superiority study, there are two alternatives: to declare failure to find a significant difference or to produce a power analysis to determine how confident we are to declare that the interventions (or risk factors) under study are indeed similar. The latter alternative is more appealing when it is preplanned as a noninferiority trial rather than as an afterthought in a superiority study. Ideally, all studies should report a power analysis.

Whether statistical power is calculated beforehand (ideally) or afterward (better than not at all), it must always contain the following four essential components: (1) power, minimal of 0.80 or 80% (another arbitrary cutoff in the statistical arena); (2) confidence, usually 0.95 or 95%; (3) value of the outcome of interest in the control group/comparator; and (4) minimum difference to be detected. For example, in the RCT by Gonzalez et al[54] comparing goal-directed resuscitation guided by viscoelastic tests to standard resuscitation with preestablished blood product ratios and guided by conventional coagulation tests:

> A 30% death rate was estimated in the control group[71]; thus, a sample size of 122 patients would have 80% power to detect a minimum of 20% points difference in survival rate between the 2 groups with 95% confidence.

We call attention to how Gonzalez et al[54] proposed the control difference (30%) *based on data from a previous similar trial* by Bulger et al.[71] The minimum difference that a study is powered to detect is based on clinical significance. For example, a difference of 1% in mortality is not likely to be of clinical significance and would require a prohibitively large sample size. However, a sample that can only detect a difference of 50% or larger is too underpowered, because only a miraculous intervention could operate such dramatic difference.

Power analysis can become more complex when we need to take into account the following: (1) multiple confounders (covariates), in which case the correlation between the covariates needs to be taken into account; or (2) cluster effects (explained in more detail later), in which case an inflation factor, dependent on the level of intracluster correlation and number of clusters, is used in the sample size estimation. Not surprisingly, all of these increase the required sample size.

Some clever but complex designs can decrease the required sample size, such as factorial designs, in which two (or more) factors are tested at once. For example, in an elegant RCT[74] about the effect of erythropoietin (EPO) and transfusion threshold (hemoglobin [Hgb] <7 g/dL or <10 g/dL) on neurologic recovery after traumatic brain injury, patients were randomized to one of four groups (EPO + Hgb <7 g/dL; placebo + Hgb <7 g/dL; EPO + Hgb <10 g/dL; or placebo + Hgb <10 g/dL). This design approach basically runs two trials in the same group of patients. The analysis is a bit more complex and includes testing for an interaction between the two interventions.

Power analysis for noninferiority studies requires a couple of extra steps. Noninferiority studies are becoming much more common in the era of comparative effectiveness.[75,76] Their null hypothesis assumes that there is a difference between arms, whereas for the more common superiority trials, the null hypothesis assumes that there is no difference between groups. A noninferiority trial seeks to determine whether a new treatment is not worse than a standard treatment by more than a predefined margin of noninferiority for one or more outcomes (or side effects or complications). Noninferiority trials and equivalence trials are similar, but equivalence trials are two-sided studies, where the study is powered to detect whether the new treatment is not worse and not better than the existing one. Equivalence trials are not common in clinical medicine.

In noninferiority studies, the researchers must prespecify the difference they intend to detect, known as the noninferiority margin (also known as irrelevant difference or clinical acceptable amount based on literature).[75] Within this specified noninferiority margin, the researcher is willing to accept the new treatment as noninferior to the standard treatment. This margin is determined by clinical judgment combined with statistical factors and is used in the sample size and power calculations. For example, is a difference of 4% in infection rates between two groups large enough to sway your decision about antibiotics? Would a difference of 10% make you think they are different? Or do you need something smaller? These decisions are based on clinical factors, such as severity of the disease, and also on known variation in the outcomes.

The USA Multicenter Prehospital Hemoglobin-Based Oxygen Carrier Resuscitation Trial is an example of a dual superiority/noninferiority assessment trial.[77] The noninferiority hypothesis assumed that patients in the experimental group would have no more than a 7% higher mortality rate compared with control patients, based on available medical literature as well as the feasibility of the study. The implication of a noninferiority outcome in this study was that the blood substitute product would not be used interchangeably with available blood products; rather, it applied to scenarios in which blood products are needed but not available or permissible.

Reviews of the quality of noninferiority trials have shown major problems due to underreporting.[78,79] Essential elements to be included in the reports of this type of study include the following: (1) the noninferiority margin and its rationale; (2) whether the participants in the noninferiority trial were similar to those included in the previous trials that established the efficacy of the control treatment; (3) whether the control intervention is in fact similar to the intervention tested in efficacy trials; and (4) whether secondary outcomes are also being tested for noninferiority rather than superiority.[76]

We close this section with a final message about significance and power. We often hear the comment that a small study with a significant difference may lack power. This is incorrect. Once a study has a significant difference, questions about statistical power are irrelevant. The issue then is related to external validity or generalizability: Are the study findings applicable to the general population they are supposed to represent?

Association and Causation

Most studies describe associations between outcomes and effects of interest. Whether these associations represent a cause-effect relationship, or rather an association without causality, is often up for debate. To strengthen the case for causation, we can apply the set of nine criteria proposed by Sir Austin Bradford Hill in 1965 as a guideline.[80,81]

1. *Strength of the association:* Large effect sizes are more likely to be causal than noncausal associations (effect size, not *P* value). For example, in the initial studies on risk factors for multiple organ failure (MOF), there was a strong association between transfusions of red blood cells (RBCs) and postinjury MOF, which triggered further investigations on the specific causative, harmful role of RBCs.[82-84]
2. *Consistency:* The results have been replicated under different conditions by independent investigators.
3. *Specificity:* The effect of interest is associated with a specific outcome rather than a wide range of outcomes. Its presence can help the case for a causal effect, but its absence does not discard it, as most outcomes have multifactorial, interdependent causes.
4. *Temporality:* There is a temporal relationship in which the effect of interest clearly precedes the disease. Although

this may seem obvious, it is important that we take into account how the outcomes and the effect are measured. For example, although lung failure seems to precede liver and renal dysfunction in the development of postinjury MOF, lung function tests are more sensitive than clinically used liver and renal function tests. Pao_2/Fio_2 ratios may detect early, mild levels of pulmonary failure, whereas bilirubin and creatinine only rise after substantial organ derangement.[85,86] Thus, the temporal relationship may be unclear.

5. *Biological gradient or dose response:* Increasing/decreasing exposure is associated with increasing/decreasing risk of disease. This is a powerful criterion when measurements are accurate. In the previously mentioned studies on the association between RBC and MOF, a dose-response relationship was observed: larger numbers of RBC units transfused were associated with progressively higher MOF rates.[87] Moreover, we observed that judicious transfusion practices that drastically limited the amount of RBCs transfused were associated with a decrease in postinjury MOF.[84]
6. *Plausibility:* When there is a plausible scientific mechanism that can explain the association, the case for causation is strengthened. The lack of such mechanism does not eliminate causation, as new mechanisms may be discovered; however, if one already exists, it enforces the case for causation.
7. *Coherence:* The association is consistent with what is known about the disease. Of course, novel observations may not fit this criterion. Yet, there is no denying that if the reported finding does not fit with current knowledge, there is a tendency toward a healthy skepticism.
8. *Experimental evidence:* Hill[80] proposed that "causation is more likely if evidence is based on randomized experiments."
9. *Analogy:* In the presence of previous evidence of a causal effect by one class of agent (eg, RBC and MOF), we are more likely to accept causation when another agent from the same class (eg, plasma) is implicated as a risk factor for the same outcome. Again, as Rothman and Greenland[88] indicate, we must be careful in the application of this criterion: "Whatever insight might be derived from analogy is handicapped by the inventive imagination of scientists who can find analogies everywhere. At best, analogy provides a source of more elaborate hypothesis about the associations under study; absence of such analogies only reflects lack of imagination or lack of evidence."

These criteria are to be used as guidelines, as Sir Bradford Hill himself wrote: "None of my nine viewpoints can bring indisputable evidence for or against the cause-and-effect hypothesis and none can be required as a sine qua non."[80]

Bias

Physicians can appreciate the acronym CBC as a mnemonic for the three main reasons for a spurious association: **c**hance, **b**ias, and **c**onfounding. Chance is dealt with by statistical testing, whereas appropriate designs and analytic techniques can assist with eliminating or minimizing bias and confounding. We have dealt with the "chance" reason and statistical testing in previous sections. In this section, we will deal with bias and confounding.

Bias is the deviation of results due to systematic errors in the research methods. Although there are several different names for biases, two types seem to capture most biases presented in surgical literature: (1) selection bias, which occurs when the study groups differ systematically in some way, or when the study sample differs from the study population; and (2) observer/information bias, which occurs when there are systematic differences in the way information is collected for the groups being studied. The article by del Junco et al[89] on the seven deadly sins in trauma outcome research is an excellent review of some of the most common biases in trauma research.

There are several types of selection bias commonly found in the trauma literature. One of the most common is missing data not at random. Treatment of missing data has become the focus of much attention recently. Indeed, the FDA requested that the National Academy of Sciences create the Panel on Handling Missing Data in Clinical Trials to propose appropriate study designs and follow-up methods to reduce missing data and appropriate statistical methods to address missing data for analysis of results.[90] Although their focus was on RCTs, the report is very informative for other study designs as well.

The most important things to consider about missing data are (1) the proportion of patients with missing data and (2) whether the data are missing at random, thus not biasing the results in a significant way, or there is some pattern that can bias the results. Finding out that data are missing not at random (MNAR) does not mean that the study is automatically flawed; rather, appropriate statistical methods must be used to deal with them. However, if the proportion of missing data is high and MNAR, one cannot ignore it and proceed to analyze the complete data set without further consideration. Let us illustrate this with a little story: The father of one of the authors (A.S.) was a physician interested in congenital heart defects. He was conducting a population-based study about the incidence of such defects in school-age children and visited several schools, screening children for heart defects. Some children were, of course, absent that day and were not screened. At the end of the day, this young physician researcher considered the absent children (his missing data) for a moment and, wanting complete data, decided to visit them at home. Not surprisingly, some of the absent children did in fact have a heart defect. This made sense because these ill children were more likely to miss school because of symptoms or medical appointments.

Missing data not at random in trauma occurs for two radically different reasons: (1) patients are too sick to have the test (eg, died early, intravenous access not possible, chaotic trauma scene), in which case adverse outcomes are common; or (2) patients are not sick enough to justify the test (eg, early discharge, hemodynamically stable, not in shock, not

requiring mechanical ventilation), in which case adverse outcomes are rare. For example, in the late 1990s, we developed predictive models for postinjury MOF and observed that lactate was a significant independent predictor of MOF.[82,91] As expected, lactate measurement was available only for the group of severely injured patients. We addressed the missing data using two analyses: one included only patients for whom lactate was measured, and the second included all patients and used a "missing indicator" (ie, lactate levels were categorized into three possible categories: missing, normal, and abnormal). The results of the two analyses were remarkably similar and increased the strength of our findings. In a more recent example, Odom and colleagues[92] addressed this issue in their study on the value of lactate as a predictor of trauma mortality. They astutely observed that the selection bias created by the missing lactate values would bias their results toward the null hypothesis rather than the positive effect they found. Even existing national databases suffer from the bias created by missing data not at random. Thiels et al[93] showed that clinical data missingness was much greater in firearm incidents compared to other injuries in the NTDB. Lack of personnel prepared to gather information in the sensitive circumstances surrounding gun-related episodes is likely a major culprit.

Many methods are available to deal with missing data, such as last value carried forward. Albeit highly criticized, this technique has its place in longitudinal studies, when most variables are not missing and there is high predictability of missing values.[94] For example, we used this technique to input the values of daily liver function tests using the last obtained value until a subsequent result was available.[95]

More sophisticated techniques such as multiple imputation by chained equations (MICE) are becoming popular. Simply put, this method imputes missing values based on regression equations derived M times, followed by an analysis of each imputed dataset and finalized by a combination of the M analyses using standard methods. Although multiple imputation functions better for data missing at random, it has been shown to provide good estimates even in certain cases when data are MNAR. For example, Moore and colleagues[96,97] tested the use of MICE to impute values of the Glasgow Coma Scale in 2005, and again in 2015 for the Glasgow Coma Scale, respiratory rate, and systolic blood pressure for a model to evaluate quality of trauma care with good success.

Another important type of selection bias, especially in trauma and emergency care, is survivor bias. This occurs when the individual does not survive long enough to have the "opportunity" to receive the complete intervention. These early nonsurvivors contribute to increasing the mortality rate of the group not receiving the intervention, artificially inflating the effect of the intervention. The studies on fixed, balanced blood product ratios (1:1:1 RBC:plasma:platelets) are well-known examples of this problem.[89,98,99] Survival analysis, which analyzes time to event and allows for censoring patients who died before experiencing the intervention, is a helpful technique to deal with this problem. The best solution, however, to deal with survivor bias is an RCT. Indeed, the results of the PROPPR trial, an RCT testing the effect of a fixed, balanced blood product ratio failed to find a difference, despite excellent statistical power, contradicting the results of previous observational studies that found it beneficial.[18] Another problem with the blood product studies was the "catch-up" practice. For example, if a patient received 6 RBC units and 3 units of plasma in the first 3 hours and no blood products between hours 4 and 6, the RBC:plasma ratio at 6 hours is 2:1. This is exactly the same ratio at 6 hours as someone who receives 6 RBC units in the first 3 hours and 3 units of plasma from hour 4 to the end of hour 6 (the "catch-up" practice). The big difference here is that the first patient experienced the 2:1 ratio at all times, whereas the second patient had an initial ratio of 3:0 followed by a ratio of 0:3. It is quite possible that the outcomes are different for these two extremes. Using a time-varying covariate in a survival analysis (ie, a variable that changes over time), we can actually express the changes in RBC:plasma ratio hourly.

Some authors deal with survivor bias by excluding early deaths from the analysis. This may be a solution, but it limits the generalizability, because the study findings apply only to patients who survive the acute postinjury period. Other types of commonly encountered selection biases include loss to follow-up not at random (eg, patients failed to return to follow-up visits due to death or long-term injury-related complications), refusal to participate or withdrawal due to side effects or invasiveness of the intervention, and consent not obtained due to traumatic brain injury, among others. This is a good reminder to always read the inclusion and exclusion criteria to determine whether they resulted in selection bias. Common exclusion criteria that may limit the generalizability of the investigation are advanced age, comorbidities, early deaths, and incomplete data. It is important to realize that the findings apply only to the population that fits both the inclusion and exclusion criteria.

Confounding

Now we will address the final C in the CBC acronym: **c**onfounding (ie, a third variable responsible for all or part of the association between two other variables). An often-quoted example is the association between coffee drinking and lung cancer, which is confounded by the real culprit, smoking, a variable associated with both coffee drinking and lung cancer. To be considered a confounder, a variable must be associated with both the outcome and the effect of interest (ie, a risk factor or an intervention). In trauma, injury severity, age, and comorbidities are frequent confounders of the association between an intervention and the outcome.

There are two ways to deal with confounders: (1) research designs, including RCT or matching; and (2) analytic tools, such as stratified analysis (when there are few confounders) or multivariate analysis (in the case of multiple confounders). These techniques will be discussed in a subsequent section of this chapter. Usually, the "table 1" in RCT reports the distribution of potential confounders between the control and experimental groups.

Appropriately so, readers should not find *P* values in this table, as any differences in the distribution of these confounders are, by definition, a result of chance. Randomization increases the likelihood of similar distribution of confounders, which then are not associated with group membership, allowing us to assess the effect of the intervention (the main difference between the two groups) on the outcome. Single blinding (only the patient) or double blinding (the patient and the researcher) are powerful add-ins to improve the likelihood that the researchers' and patients' own biases do not interfere with the design. Surgical and emergency interventions, however, are often not amenable to blinding.[100]

Matching is an alternative option to deal with confounders. This can be accomplished via traditional matching when only a few known risk factors exist or via PSM, which we mentioned in a previous section. In PSM, a multivariate model including potential reasons for receiving the intervention is used to derive a propensity score (ie, the probability of receiving the intervention). In this model, the "outcome" or "dependent variable" is the intervention. Using this propensity score, we can choose matching control patients (ie, patients who did not receive the intervention despite having the same propensity score as the patients who received the intervention). The downside of this procedure is that the reason why patients did not receive the intervention despite having the same propensity score is often unknown. In addition, the PSM accounts for measured variables, not for unmeasured variables (which an RCT accounts for). Finally, matching limits the ability of the investigators to examine the effects of the matching variables; once used in the matching, a variable is no longer available for analysis. Therefore, it is important that the investigators are certain that the matching variable is of no interest in the analysis of the outcomes.

Interactions and Effect Modification

In confounding, variable A is responsible for part or all of the association between variables B and C, and we want to adjust for it (in other words, minimize its effect) to be able to assess the association between B and C. There is little or no interest in any effects mediated by variable A. Conversely, in effect modification or interaction, variable A modifies the association between B and C. This type of association must be described, not adjusted for, as it provides important information of the mechanism underlying the association of B and C. Thus, when appraising multivariate models, the reader should make sure pertinent interactions were tested and, if significant, described appropriately.

An example of an interaction can be found in our study on the effect of preinjury antiplatelet therapy on postinjury outcomes. We showed that antiplatelet therapy modified the relationship between blood product transfusions and mortality.[101] Specifically, as shown in Fig. 7-1, among patients who were taking antiplatelet therapy prior to the injury, the odds of mortality associated with RBCs transfused were lower than among patients not receiving this medication.

Descriptive Statistics

Descriptive statistics, such as mean and standard deviation, median and interquartile range, frequency and percentages, are used to provide the reader with the best possible description of the sample. Because the reader does not have access to the raw data, it is up to the authors to provide readers with a clear picture of what the sample looked like. More important, this picture should allow the readers to use the PICO framework and compare the study's sample to the population

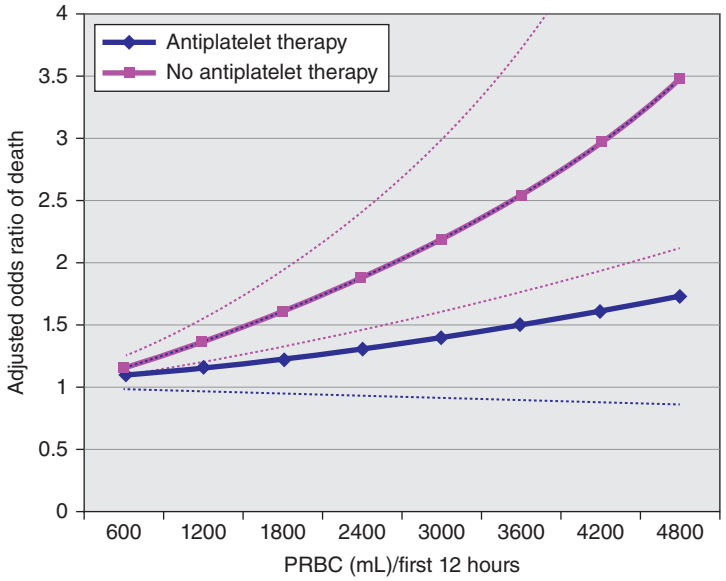

FIGURE 7-1 Example of an important effect modification (or interaction) in the study by Harr et al[101] investigating the effect of preinjury antiplatelet therapy on postinjury outcomes. These investigators showed that antiplatelet therapy modified the relationship between blood product transfusions and mortality, decreasing the risk associated with requirement for transfusions. PRBC, packed red blood cells.

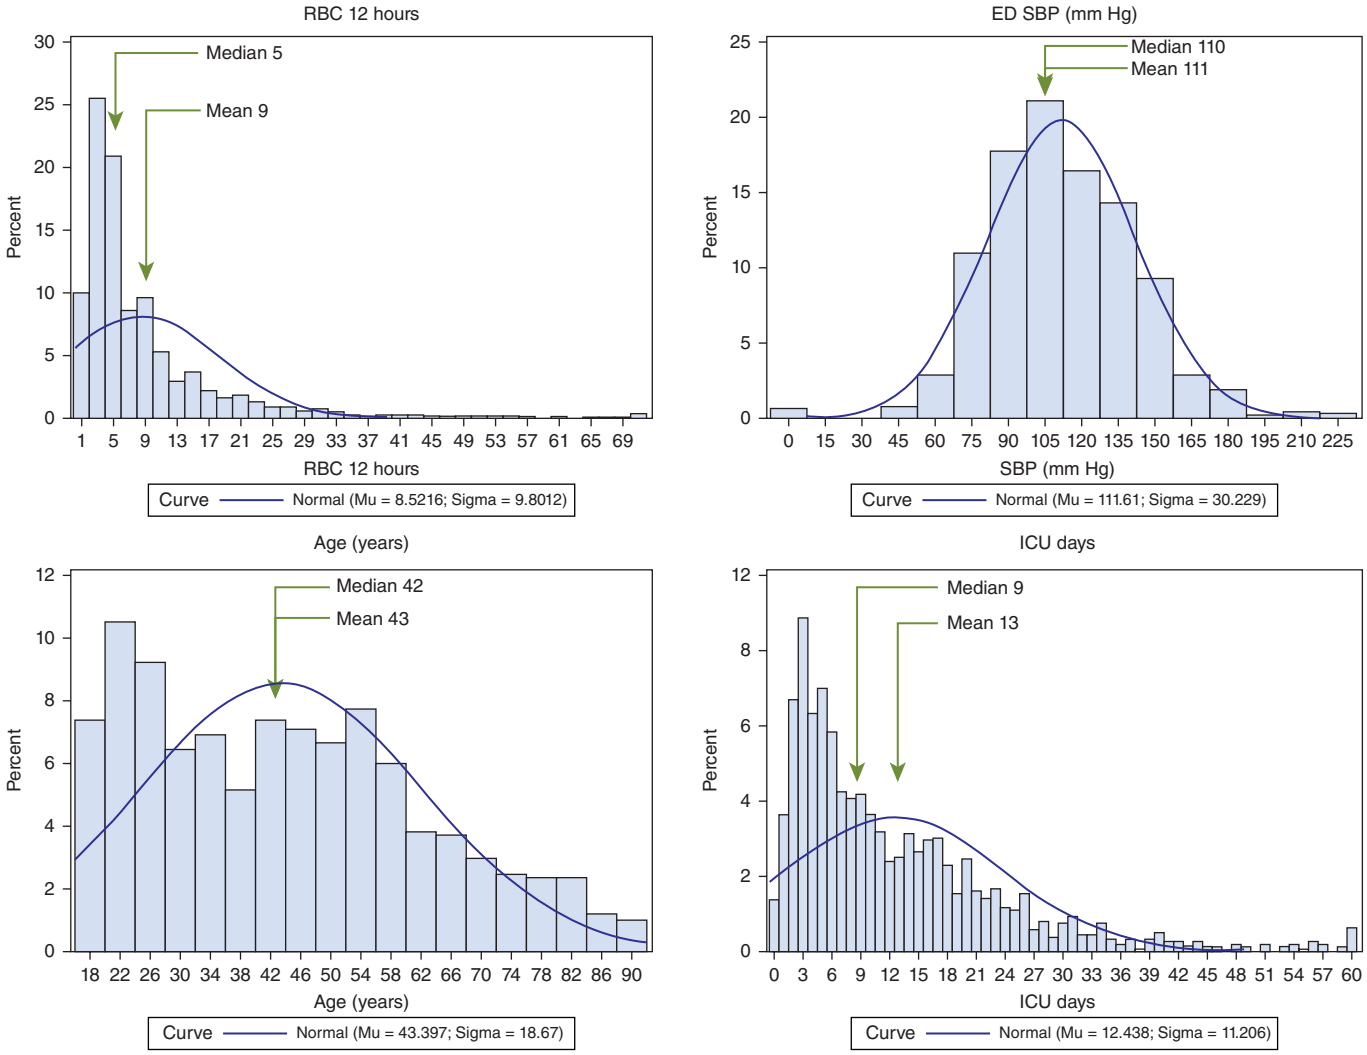

FIGURE 7-2 Distribution of variables commonly reported in trauma and surgery research. Note how means and medians differ in intensive care unit (ICU) days and RBC 12 hours (number of red blood cell units in the first 12 hours after injury), which are skewed, compared to age or emergency department (ED) systolic blood pressure (SBP), which are closer to normal. (Data from the Glue Grant; analysis by the authors.)

to whom they intend to apply the findings. Are they similar enough that one may directly apply the findings, or are they older, younger, more severely injured, etc?

Categorical variables such as sex and blunt versus penetrating mechanism are expressed as frequency (numbers) and percentages. Continuous, numeric variables, such as age, ISS, Glasgow Coma Scale, length of stay, ventilator time, and so on, are usually described by means or medians. The decision to use mean or medians can be tricky. When the variable distribution is normal and symmetric, medians and means are identical. However, when the variable is skewed or there are outliers, medians, rather than means, are better descriptors. As shown in Fig. 7-2, which illustrates data from a multicenter prospective study of severely injured patients (Glue Grant), the distributions of systolic blood pressure at the emergency department and age were approximately normal; thus, the median and mean both reflect the "typical patient." However, the mean does not describe well the typical number of RBC units transfused in the first 12 hours or the length of stay in the intensive care unit. Those are skewed variables, with most patients presenting low values and a few patients presenting with high values; thus, the median will provide a better description of the "typical patient."

Data dispersion for means is usually represented by the standard deviation (68% of the data should be contained within mean ± 1 standard deviation, 95% of the data within mean ± 2 standard deviations), whereas for medians, we most commonly use the interquartile range (the lower and upper quartile; 50% of the data are contained within this interval) or the range (maximum and minimum values). A box plot, shown in Fig. 7-3, is an excellent way to represent the data central tendency and dispersion. One may ask why not use median all the time. Especially in economics, one may be most interested in the outliers (eg, the few outlier patients

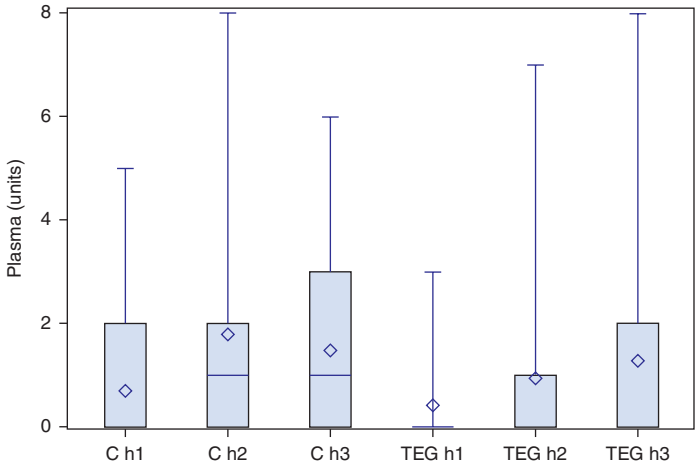

FIGURE 7-3 Example of a box plot showing the amount of plasma (fresh-frozen plasma) units given in the first (h1), second (h2), and third hour (h3) after injury in two study groups: resuscitation guided by conventional coagulation tests (C) and resuscitation guided by thromboelastography (TEG).[54] The length of the box represents the interquartile range (the distance between the 25th and 75th percentiles); the symbol in the box interior, the group mean; the horizontal line inside the box interior, the group median; and the vertical lines ("whiskers"), the minimum and maximum values (range). Note the difference in mean and median, suggesting skewness.

with longer hospital stay drive the cost; thus, the mean becomes a relevant measure).

Inferential Statistics

Studies will usually present initially bivariate analysis (sometimes called univariate). This consists of an unadjusted, crude comparison between two (or more) groups of subjects. In RCTs, this is the only comparison needed if randomization was successful (and usually it is) in distributing the confounders evenly across groups. In observational trials, the main point of this bivariate (or univariate) analysis is to detect confounders, which are variables with different distribution between the groups (thus associated with group membership) and also associated with the outcome. This difference does not need to be statistically significant, as the sample may be small and thus prone to a type II error. Deciding whether a variable may be playing a confounder role is a clinical, not a statistical, decision. After examining this information, the reader can decide which variables are potential confounders for which the researchers (hopefully) adjusted the subsequent analyses. An important differentiation here is between a confounder and a mediator variable. A mediator (eg, hyperfibrinolysis), different than a confounder, is in the pathway between the effect of interest (eg, traumatic hemorrhagic shock) and the outcome (ie, early mortality). If the mechanism by which hemorrhagic shock causes mortality involves hyperfibrinolysis, then hyperfibrinolysis is not a confounder; rather, it is a mediator. We do not adjust for mediators. As another example, in the hypothesis that the gunshot wound case-fatality rate has increased over the past decade, the association between the effect of interest (gunshot wounds) and the outcome (case-fatality rate over time) has a mediator (and not a confounder), which is injury severity (measured, for example, by the New ISS). Injury severity is how gunshot wounds cause death (ie, it is in the causal pathway). Potential confounders of this association are age (because older individuals would be more likely to die than younger individuals and age is increasing over time) and comorbidities (which also increase likelihood of death and become more common over time). Thus, we do not adjust the analysis for injury severity, but we adjust for age and comorbidities.

Analytic techniques that minimize confounding are stratification and multivariate analysis. Stratification may work when there are just a few risk factors and a large sample size. For example, in order to account for the confounding effect of smoking in the association between coffee drinking and lung cancer, one may stratify the analysis on smoking status and observe whether the association between coffee drinking and lung cancer differs by strata. We should observe that among smokers and nonsmokers alike, coffee drinking's association with lung cancer is not significant. Multivariate analyses are basically an advanced form of stratification done on multiple variables. There are several types of multivariate models depending on the distribution of the outcome. Binary outcomes (eg, death [yes or no]) are commonly addressed using logistic regression. Categorical outcomes with more than two strata can be analyzed with polytomous (or multinomial) logistic regression. When time to event is of interest or there is need to censor data (eg, patients who died or are discharged before experiencing the outcome of interest), survival analysis is an option.

Linear regression assumes that the outcome is continuous, has a distribution not too far from normal, and has, as the name says, a linear relationship with the covariates. When these assumptions do not hold (eg, outcome is categorical or too skewed), then we may apply a larger category of models, named *generalized* linear models. Please, note that there is a difference between *generalized* linear models and *general* linear models. The economic analysis by Schwartz and colleagues[102] on delays in laparoscopic cholecystectomy is an example of a study using a generalized linear model. The generalized linear

models are a broad class of models that include the logistic regression, the Poisson regression, log-linear models, gamma distribution models (as used in the previously mentioned article), and others.

The description of generalized linear models usually includes the word *link*, which is a function linking the actual outcome Y to the estimated Y in a model. Put simply, it is the transformation done to the outcome variable to convert it to continuous. In a linear regression model, the link is the identity (ie, the estimated and the actual outcome are expressed the same), and no transformation is needed. In a logistic regression, the transformation or link used is called the logit and the distribution is binomial (ie, yes or no type of variable). For the gamma model (used in the publication by Schwartz et al[102]), the link is the log, and the distribution is right-skewed with a variation that increases with the mean. This type of model is often used in econometrics because it fits the distribution of cost in health care (ie, care for most patients results in little costs, but a few patients require very costly treatments). In the log-linear and the Poisson regression, the link is a log and the distribution is the Poisson distribution. Poisson regression is usually applied to count data; for example, number of trauma deaths over a period of time, as seen in a 2013 article by Kahl et al[103] assessing time trends in annual trauma mortality rates.

Each multivariate model has its own set of assumptions, and although many are robust to small violations, this is an important consideration when appraising the article. For example, the Cox proportional regression model, a type of survival analysis, requires, as the name says, that the risks are proportional (ie, do not vary over time). This type of violation (ie, variation over time) is not, however, an insurmountable problem: when this model is used, we should verify whether the authors tested the proportionality assumption and, if violated, whether they reported remedying it (eg, by introducing time-varying covariates in the model).

POLYNOMIALS

Another assumption in regression models relates to the shape of the association between the outcome and the risk factor. Is it linear? If linear, is it a straight line or U-shaped? The computer software used for linear regression will draw a straight line, unless we add what is called a quadratic term (or second-order polynomial), in which case it will draw a U-shaped line (the U can face up or down). For example, in a recent study on fibrinolysis, we showed that the association of fibrinolysis and mortality was U-shaped, with higher mortality associated with very low (shutdown) and very high (hyperfibrinolysis) levels of fibrinolysis and a mortality nadir with moderate fibrinolysis levels.[104] Interestingly, we showed a similar U-shaped relationship between RBC:plasma ratios and mortality, with highest mortality peaking with both low and high ratios and lowest mortality associated with medium ratios.[105] More complex forms, such as those achieved by introducing third- or higher-order polynomials, are rarely found in the literature as they complicate the interpretation.

CLUSTER EFFECTS

Most multivariate models assume independence between observations. In other words, if one cannot predict a subject's outcome based on the outcome of other subjects, their outcomes are said to be independent. This is not completely true for patients within the same center or even treated by the same surgeon. Patients within a center tend to have similar outcomes, violating the independence assumption. This similarity between patients in the same center or treated by the same provider is called a cluster effect, and it should be accounted for in the statistical modeling and in sample size calculations. The larger the correlation between subjects within a cluster, the larger is the required sample size. This correlation can be assessed by the intraclass correlation coefficient, which measures how similar patients are within centers.[106]

MODEL PERFORMANCE

Another important issue in multivariate models is their performance (ie, how well they fit the data), which can be evaluated in several ways, depending on the model. Indeed, a model is only as good as its performance, and with rare exceptions, all multivariate models should be accompanied by performance measures in an article. The *R*-square, an often-reported measure of model performance of linear regression, gauges the percentage of the variation of the outcome that is explained by the independent variable(s) in the model. We must keep in mind that in clinical studies, given the multifactorial nature of most diseases and clinical scenarios, it is uncommon to see large *R*-squares (>0.30). The *R*-square should be accompanied by a *P* value that provides the probability that the observed *R*-square was due to chance. Together, the *R*-square and its correspondent *P* value compose an assessment of the model's performance. For example, Rourke et al[107] predicted admission fibrinogen levels with a multiple linear regression model including injury severity, base deficit, prehospital fluid resuscitation, and systolic blood pressure; the *R*-square for this model was 0.27, suggesting that 27% of the variation of the postinjury fibrinogen upon hospital admission was explained by the model variables. Although the *R*-square is a measure of performance for linear models, "pseudo" *R*-square exists for other models.

Model discrimination (ie, the ability of the model to discriminate individuals with and without the outcome; eg, survivors and nonsurvivors) is often evaluated for binary outcomes by the area under the receiver operating characteristic curve (AUROC; also known as the c-statistic). Receiver operating characteristic (ROC) curves were derived from studies on radar and sonar detection during World War II to ascertain the best radar setting to distinguish enemy airplanes from harmless targets (eg, flocks of birds). As you can see in Fig. 7-4, which shows the AUROC for thromboelastography values as predictors of massive transfusion, the *y*-axis depicts the sensitivity (eg, percentage of all deaths that were predicted), whereas the *x*-axis depicts [1 – specificity] (eg, [1 – percentage of survivors correctly predicted to survive]). The AUROC is a good assessment of the accuracy of the

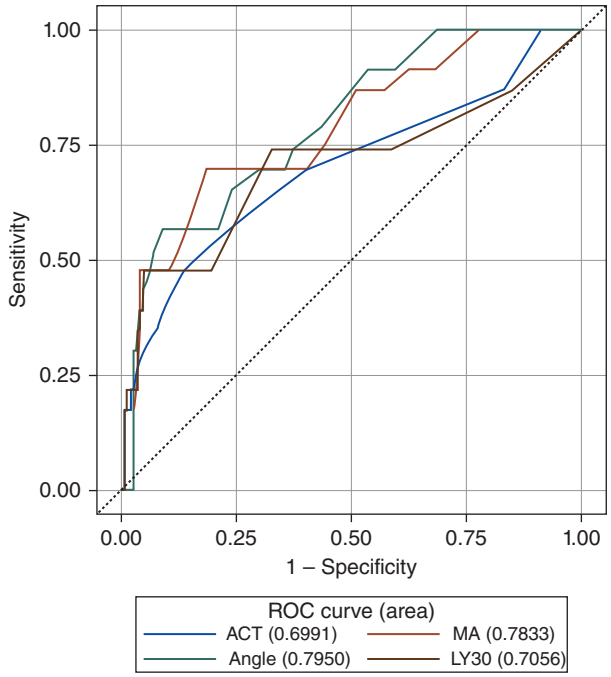

FIGURE 7-4 Example of a receiver operating characteristic (ROC) curve to compare the predictive power of the thromboelastography values (activated clotting time [ACT]; maximum amplitude [MA]; angle; and fibrinolysis [LY30]) for massive transfusion defined as ≥4 units of red blood cells in the first hour after injury (excludes deaths within 1 hour after injury). The areas under the ROC curve were as follows: angle, 0.79 (95% confidence interval [CI], 0.69–0.89); MA, 0.78 (95% CI, 0.68–0.89); LY30, 0.71 (95% CI, 0.56–0.85); and ACT, 0.70 (95% CI, 0.57–0.83).[108] Note that the 95% CIs overlap, suggesting no difference in prediction performance.

model, and it has been arbitrarily categorized as follows: 0.90 to 1 = excellent; 0.80 to 0.90 = good; 0.70 to 0.80 = fair; 0.60 to 0.70 = poor; and 0.50 to 0.60 = fail. AUROCs should be accompanied by 95% CIs to allow the reader to determine whether they are significantly different than the 0.50 no-value AUROC and to compare different AUROCs (if 95% of CIs overlap, the AUROCs are not significantly different). In another example, our group conducted a comparison of two MOF scoring systems (Denver MOF score and the Marshall Multiple Organ Dysfunction Score [MODS]) as predictors of death using AUROCs.[108] The Denver MOF score's AUROC was 0.88 (95% CI, 0.84–0.92), whereas the Marshall MODS's AUROC was 0.86 (95% CI, 0.82–0.89), suggesting that both scoring systems performed similarly well.

The ROC curve can also be used to determine the best threshold to discriminate between normal/abnormal values for a continuous variable. There are several methods to define the best cutoff, such as the Youden Index (also known as the Youden J statistic), which is defined as J = Sensitivity + Specificity – 1 and ranges from 0 (no discrimination) to 1 (complete discrimination). The Youden Index corresponds to the maximum vertical distance between the ROC curve and the diagonal, noninformative line. Another common measure is the upper leftmost point, which often (but not always) coincides with the Youden Index. Although these points represent an optimal combination of sensitivity and specificity, researchers may decide to privilege sensitivity or specificity depending on the condition. Certain conditions demand more sensitivity (eg, when one does not want to miss a case due to potential disastrous consequences), whereas others may require more specificity (eg, when the consequences of missing a case are minimal, but the cost of the test is high). In Fig. 7-4, the upper leftmost point in the ROC for angle was 65° and the Youden Index was 60°; thus, researchers may choose a cutoff between these two values to define a cutoff that is predictive of the need of massive transfusion. Tests or biomarkers with good sensitivity and specificity can disappoint clinicians when used in clinical practice, because they may present low predictive value. Predictive value is a function of prevalence; thus, predictors of relatively rare outcomes may show low predictive value, despite good sensitivity and specificity.

Calibration is another important assessment of model performance. It gauges the model's ability to correctly estimate the probability of an event. It is commonly assessed using the Hosmer-Lemeshow statistic, which compares the predicted and observed rates within deciles. In this statistic, the larger the *P* value (ie, the lower likelihood of disparity between predicted and observed rates), the better is the model's calibration. It is important to be careful, however, with sample sizes, when the *P* value can be small (ie, significant) for models that are not poorly calibrated.[109]

When assessing models, we should also contemplate whether there was overfitting (ie, the model has more variables than it can handle). This may seem counterintuitive: Is it not appropriate to adjust for all possible confounders? Yes, but only if you have the necessary sample size to do that. If one imagines a multivariate model as multiple stratifications by the various confounders, it is not difficult to see that in small samples some of these stratifications will end up having very small numbers or even zeros. It is important to note that the multivariate model needs subjects with and subjects without the outcomes. When we say we need large samples to model several confounders, we mean that we need a large enough number of subjects both with and without the outcome. A good rule of thumb, used even by expert statisticians, is 10 subjects with the outcome per variable in the model (not 10 subjects per variable, but 10 subjects with the outcome). When the number of confounders is higher than this threshold, an alternative is to use the previously mentioned propensity score, this time as an adjustment. Thus, instead of 20 variables, one has only one propensity score, representing the combined effect of the 20 variables. For example, Brown and colleagues[110] used this approach in a study on the scope of prehospital (PH) crystalloids in patients with and without PH hypotension. A propensity score was used to adjust the mortality comparison between the group receiving high versus low volumes of PH crystalloids. Instead of using five covariates (PH time, PH blood, PH systolic blood pressure, ISS, and initial base deficit), the authors had a single variable,

a propensity score ranging from 0 to 1. A final note on overfitting is that overfit models may have good performance for the data set from which they were derived, but because they address all the peculiarities of the derivation sample, they are unlikely to perform as well in other data sets.

There is controversy regarding whether multivariate adjustment for confounders is better than propensity score.[111] The answer seems to be that it depends. When the sample is large (>8–10 patients with the outcome per confounder), the multivariate method provides more information because one can assess the effect of individual confounders. Conversely, the propensity score is better when sample is limited and there are less than 8 to 10 patients with the outcome per confounder.

When using a multivariate model for confounder adjustment, it is important to compare the unadjusted effect and the adjusted (with confounders) effect. For example, if the unadjusted RR of a given variable is 2.0 (95% CI, 1.5–2.5) and the same variable, after adjustment of confounders, shows an adjusted RR of 1.2 (95% CI, 0.8–1.6), one can conclude that confounders were responsible for the effect seen in the unadjusted analysis.

Principal Components, Latent Class, and Cluster Analyses

So far, we have discussed how to analyze values of specific variables. Sometimes, however, researchers need to analyze the variables themselves. This is especially true when there are numerous variables and researchers may wish to reduce the number of variables, or when they want to examine patterns and combinations of variables using factor analysis. A special case of factor analysis is principal component analysis (PCA), in which the factors or components are combinations of variables that do not correlate, thus representing independent components. Two examples in the trauma literature may help illustrate the use of PCA. In the first example, the San Francisco group used PCA to define three uncorrelated groups of coagulation assays (prothrombin; factors V, VII, VIII, IX, and X; D-dimer; activated and native protein C; and antithrombin III levels): component 1 was defined as global clotting factor depletion, component 2 corresponded to the activation of protein C and fibrinolysis, and component 3 corresponded to factor VII elevation and factor VIII depletion.[112] The authors reported that component 1 predicted mortality and international normalized ratio/partial thromboplastin time elevation, whereas component 2 (fibrinolytic coagulopathy) predicted infection, end-organ failure, and mortality. A second example is seen in a similar study by our Denver group, this time using thromboelastography values.[113] As shown in Table 7-2, PCA generated a number of components, each of which contained a number of variables, each one associated with a factor loading (which can be interpreted much like a simple correlation coefficient, ranging from –1 to 1). Together these three components were responsible for 93% of the variation in the data. Component 1 included K (coagulation time), angle, maximum amplitude, maximal rate of thrombus generation, and total thrombus generation; component 2 included activated clotting time and time to maximal rate of thrombus generation; and component 3 reflected fibrinolysis. Taken together, both studies support the conclusion that trauma-induced coagulopathy has distinct, independent mechanisms, which may require tailored hemostatic therapeutic approaches.

TABLE 7-2: Principal Component Analysis (using thromboelastogram [TEG] values in trauma patients)[113]

Composition of principal components (PC)

	PC 1	CP 2	PC 3
% variance explained by component	63%	17%	13%
Activated clotting time	–30	90	6
K	–95	15	–4
Angle	92	–26	5
Maximum amplitude	95	–15	–10
% lysis at 30 min	–4	0	99
Time to maximal rate of thrombus generation	–13	95	–5
Maximal rate of thrombus generation	94	–23	3
Total thrombus generation	94	–14	–16

K, coagulation time.

PCA also has assumptions, including normal distribution and more subjects than variables. Therefore, this technique may not be applicable to many of the "omics" studies (eg, genomics, proteomics, and metabolomics), where the number of variables far exceeds the number of subjects. In this case, an option is the primary latent structures (PLS; formerly known as partial least squares) analysis, commonly followed by a discriminant analysis (PLS-DA). For example, in a metabolomics analysis of human plasma and lymph in deceased trauma patients, D'Alessandro et al[114] used this technique to group (ie, reduce) 215 metabolites with similar variance regarding the outcome (ie, lymph vs plasma). These groups of metabolites are named components or latent variables, which can then be used to predict outcomes. An examination of the combinations can reveal the commonalities between the members of a component; for example, a latent variable may well represent specific pathways (eg, glycolysis), or using specific measures, such as the variable importance in projection, can help identify the variables that contributed the most to groups' separation (eg, succinate), which can then be targeted for specific research. An excellent, very didactic review on the analytic approach for metabolomics was published in 2018 by Jayaraman and colleagues.[115]

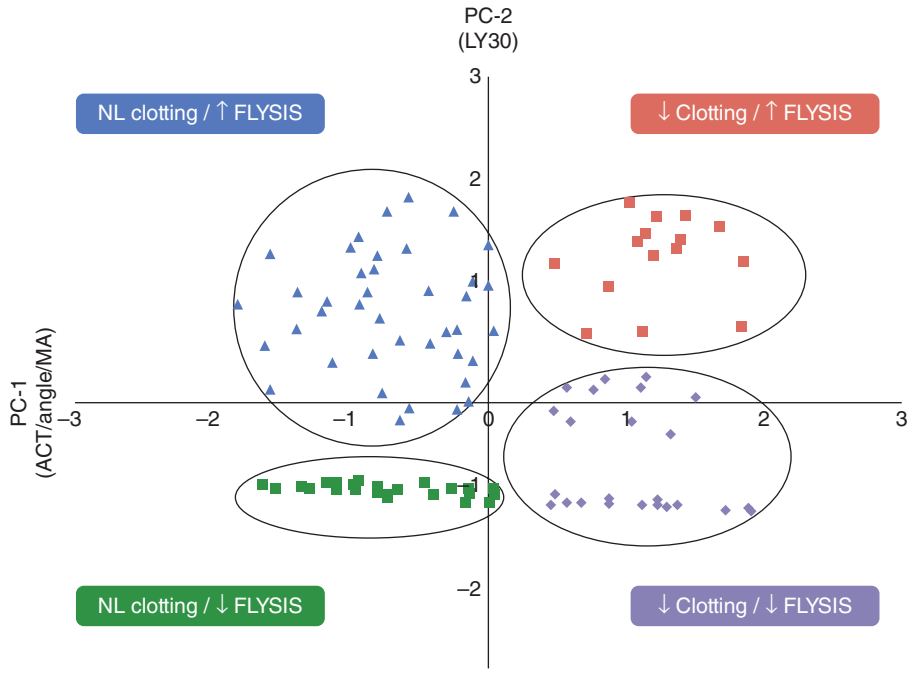

FIGURE 7-5 Cluster analysis: trauma patients plotted according at activated clotting time (ACT)/angle/maximum amplitude (MA) (*x*-axis) and fibrinolysis (FLYSIS; *y*-axis). NL, normal; PC, principal component.

Latent class analysis is a technique used to identify subgroups within a population. For example, Calfee et al[116] defined two subphenotypes within acute respiratory distress syndrome (ARDS) using this technique. The two subphenotypes within ARDS differed by magnitude of inflammation, shock, and metabolic acidosis and also by clinical outcomes. Moreover, the response to treatment also differed on the basis of subphenotype.

Cluster analysis groups subjects into groups or clusters based on their responses. One can use the factor or components derived from the PCA or the PLS to define the clusters. Cluster analysis is not really a statistical tool; rather, it is a mathematical model to group subjects based on their responses. In a recent example, the Denver group used cluster analysis to group patients according to PCA-derived thromboelastography components (Fig. 7-5). Patients in cluster 2 (hypocoagulable with no fibrinolysis) were more severely injured (higher ISS) but had a lesser degree of shock compared to patients in clusters 3 and 4. Patients in cluster 4 required significantly more blood products and had an increased hemorrhage-related mortality compared to the other groups.

SYNTHESIZING EVIDENCE

Systematic Reviews and Meta-Analysis

A systematic review (SR) collects, appraises, and collates all evidence addressing a specific research question by using explicit, reproducible, systematic methods. SRs were created to assist professionals involved in medical and health policy decisions in managing the daunting amount of information regarding heath care. If the reader is naïve about a topic, a good-quality SR is the essential first step to begin to understand that topic. The Cochrane Collaboration has led the field by establishing the Cochrane Library, one of the most important, useful, and regularly updated SR collections (available at http://www.cochranelibrary.com/; accessed July 6, 2018). Their use of rigorous methods assures the reader that available evidence has been collected in a manner that minimizes bias and informs medical decision making. In addition, the *Cochrane Handbook for Systematic Reviews of Interventions* contains methodologic guidance for anyone preparing or appraising SRs.[117]

Some SRs are accompanied by a meta-analysis (MA), in which the results of the SR independent studies are combined with the goal of deriving more precise estimates than each individual study.[117] Well-done SRs/MAs carefully examine the consistency of evidence and explore the differences across studies. As explained in more detail later in this chapter, an MA requires reasonable homogeneity between the studies. Many SRs/MAs are now registered in the PROSPERO, an international registry of SRs with a searchable database (available at http://www.crd.york.ac.uk/PROSPERO/; accessed July 7, 2018). As of September 7, 2018, a simple search using the term *injury* listed 3240 records of SRs completed or in progress.

To make this as practical and applied as possible, we will examine these concepts using a 2015 Cochrane Library SR/MA, "Blood-Clot Promoting Drugs for Acute Traumatic Injury," produced by the Cochrane Injuries Group based in the London School of Hygiene and Tropical Medicine.[118] This was the third update of this review of RCTs assessing the effects of antifibrinolytics in trauma patients; the first was published in 2004 and the second in 2012, all available from the same website. Although this review was restricted

to RCTs, there are SRs that include other types of studies. The search strategy included a variety of databases (PubMed, EMBASE, Cochrane Injuries Group Specialised Register & Cochrane Central Register of Controlled Trials, ClinicalTrials.gov, WHO International Clinical Trials Registry Platform, and others). In addition, as it is common, the authors checked all references in the identified trials and background papers and contacted study authors and pharmaceutical companies to identify relevant published and unpublished data.

The search for unpublished data is essential to minimize publication or reporting bias, which occurs when the dissemination of research findings is influenced by the nature and direction of results. In general, this affects negative (nonsignificant) studies, which are less likely to be published and, when published, are less likely to appear in a high-impact, English-language journal. In addition, publication bias should be further assessed by using funnel plots, which are scatterplots of the intervention effects from individual studies usually plotted on the horizontal axis and some measure of study size in the *y*-axis (eg, sample size, standard error, variance). The effects from small, less precise studies will spread widely at the bottom of the graph, whereas larger studies' effects will cluster together at the top. Unfortunately, our example did not contain a funnel plot, because there were too few studies. However, we refer the reader to the excellent examples in the *Cochrane Handbook for Systematic Reviews of Interventions*.[117] In the presence of publication bias (eg, unpublished small negative studies), the funnel plot will have an asymmetrical appearance, and a combined effect derived in the MA may overestimate the treatment's effect. It is important to mention that there are other reasons for asymmetry, such as trials of lower quality, which overestimate effects.[119]

Our example SR was not restricted by publication date or language, but some reviews limit searches to articles in the English language, which can create substantial bias. The terms used for the search are found in their Appendix 1 and can be useful to guide the readers' own searches. Our example's first figure shows that of 1371 records plus four trials already identified in previous versions of this SR, three RCTs were finally included in the MA. This information educates the reader about the amount of research available in the area, and it also provides information on trials still being conducted.

In an SR, each study's risk of bias (ie, quality) should be appraised; in the previous example,[118] the GRADE system, which is described in more detail later in this chapter, was used for this purpose. The risk of bias was considered low (high quality) for outcomes on mortality, need for further surgery, and blood transfusion, whereas the quality was considered moderate for the vascular occlusive outcomes (including heart attacks, deep vein thrombosis, stroke, and pulmonary embolism).

Many SRs will stop here and derive some qualitative conclusion from the summative body of evidence. Others, such as the previous example, will move forward to combine the results of the independent studies in an MA. As mentioned earlier, before combining studies, their statistical and clinical heterogeneity must be assessed. Statistical heterogeneity (ie, variability in intervention effects) is usually assessed using the I^2 statistic, which describes the percentage of total variation across studies due to heterogeneity rather than chance. The I^2 statistic should be accompanied by 95% CIs or a chi-square test, for which a larger *P* value indicates less heterogeneity. When statistical heterogeneity is high (I^2 >50%), an MA is usually inappropriate. In addition to statistical heterogeneity, clinical heterogeneity (variability in designs, populations, measurement of outcomes, etc) is also an important consideration.

The studies included in the postinjury antifibrinolytic SR/MA showed no evidence of statistical heterogeneity (I^2 = 13%, *P* = .32). Therefore, based on the pooled data, the authors concluded that these agents reduced all-cause mortality from 16% to 14.5% (RR, 0.90; 95% CI, 0.85–0.96; *P* = 0.002). However, we should note that one of the three included studies (CRASH-2[72]) was responsible for 98% of the data, thus likely exerting major influence in the final result; the second study[120] focused on traumatic brain injury only, and the third study assessed aprotinin[121] (the other two used TXA) in 77 participants with major skeletal trauma and shock. We wonder whether the clinical heterogeneity of these studies should not preclude pooling the data.

In another example of conflicting clinical and statistical heterogeneity, Natanson and colleagues[122] in an SR/MA on blood substitutes combined 16 trials and concluded that these products were associated with a statistically higher risk of death (RR, 1.30; 95% CI, 1.05–1.61) and of myocardial infarction (RR, 2.71; 95% CI, 1.67–4.40). However, the SR/MA encompassed different populations (elective surgery, trauma, acute care surgery, and ischemic stroke patients), different controls (fluids, blood products), and different blood substitutes. Although the statistical heterogeneity among these studies was not significant for either mortality or myocardial infarctions (for both, I^2 = 0, *P* ≥.60), conclusions based on a mix of studies differing at so many design and clinical levels must be taken with caution.[123]

A final note, heterogeneity is not a failure, rather it is an important finding that should be further explored and described. Understanding the differences between studies addressing the same topic can provide more information than inappropriately combining them to increase sample size.

When Studies Collide

It is not rare that we find articles, sometimes in the same issue, with conflicting results. How should we decide between them? Again, to make this practical and applicable, we can invoke two examples of these "collisions." In the May 2013 issue of the *Journal of Trauma and Acute Care Surgery*, two articles[29,124] explored the role of crystalloids in early trauma resuscitation. Both studies used data from the same database (Inflammation and the Host Response to Injury, also known as Glue Grant) and arrived at seemingly disparate conclusions. The accompanying editorial by Dr. David Hoyt was able to reconcile these differences, expertly navigating the reader through the two research studies and coming up with

a unified message.[125] Dr. Hoyt highlighted that the exclusion of patients who died within the first 48 hours in the study by Kasotakis et al[124] resulted in a dramatically different population than the study by Brown et al.[29] Basically, the message of both studies was that fluid resuscitation should be guided by blood pressure and oxygen delivery to avoid the harmful effects of excess fluids.

In a second example, in March 2014, we published a comprehensive review on the temporal trends of postinjury MOF using the previously mentioned Glue Grant database and concluded that the incidence of postinjury MOF decreased over time, while the MOF case-fatality rate remained stable.[95] Conversely, in April 2014, Fröhlich et al,[126] using the Trauma Register DGU of the German Trauma Society, reported a significant increase in MOF incidence but a decrease in case-fatality rate. We were left with two apparently disparate messages. How can they be reconciled so the messages can be appropriately translated to our clinical practice and/or advance our research agenda? As astutely done by Dr. Hoyt in the previous example, we invoked the PICO framework to determine to which population each study specifically applied and also to ensure that the outcomes (ie, postinjury MOF) were indeed similarly measured. Once this was done, the differences were glaring. The entry criteria for the two studies were different: the patients enrolled in the Glue Grant study were more severely injured (ie, blunt torso trauma with hemorrhagic shock; all required at least 1 unit of RBCs/12 hours) than the German patients (24% required 1 unit of RBCs between hospital arrival and intensive care unit admission). The German study population included a large proportion of traumatic brain injury victims (59%), whereas the Glue Grant study specifically excluded these patients. Second, the two studies used different definitions of the outcome (postinjury MOF). The German investigators employed the Sequential Organ Failure Assessment score, which assesses the dysfunction of six organ systems including the central nervous system (CNS). In contrast, the Glue Grant investigators used the Denver MOF score, which does not assess the CNS, and a modified version of the Marshall MODS without its CNS component. Thus, the two studies apply to different populations and to somewhat different outcomes.

Guidelines and Recommendations

According to the Institute of Medicine 2011 report, "clinical practice guidelines are statements that include recommendations intended to optimize patient care that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options."[127] This report established standards for the rigorous development of guidelines including the following:

- Based on systematic review of the evidence
- Led by a knowledgeable, multidisciplinary expert panel and representatives from key affected groups
- Considers relevant patient subgroups and patient preferences
- Based on an explicit and transparent process that minimizes distortions, biases, and conflicts of interest
- Explains the association between care options and health outcomes
- Rates both the quality of evidence and the strength of recommendations
- Reconsidered and revised as appropriate

The GRADE, mentioned earlier in this chapter, is widely adopted as a transparent, systematic process to appraise the quality of the summative body of evidence and define the strength of the recommendation.[8] We will use a recent example of a guideline presented at the Eastern Association for the Surgery of Trauma (EAST) meeting and subsequently published in the *Journal of Trauma and Acute Care Surgery*. Fox et al[128] addressed the evaluation and management of blunt traumatic aortic injury (BTAI). They formulated several pertinent questions using the PICO framework, of which we will follow the process for PICO question 2: In patients with BTAI (P), should endovascular (I) repair be performed versus open repair (C) to minimize mortality, stroke, paraplegia, and renal failure (O)? These four outcomes were deemed "critical for decision making" using the GRADE priority scale for outcomes, whereas other outcomes (cost, length of stay) were considered less important.

Using a standardized search covering the period from 1997 to 2013, the authors selected 37 studies; all 37 addressed the mortality outcome, 21 reported on paralysis, and 12 reported on stroke. No reliable evidence on the renal failure outcome was available. The selection process (ie, how many articles were initially found, how many were excluded and why) was well detailed in the article, reassuring the reader that no articles were excluded due to the researchers' bias and that all pertinent studies on this research question were considered. Often, this process is illustrated using a Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) diagram, which depicts the flow of information through the SR phases, mapping out the number of records identified, included and excluded, and the reasons for exclusions (available at http://www.prisma-statement.org/; accessed September 9, 2018).

The grading of the evidence was accomplished using the GRADE system, which begins with the research design of the included studies.[129] In intervention-related topics, RCTs start as high quality, whereas observational designs start as low quality. Any other design starts as very low quality. For diagnostic studies, the GRADE system allows observational studies to be rated initially as high quality if there was a direct comparison of the test results with an appropriate reference standard.[130] From this starting point (high- or low-quality research design), other factors may increase or decrease the quality of evidence.

FACTORS THAT DECREASE THE QUALITY OF THE EVIDENCE

The factors that can further decrease the quality of the evidence fall into five domains, as follows: risk of bias,

consistency, directness, precision, and publication bias. Incidentally, the Effective Health Care Program sponsored by the Agency of Healthcare Quality and Research uses similar domains.[131]

- *Risk of bias:* This domain refers to the execution of the studies. For RCTs, problems in the allocation concealment, lack of blinding, and loss to follow-up increase the risk of bias and decrease the quality. For other comparative studies, the researchers need to identify the potential for biases as described in previous sections of this chapter.
- *Consistency:* This refers to the degree to which included studies find either the same direction or similar magnitude of effect. In diagnostic studies, this involves looking at the sensitivity and specificity observed in the studies included in the review.
- *Directness:* This refers to the extent to which the population, interventions, diagnostic tests, and outcome measures are similar to those of interest. For example, if the patients in the selected studies were less injured or older than those to whom the intervention would be applied, directness would be low, and the quality would be downgraded. Lack of studies directly comparing two interventions or diagnostic tests of interest can also lower the quality.
- *Precision:* This refers to the degree of certainty surrounding an effect estimate with respect to a given outcome.
- *Publication bias:* As explained in previous sections of this chapter, this relates to the possibility of selective publication or reporting of research findings based on the favorability of direction or magnitude of effect.

FACTORS THAT CAN INCREASE THE QUALITY OF THE EVIDENCE

These factors include large effects (significant RR >2.0 or <0.5) and evidence of dose-response. In addition, if it is reasonable to assume that the observed effect would have been larger if potential confounders were accounted for, the quality may be upgraded.

In the Fox et al[128] SR on BTAI, there were no RCTs, only observational studies; thus, quality started low. They did not observe any serious risk of bias, inconsistency, indirectness, imprecision, or publication bias for any of the outcomes. Thus, the quality of the evidence remained at low (ie, it was not downgraded to very low). Heterogeneity was low for all outcomes; thus, the studies were combined into an MA. Endovascular repair was associated with reduced mortality rates compared to open repair (RR, 0.56; 95% CI, 0.44–0.73), which was not large enough to upgrade the quality of the evidence for the outcome mortality. However, endovascular repair was associated with a significantly lower rate of the outcome paraplegia (RR, 0.36; 95% CI, 0.19–0.71). Thus, for this outcome, the quality of the evidence was upgraded to moderate. Regarding stroke, there were no significant differences between the two procedures (RR, 1.48; 95% CI, 0.67–3.27); thus, the quality of the evidence remain unaltered.

Appropriately so, the EAST panel took into consideration the patients' perspective and deliberated that, despite a low to moderate quality of evidence, patients would likely place a high value on a less invasive procedure associated with lower mortality and risk of paraplegia. Based on these considerations as well as other logistical issues, the panel strongly recommended the use of endovascular repair in BTAI patients who did not have contraindications to endovascular repair. A limitation of this review was the lack of evaluation of long-term outcomes of endovascular repair.

TOOLS FOR APPRAISING THE QUALITY OF STUDIES

Critical appraisal is the systematic evaluation of research reports regarding the quality of several items, including:

- *The research question:* Is it well formulated? Does it address an existing gap in current knowledge?
- *Internal validity:* Is the research design appropriate to address the research question? Was sampling well conducted, bias and confounding minimized, effect modification explored, and an appropriate analytic technique used? Were the effects appropriately measured, and were their size, direction, and uncertainty well estimated?
- *Relevance:* Are these valid results relevant?
- *External validity:* To whom do these valid, relevant results apply?

There are several tools to conduct critical appraisal of evidence. Although originally created to guide peer review of manuscripts, the *Journal of Trauma and Acute Care Surgery*'s standardized research methods review can be a helpful tool to guide critical appraisal (Table 7-3). The Oxford Centre for Evidence-Based Medicine (CEBM) provides appraisal worksheets specific for SRs as well as for prognostic, diagnostic, and therapeutic studies (available at http://www.cebm.net/critical-appraisal/; accessed September 7, 2018), along with helpful examples.

Alternatively, the reporting standards, created to promote transparent and accurate reporting of research studies, may be used to appraise them. The first high-impact reporting guideline was the CONSORT (Consolidated Standards of Reporting Trials; available at http://www.consort-statement.org/; accessed July 7, 2018), mainly directed to RCTs. The CONSORT diagram, which describes the inclusion and exclusion criteria of patients in trials, is now considered an obligatory component by most of the important medical journals. The impact of the CONSORT was so dramatic that reporting standards quickly appeared for other types of studies, including STROBE for observational studies; PRISMA for SRs and MAs; CHEERS for economic evaluations; COREQ for qualitative research; GRADE for guidelines; and others. These reporting standards have checklists that may guide critical appraisal. They are available at the website of the Enhancing the Quality and Transparency of Health Research (EQUATOR) network, a group of renowned international experts that grew out of the work of CONSORT and other guideline development groups (http://www.equator-network.org/; accessed July 7, 2018).

TABLE 7-3: *Journal of Trauma and Acute Care Surgery* Standardized Biostatistical and Research Methods Review

Checklist for statistical assessment of general papers:

Appropriate study design used to achieve the objective(s).
Source of subjects/data appropriately described.
Sampling/sample size appropriately described.
Entry and exclusion criteria clearly defined.
Data exclusions are stated/explained, and impact on results is explored.
N reported at the start of the study, for each data set and for each analysis.
Discrepancies in value of *N* between analyses clearly explained/justified.
Missing data are explained, and impact on findings minimized/explained.
Satisfactory follow-up/response rate.
Appropriate measure(s) of center (eg, mean or median).
Appropriate measure(s) of variability (eg, standard deviation or range).
Adequate uni-/bivariate statistical analyses used/described.
Adequate multivariate statistical analyses used/described.
Confounding and bias explored and minimized.
Assumptions of tests applied met (particular attention paid to nonnormal data sets or small sample sizes).
Effects (odds ratios, relative risks, risk differences) in the "expected" direction, or if not, unexpected direction explained.
Adjustments made for multiple testing explained.
Unit of analysis given for all comparisons.
Alpha level given for all statistical tests.
Actual *P* values are given for primary analyses.
Unusual/complex statistical methods clearly explained.
Method of group assignment (eg, randomization) explained and justified.
Any data transformations clearly described and justified.
Confidence intervals given for the main results.
Conclusion drawn from the statistical analysis is justified.

Acute Care Surgery

John E. Griepentrog • Anthony J. Lewis • Matthew R. Rosengart • Andrew B. Peitzman

KEY POINTS

- Acute care surgery includes trauma, emergency general surgery, surgical critical care, elective general surgery, and surgical rescue.
- The need for expeditious source control is imperative whether we are dealing with a trauma patient with a ruptured spleen or the emergency general surgery patient with a perforated viscus.
- Treat the patient empirically. Determining a specific diagnosis or injury is not the immediate goal.
- Secure the airway, initiate fluid/blood resuscitation, and administer early broad-spectrum antibiotics if sepsis is in the clinical picture.
- In any critically ill patient, resuscitate the patient according to Advanced Trauma Life Support guidelines.

Every important hospital should have on its resident staff of surgeons at least one who is well trained and able to deal with any emergency that may arise.

Dr. William S. Halsted

INTRODUCTION

Over the past decade, a new paradigm in the management of acutely ill surgical patients has emerged, emphasizing surgeons trained in trauma, emergency general surgery (EGS), and surgical critical care.[1] The need has been established for a specialized group of surgeons to care for patients with time-sensitive surgical disease of high acuity, at any time of the day or night.[2] This need comes at a time when we are experiencing an ever-increasing volume of EGS patients. Emergency conditions accounted for more than one-third of all general surgery admissions and over 2.6 million hospitalizations in 2010.[3,4]

As estimated by the Centers for Disease Control and Prevention, nearly 35 million hospital discharges occur annually in the United States.[5] Forty-one percent are emergent, 25% urgent, 24% elective, and 10% unknown. Furthermore, 10 of the most common diagnoses are within the scope of practice of the acute care surgeon (Table 8-1). An important diagnosis on the list is complication of medical or surgical care; this accounts for more than 1 million hospital discharges yearly. Patients who have sustained a major complication of medical or surgical care may be the most vulnerable of our patients. Time-dependent intervention is critical to ensuring an optimal outcome for these patients.

To address this need, the specialty of acute care surgery (ACS) was proposed by the American Association for the Surgery of Trauma (AAST). ACS, as initially presented, was composed of trauma, surgical critical care, and emergency surgery. We have added and redefined the components of ACS as to now encompass trauma, surgical critical care, emergency surgery, elective general surgery, and surgical rescue.

THE BIRTH OF ACUTE CARE SURGERY

The impetus to transform trauma surgery was twofold. First, as surgical specialty care has become more narrowly focused and tertiary and quaternary hospitals have proliferated, the general surgical patient has been left behind. Second, an identity crisis grew from the gradual erosion of the many defining aspects and characteristics of what was once considered a broad-based and fully trained general surgeon.[6] The rise of nonoperative management of many trauma diagnoses resulted in low operative volumes.[7,8] Surgical subspecialists had slowly subsumed many of the fundamental surgical diseases, a process that heralded the disappearance of the trauma surgeon as the master surgical technician.[9] Ironically, these same specialists did not wish to treat trauma patients. These factors, combined with long, unpredictable work hours and high levels of stress, including the high-stakes nature of the work, were not balanced by sufficient reward.[1,7,10]

TABLE 8-1: 2005 Hospital Discharge Diagnoses

Of the leading 29 first-listed diagnoses, 10 were within the practice of general surgery:

1. Complications of surgical and medical care
2. Cellulitis and abscess
3. Septicemia
4. Cholelithiasis
5. Appendicitis
6. Noninfectious colitis and enteritis
7. Diverticula of the intestine
8. Intestinal obstruction
9. Acute pancreatitis
10. Injury

Source: Data from Centers for Disease Control and Prevention. National Center for Health Statistics data. http://www.cdc.gov/nchs/data. Accessed November 21, 2019.

In addition, this high prevalence of specialization meant that only a minority of general surgery graduates would remain in the true general surgery workforce, available to address the most common surgical emergencies.[11] Overall, the number of general surgeons in the United States decreased by 25% from 1981 to 2005, with losses noted in both rural and urban areas.[12] Thus, a need clearly existed to encourage these trainees to remain in the business of caring for general surgical emergencies.

This need was equally visible to those who stood outside the field of surgery. A survey of emergency departments (EDs) documents that 74% of departments experienced problems with specialist coverage, 37% had incomplete or completely lacked general surgery coverage, and 55% reported inadequate trauma staffing[13]; in addition, 23% of facilities either lost or were downgraded in their trauma center level designation.[13] The problem extends beyond the ED to encompass the realm of intensive care; data from the United States underscore a shortage of critical care providers despite an increasing need.[14]

In response to these developments, a task force of the AAST, including members of the American College of Surgeons Committee on Trauma, the Eastern Association for the Surgery of Trauma, the Western Trauma Association, and invitees from additional surgical and critical care organizations convened to discuss the future of trauma surgery. A new field emerged, known as ACS in the United States and emergency surgery or visceral surgery in Europe. This newly defined specialty was to encompass trauma surgery, EGS, and surgical critical care.[1,8,15–17] As mentioned previously, we have redefined and expanded the field to encompass elective surgery and surgical rescue.

THE FIVE PILLARS OF ACUTE CARE SURGERY

The triad of trauma, EGS, and surgical critical care provided the initial foundation for ACS. The two additional pillars of ACS are elective general surgery (fourth pillar) and surgical rescue (fifth pillar) (Fig. 8-1).

Elective General Surgery

Although not universally agreed upon, we and others have always considered elective general surgery a fundamental component of ACS (the fourth pillar). Two reasons drive this approach. First, as a busy operative surgeon, you maintain your surgical skills and the operating room (OR) becomes your default in the management of a critically ill patient. Second, to become a master general surgeon requires commitment of time and effort to develop surgical skills to this high level. The depth and breadth of technical skillsets for emergency operative procedures are attained when you have the time to fully commit to managing the complicated elective general surgical patients. As an example, competence with laparoscopic elective sigmoid colectomy enables you to perform a sigmoid colon resection with or without anastomosis in the patient with perforated diverticulitis.

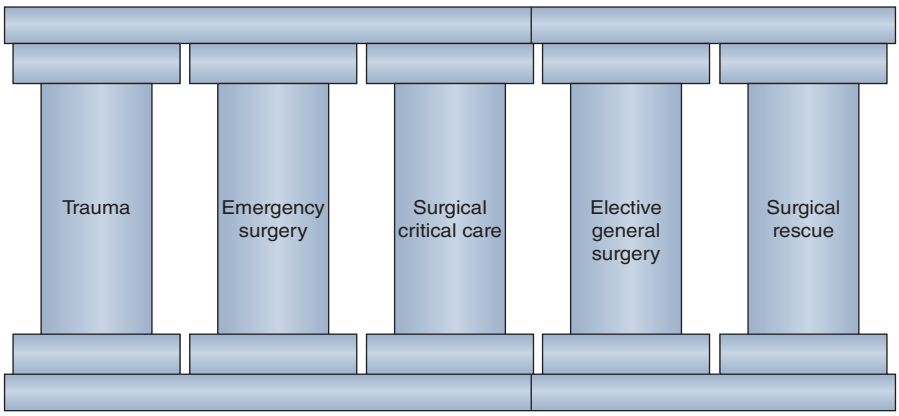

FIGURE 8-1 The five pillars of acute care surgery.

Let's discuss further how involvement in elective general surgery expands your abilities while on call for trauma. The common etiologies of mortality on our trauma patients are central nervous system injury and hemorrhage. These exsanguinating injuries are uncommon—major hepatic or juxtahepatic injury, major vascular injury, and thoracic injury. Even at busy trauma centers, these injuries are infrequent enough that simply taking additional trauma calls does not provide sufficient clinical volume to learn access and management of these injuries. In both our ACS fellowships and early practices as attending acute care surgeons, we should learn these techniques from our specialty partners. Scrub or observe your hepatobiliary surgeons on elective major operations; they resect the liver or repair the inferior vena cava or hepatic veins routinely. Do this as often as possible. The same approach applies for thoracic and vascular surgery; scrub or observe the major operations routinely. Additionally, performing spine exposures for our neurosurgical or orthopedic colleagues augments our ability to expose the vasculature from the clavicles to the inguinal ligaments. Lastly, teach or attend the Advanced Surgical Skills for Exposure in Trauma course as often as possible.

What distinguishes the practice of ACS from purely elective general surgery? The practice of elective general surgery focuses on the anatomy and pathology of the disease (eg, colon cancer). This skillset and knowledge base are also essential to the acute care surgeon. However, should the patient with colon cancer present critically ill with perforation or obstruction, then a different scenario evolves that necessitates a shift in priorities and a more complex delivery of care. It is this additional perturbation in physiology, superimposed upon a primary surgical pathology, with which the acute care surgeon must contend. Thus, ACS surgeons can be considered to be *physiologic surgeons*, compared to their more anatomically oriented colleagues.

Surgical Rescue

Surgical rescue is the fifth pillar of ACS, with the goal of early management of a surgical complication.[18] *Surgical rescue* is successful management of this postoperative or postprocedural complication, whereas *failure to rescue* is a death after either a medical or surgical complication. Thirteen to 20% of general surgery patients in our service are admitted with a primary diagnosis of complication, the vast majority from prior operations by other services or from other hospitals. Most of these patients require an operation, and over 50% require multiple operations to be surgically rescued. Other major components of surgical rescue include intensive care unit (ICU) care, ventilator support, nutritional support, management of sepsis, interventional radiologic procedures, and care by other surgical subspecialties[19] (Fig. 8-2A and B). As mentioned earlier, understanding of the anatomy and principles of the initial elective operation is vital to rescue the patient from the postoperative complication. The complex skill set required to manage the deranged physiology to achieve surgical rescue raises the bar for ACS. The concept of *failure to rescue* was introduced in 1992 by Silber et al[20] in their seminal paper in which they defined failure to rescue as death after an adverse event. Silber and colleagues[20] reported that deaths were related to hospital attributes (eg, nurse staffing, nursing education, hospital size, hospital technology, number of ICU beds) and patient factors (eg, age, comorbidity), whereas complications were due primarily to patient characteristics, and importantly, failure to rescue was related to hospital resources and staffing, as listed earlier. Interestingly, multiple papers have observed that what differentiates high-performing hospitals (lower mortality) from low-performing hospitals (high mortality) is failure to rescue, rather than frequency of the complication in the first place.[21–24]

Another important variable in failure to rescue is inadequate escalation of care. For successful rescue of a patient with a major complication, three steps must occur.[25] First, the bedside provider of care (nurse, respiratory therapist) must recognize the event in a timely fashion. Second, the adverse occurrence must be communicated quickly to the medical staff. Third, a physician/surgeon must be on site and intervene promptly—emphasizing the importance of the in-house ACS surgeon. This escalation of care fails in 21% to 47% of failure-to-rescue deaths.

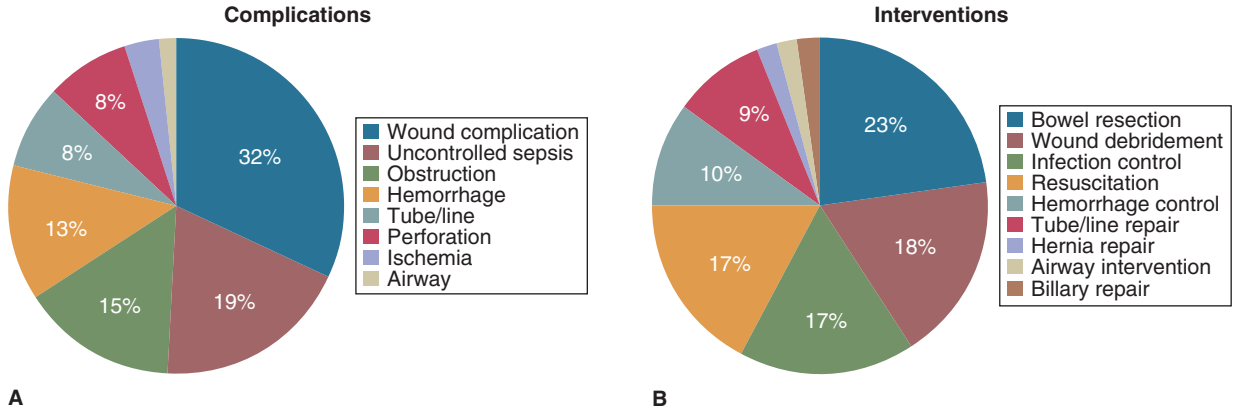

FIGURE 8-2 (**A**) Complications in emergency general surgery (EGS) patients requiring surgical rescue. (**B**) Interventions in EGS patients requiring surgical rescue. (Reproduced with permission from Kutcher ME, Sperry JL, Rosengart MR, et al. Surgical rescue: the next pillar of acute care surgery. *J Trauma Acute Care Surg.* 2017;82:280-286.)

Even a single postoperative complication significantly affects a patient's prognosis; 60-day mortality increases 3.4-fold in patients with complications.[26] Recognition and expeditious management of the first complication are crucial. The risk of secondary complications after the occurrence of five primary complications (pneumonia, myocardial infarction, deep space surgical site infection, bleeding or transfusion event, and acute renal failure) increases significantly.[27] Prompt recognition and treatment of the first complication (rescue) abort the cascade that may proceed to subsequent complications and death (failure to rescue).

EGS is burdened by significant morbidity and mortality, more frequently than in nonemergency surgical patients. EGS composes only 14.6% of general surgery procedures in the National Surgery Quality Improvement Program (NSQIP), but accounts for 53.5% of deaths in the general surgical population.[28] Bleeding, stroke, myocardial infarction, and pneumonia carry a high risk of postoperative death compared to surgical site infection or urinary tract infection.[29] Havens et al[30] reported mortality of 12.5% in EGS patients versus 2.7% in elective operation patients, and the corresponding morbidity rates were 32.8% versus 12.7%.[30] The increased complication rate is further supported by a 17% readmission rate for EGS patients.[30] Furthermore, seven EGS procedures account for 80% of deaths, morbidity, and costs of EGS—partial colectomy, small bowel resection, operations for peptic ulcer disease, cholecystectomy, lysis of adhesions, laparotomy, and appendectomy.[31]

FAILURE TO RESCUE IN THE TRAUMA PATIENT

Failure to rescue in the trauma patient is less common than in the EGS population. The majority of trauma deaths do not have a precedent event (complication) and are dictated by injury burden. Most trauma deaths occur within 24 to 48 hours of admission. Deaths from hemorrhage occur at a median of 1.6 hours after admission, and central nervous system deaths peak at 24 to 48 hours. A review of 35,000 admissions reported preventable deaths in 2.5% of fatalities, with bleeding being the most common etiology of preventable death, generally from delay in treatment.[32] Other causes of preventable deaths were judgment errors and missed injuries. This is in contrast to the EGS patient, in whom complications and failure to rescue generally occur later postoperatively. Holena et al[33,34] have contributed several important papers on failure to rescue in the trauma patient. In a detailed review, they observed that a minority of trauma deaths (6%) were truly preventable. However, the majority of failure-to-rescue cases were deemed preventable or potentially preventable.[33,34]

SURGICAL RESCUE IN THE MEDICAL ICU PATIENT

Although not strictly defined as surgical rescue, management of a major surgical complication in the ICU patient is an important function of the acute care surgeon. In addition, abdominal complications occur in 1% to 4% of medical ICU (MICU) patients. We have recently reviewed our experience of EGS consults on 911 MICU patients. One-third of the consults were for a nonabdominal issue, with 66% of patients undergoing intervention (eg, tracheostomy, soft tissue procedures, feeding tubes, vascular access). Sixty-three percent of the MICU consults were to evaluate an abdominal process; operative intervention was required in one-third (186 of 578 patients). Thus, abdominal operations were required in 1.7% of all MICU admissions (186 of 1192 admissions). The abdominal procedures, in declining frequency, were bowel resection, procedures for *Clostridium difficile* colitis, nontherapeutic laparotomy/laparoscopy, operation for peptic ulcer disease, cholecystectomy, and decompressive laparotomy, and the mortality rate was 37%.

ACUTE CARE SURGERY AND CLINICAL OUTCOMES

The rapid adoption of an ACS paradigm has provided the opportunity to analyze the ramifications of this new specialty on several important operational and clinically relevant outcomes. In a single-center study, implementation of an ACS service was associated with reduced surgical decision time by 15%; the authors hypothesized that this was due to the more immediate availability of an attending surgeon. This correlated with shortened average time to stretcher from the waiting area for all patients in the ED by 20%, thereby reducing ED overcrowding.[35] Another study showed reduced time to the OR for patients (192 vs 221 minutes, $P = .015$) and proportionally fewer after-hours operative cases (60% vs 72.6%, $P < .0001$).[36] Additionally, time in the ER, hospital length of stay (LOS), and complications were reduced after the establishment of an emergency surgical service.[3]

The associations between development of an ACS service and specific disease outcome have been reported. For patients with appendicitis, care provided by an ACS team compared to a traditional general surgery call practice had reduced time from consultation to the OR (3.5 vs 7.6 hours, $P < .05$), decreased time from presentation to the ED to the OR (10.1 vs 14.0 hours, $P < .05$), decreased rate of appendiceal rupture (12.3% vs 23.3%, $P < .05$), decreased complication rate (7.7% vs 17.4%, $P < .05$), and decreased hospital LOS (2.3 vs 3.5 days, $P < .001$).[37] Similar results were reported in other studies comparing ACS to traditional general surgery call, with reduction in patient time to surgical evaluation, shorter time to OR, shorter LOS, and increased cost savings.[36-40] This was due to around-the-clock presence of the ACS attending; in addition, cases that presented in the night hours were not delayed until the following morning, as was the previous practice with the traditional on-call model.[40]

The influence of an ACS service on the surgical management of biliary pathology has also undergone study with supportive observations. Mean time to surgical evaluation was reduced by nearly 6 hours, operative intervention occurred more than 24 hours earlier, fewer complications were incurred, there was a 2-day reduction in hospital LOS and cost savings of approximately $3000 per case.[38] Nearly identical observations have been reported in several independent single-center

studies with the additional benefits of decreased after-hours cases (5.6% vs 21.0%, $P = .004$)[40,41] and fewer conversions from laparoscopic to open cholecystectomy (4.2% vs 11.6%, $P = .013$).[42] An initial concern that combining EGS with a trauma practice would negatively impact trauma outcomes has been dispelled. Multiple studies have shown that despite the increase in workload that occurs with development of an ACS service, times to OR for the injured patient are not untowardly affected, and morbidity and mortality rates do not increase.[15,43,44] In addition, the impact an ACS group has on the practice and productivity of general surgeons has been shown to be symbiotic—both ACS surgeons and elective general surgeons thrive under the new model.

Finally, implementing an ACS service at a nontrauma hospital again demonstrated beneficial effects, with fewer complications, shorter hospital LOS, and monetary savings. After formation of an ACS service, appendectomy complications fell from 13% to 3.7% ($P < .0001$), and hospital LOS decreased from 3.0 days to 2.3 days ($P < .0001$). Cholecystectomy patients experienced fewer complications as well (9% vs 21%, $P = .012$) and also were noted to have shorter LOS (3.8 vs 5.3 days, $P = .0004$).[45] This study highlights the flexibility and variation of ACS groups between different practice locations and settings.

FELLOWSHIP TRAINING

The AAST Committee on Acute Care Surgery has established guidelines for a 2-year curriculum for fellowship training in ACS.[1] Nine months of critical care, the standard of the Accreditation Council for Graduate Medical Education–accredited fellowship in surgical critical care, are paired with an additional 15 months of exposure to various emergency and elective surgical disciplines. Some flexibility and variation are encouraged to capitalize upon the strengths of the local training environment and the perceived individual needs and talents of the fellow in training.[1,16,46] The first year is primarily designed to fully train the fellow in surgical critical care. The focus of the second year is threefold: (1) It provides a period of focused training in those areas most challenging to all trauma surgeons: major hepatic, thoracic, and vascular injuries. (2) Voids that may exist in operative experience and training during the fellow's residency are identified and addressed. (3) The fellow matures in both form and function as an attending through supportive participation on a busy trauma or general surgery service with help nearby. The fellow can also learn about trauma systems, performance improvement, and prehospital care and engage in the research opportunities in the program.

Case Log

Analysis of ACS fellow case logs from the first year of organized reporting revealed that fellows were performing approximately 200 cases in a year, with a 41% to 59% split between elective and urgent/emergent, respectively.[47] Up to half of these cases were in the abdomen, with cases of the head and neck underrepresented. Case requirements for the ACS fellowship have been revised since their initial release in 2007, with cases now divided into anatomic subsections with a minimum number of cases required in each section.[1,46] The goal is to train surgeons to be comfortable in numerous anatomic regions.

FUTURE DIRECTIONS

ACS will continue to evolve and grow. As interest and experience with ACS and the EGS patient cohort expand, so will initiatives to benchmark outcomes and quality improvement tracking, similar to what has been applied to trauma. Analyses of NSQIP data reveal significantly worse outcomes in operations on EGS patients versus nonemergent operations of the same type, with significantly higher prevalence of systemic inflammation and other alterations in physiology in the emergent group.[48,49] These data have led many to propose that different outcome metrics should be applied to emergent versus nonemergent cases of the same operation.[48] Efforts have been made to determine what preoperative characteristics are predictive of a deviation in outcome in EGS.

Genomics and Acute Care Surgery

Scott C. Brakenridge • Philip A. Efron • Lyle L. Moldawer

KEY POINTS

- Variability in clinical phenotypes results from the following: differences in DNA sequence (genomics), RNA transcription (transcriptomics), and protein translation and structure (posttranscriptional regulation and posttranslational modification).
- It is estimated that only 2% of total DNA includes the code for the approximately 20,000 protein-coding genes of the human genome.
- Exons are the regions of DNA that are transcribed to mRNA and then translated into the amino acid structure of proteins.
- Histone proteins play a key role in the functional regulation of the genome.
- The most common type of DNA sequence variations are single base substitutions termed *single nucleotide polymorphisms* (SNPs).
- SNPs relevant to acute care surgery are found within the promotor regions of genes for Toll-like receptor 1 and tumor necrosis factor-α, both associated with increased mortality after trauma and sepsis.
- MicroRNAs are short single-stranded RNA fragments that downregulate gene expression when bound to messenger RNA.
- Postinjury systemic inflammatory response syndrome–induced early multiple organ failure is related to a "genomic storm" at the level of circulating leukocyte gene transcription and occurs simultaneously with a compensatory anti-inflammatory and immunosuppressive response.
- Chronic critical illness is characterized by an underlying pathophysiology of persistent inflammation, immunosuppression, and catabolism.
- A 63-gene transcriptomic metric score within 24 hours after injury has been shown to be associated with subsequent adverse outcomes including multiple organ dysfunction, length of mechanical ventilation and hospital stay, and infection rates.

INTRODUCTION

Perhaps more than in any other surgical disease, outcomes after traumatic injury have improved through evidenced-based standardization of care.[1] Nevertheless, despite seemingly optimized care, unexpected and complicated outcomes continue to occur in critically ill surgical patients. The question then becomes: Why do patients with similar injuries or severity of acute illness, despite receiving comparable and appropriate treatment, often follow different clinical trajectories? Although one patient recovers uneventfully from hemorrhagic shock after a motor vehicle collision, another follows a prolonged intensive care unit course complicated by nosocomial infections and persistent organ dysfunction. Similarly, despite our understanding of the biology of coagulation and the widespread implementation of prophylactic pharmacologic strategies, venous thromboses and pulmonary emboli still occur, often with fatal consequences.

Numerous clinical, environmental, and genetic factors contribute to variability in the innate inflammatory response, variable rates of drug metabolism, and risk for venous thromboembolic disease. The completion of the Human Genome Project and technologic advances in nucleic acid sequencing and small-molecule identification have provided the foundation on which to build knowledge regarding genetic variation in both humans and animal models.[2] This, in turn, has been used to establish genotype-phenotype associations for common polygenic diseases, such as diabetes mellitus, cancer, and hypertension. Using this genetic variability to understand disease biology, predict risk of disease onset, and calculate an individual's response to a given therapy (eg, drug selection and dosing) are the goals of the field of genomic medicine.[3]

At the molecular level, differences in DNA sequence (genomics), RNA transcription (transcriptomics), and protein translation and structure (posttranscriptional regulation

and posttranslational modification) all result in variability in clinical phenotypes. For instance, drug absorption, metabolism, and excretion are all affected by genetic variation and are the focus of the field of pharmacogenomics. Therefore, understanding the information contained in an individual's genetic fingerprint has the potential for further enhancing the prediction of disease risk, clinical course, and response to any given therapy and facilitating an individualized approach to the severely injured or critically ill patient. Proteomics, metabolomics, and epigenetics are additional aspects of systems biology that are rapidly evolving and promise to deliver new discoveries that are likely to improve patient care. Together, these concepts, techniques, and applications form the foundation of precision medicine. This chapter focuses on select aspects of these fields and their potential application to the care of severely injured and critically ill surgical patients.

STRUCTURE AND FUNCTION OF THE HUMAN GENOME

Since the discovery of the molecular structure of nucleic acids by Watson and Crick in 1954, the genetic basis for many conditions has been determined; however, many misconceptions exist regarding both the past and current role of genomics in clinical medicine.[4] Despite the commonly held notion that knowledge of genetics has had little influence on clinical medicine, it has in fact played an important role in understanding disease, but only for a small number of conditions and patients. Due to rapid advancements in knowledge and technology, however, we have entered a period of tremendous growth in the application of clinical genomics that will eventually influence the care of nearly all patients.[2] In order for clinicians to understand and apply these advances, we must become literate in the "language" of genomic medicine. Table 9-1 lists some

TABLE 9-1: Genomics Nomenclature and Definitions

Allele: One of two or more alternative versions of a genetic sequence at a particular location in the genome.
Epigenetics: The study of changes in organisms caused by modification of gene expression rather than alteration of the genetic DNA sequence.
Exome: Part of the genome composed of exons, the sequences of which remain within messenger RNA after introns are removed by RNA splicing and contribute to the final protein product encoded by that gene.
Gene: An ordered sequence of nucleotides located in a particular position on a particular chromosome that encodes a specific functional product (ie, a protein or an RNA molecule).
Genome: The complete set of DNA found in a cell. In humans, this consists of 23 pairs of chromosomes (~20,000 genes) in the nucleus, as well as a small chromosome found in the cells' mitochondria.
Genomics: The utilization of genetics and molecular biology techniques to analyze the structure, function, and mapping of either sets of genes or the complete genome.
Genome-wide association study (GWAS): An approach used to look for associations between many (typically hundreds of thousands) specific genetic variations (most commonly single nucleotide polymorphisms) and particular diseases or clinical conditions.
Genotype: A person's complete collection of genes. The term can also refer to the two alleles inherited for a particular gene.
Metabolomics: The systematic identification and quantification of the small-molecule metabolic products (the metabolome) of a biological system (cell, tissue, organ, biological fluid, or organism).
Microarray: An analytic technology where thousands of gene sequences are placed in known locations on a glass slide. A sample containing DNA or RNA is deposited on the slide (a gene chip), and the binding of complementary base pairs from the sample and the gene sequences on the chip can be measured with the use of fluorescence to detect the presence and quantity of specific sequences in the sample.
MicroRNA (miRNA): A small noncoding RNA molecule (~22 nucleotides) that selectively turns genes off and on within a cell via posttranscriptional regulation of gene expression (RNA silencing).
Next-generation sequencing: High-throughput technologies that allow nucleic acid sequencing without the physical separation of individual reactions into separate tubes, capillaries, or lanes. Sequencing reactions occur in parallel, allowing millions of sequencing reactions to occur and be analyzed simultaneously.
Pharmacogenomics: The study of the influence of genetic variation on drug response in patients by correlating gene expression or single nucleotide polymorphisms with a drug's efficacy or toxicity.
Phenotype: The set of observable characteristics or traits (eg, morphology, behavior, biochemical or physiologic properties) of an individual resulting from the interaction of its genotype with the environment.
Precision medicine: An approach for disease treatment and prevention that takes into account individual variability and interaction of genes, environment, and lifestyle for each person.
Proteomics: The utilization of molecular biology, biochemistry, and genetic biotechnology to analyze the structure, function, and interactions of proteins produced by the genes of a particular biological system or organism.
Single nucleotide polymorphism (SNP): A single nucleotide variation in a genetic sequence; a common form of variation in the human genome.
Systems biology: Interdisciplinary field of study that focuses on complex interactions within biological systems, using a holistic approach (holism instead of the more traditional reductionism) to biological research.
Transcriptomics: The study of the complete set of RNA transcripts that are produced by the genome, under specific circumstances or in a specific cell type, using high-throughput methods, such as microarray analysis.

important definitions of genetic concepts that clinicians should be able to recognize and understand and that will be discussed throughout this chapter.

Although much is known about the structure and function of the human genome, our knowledge continues to evolve. We now know that the minority of the three gigabases of DNA in the human genome actually code for proteins. It is estimated that only 2% of total DNA includes the code for the approximately 20,000 protein-coding genes of the human genome. The function of the remaining 98% of DNA (specifically, DNA-protein interactions, macrostructure changes, and molecular modification) is perhaps the most evolving and fascinating aspect of genomics. The structure of protein-coding genes is well known. The 5′ control region, often termed the *promoter*, includes DNA sequences that recognize and bind to proteins called transcription factors, whose function is to modify gene expression by modulating transcription. The "start codon" is a series of nucleotides that are recognized by the transcriptional machinery, which initiates the generation of messenger RNA (mRNA) from DNA. Not all of either the DNA or transcribed RNA sequence within an overall "gene" encodes for protein. Exons are the regions of DNA that are transcribed into RNA to make amino acids. In most genes, multiple exons are separated by introns, which are removed from mRNA prior to translation into protein. The end of transcription is signaled by a series of nucleotides at the end of the coding sequence, referred to as a *stop codon*. The DNA sequence after this stop codon, termed the *3′ control region*, can also influence the rate of gene transcription and may affect the stability of the mRNA sequence and its subsequent translation into protein.

Although the mechanisms of transcription and translation are well established, the macrostructure of the human genome is also now emerging as an important regulator of overall genomic function. Genomic DNA is intimately associated with histone proteins that ultimately determine chromosome structure. Although previously thought to be important primarily for chromosomal organization and cell division, it is now known that histones play a key role in the functional regulation of the genome. Through the rapidly advancing field of *epigenetics*, we now understand that histone organization, DNA-histone binding, and molecular DNA modification (eg, DNA methylation) have a strong influence on gene activation and expression (Fig. 9–1). Many epigenetic factors (eg, environmental, drug, nutritional, DNA methylation) have been identified that modulate the DNA-histone interaction and have a direct effect on accessibility of transcriptional factors to individual protein coding genes. This then directly affects gene activation, which can contribute to or directly cause many known disease processes.[5]

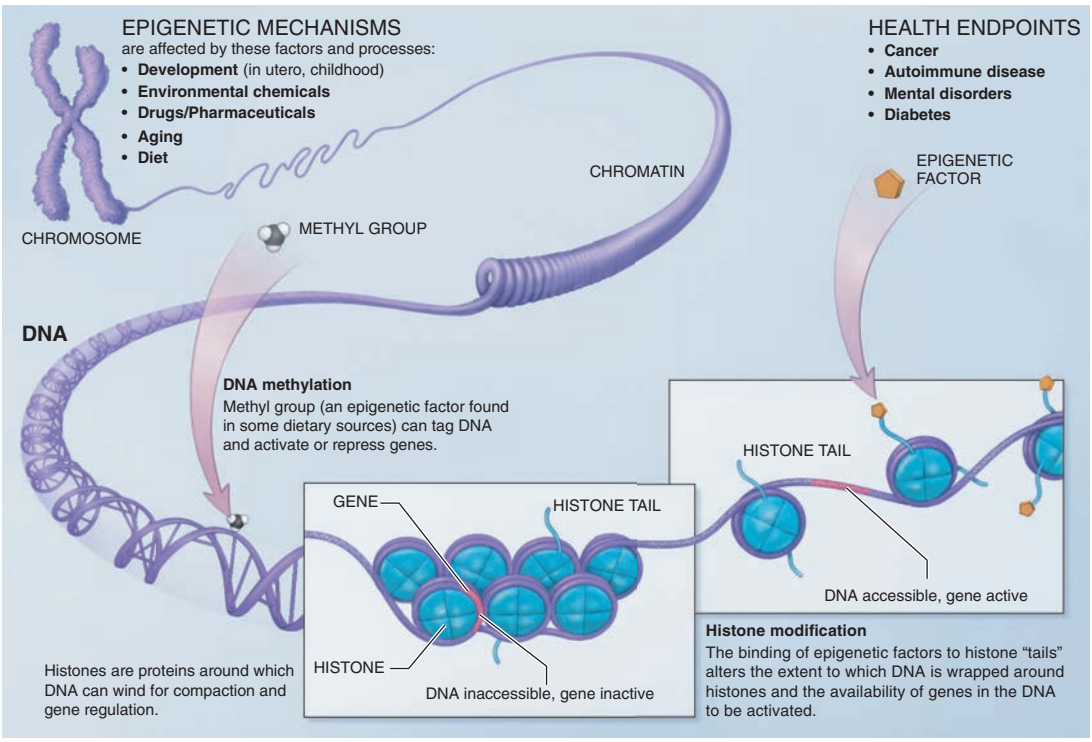

FIGURE 9-1 Epigenetic mechanisms. Epigenetic mechanisms are affected by several factors and processes including development in utero and in childhood, environmental chemicals, drugs and pharmaceuticals, aging, and diet. DNA methylation is what occurs when methyl groups can tag DNA and activate or repress genes. Histones are proteins around which DNA can wind for compaction and gene regulation. Histone modification occurs when the binding of epigenetic factors to histone "tails" alters the extent to which DNA is wrapped around histones and the availability of genes in the DNA to be activated. THE GENETIC BASIS OF DISEASE

Despite the current limited information regarding the function of a large (noncoding) portion of the human genome, our knowledge of the genetic basis for disease is extensive. Basic research and clinical observations have elucidated the inheritance of single-gene Mendelian disorders. Most of these diseases are uncommon, and taken together, the most prevalent (eg, cystic fibrosis and hemochromatosis) affect no more than one in several hundred people. When a genetic variant is present, however, its phenotypic effect on individual patients can be substantial. Understanding the mechanisms underlying many monogenic disorders has provided pathophysiologic information about related, more common disorders. For example, we have learned a great deal about the pathophysiology of cardiovascular disease from discoveries related to familial hypercholesterolemia, a rare genetic disorder leading to premature atherosclerosis.

The most common type of DNA sequence variations are single base substitutions termed *single nucleotide polymorphisms* (SNPs). These SNPs have emerged as important genetic markers for studying multifactorial diseases.[6] Genetic polymorphisms occur in all individuals, but by definition, SNPs exist with a population frequency of greater than 1%.[7] Therefore, the term *SNP* does not include numerous other single base substitutions in which the least common allele is present at a frequency of less than 1% (eg, "personal mutations" that may be limited to one family) or other variations such as insertion/deletion polymorphisms. Importantly, SNPs should be distinguished from disease-"causing" mutations, which are generally much less common but have higher penetrance (eg, sickle cell anemia). SNPs typically do not cause disease but, in aggregate, may be associated with the risk for developing a disease (eg, diabetes mellitus, asthma) or may predict the outcome from a disease or condition. SNPs that exist in mRNA-coding regions (exons) of DNA can lead to amino acid substitutions (missense mutations; eg, sickle cell disease) and, therefore, may change the structure and function of the resultant protein. Although this type of SNP variant potentially has the most profound impact on protein function, it is the least common.[8] SNPs in the regulatory (promoter) region of a gene may influence transcription of that gene and, therefore, may influence the amount of protein available (eg, tumor necrosis factor-α [TNF-α] polymorphism in sepsis).[9,10] Yet, other SNPs may not directly alter protein abundance or function but may be important markers for other (unidentified) functional variants—a concept known as linkage.[8] The analysis of SNPs has been facilitated by two related developments: (1) the establishment of large genomic data repositories, and (2) the increased availability and rapidly declining costs of high-throughput methods for genotyping. These analytical techniques have identified at least 10 million SNPs interspersed throughout the human genome, at a frequency of one SNP per approximately 300 base pairs.[11] Examples of SNPs relevant to acute care surgery are ones found within the coding or promotor regions of genes for Toll-like receptor 1 and TNF-α that are associated with increased mortality after trauma and sepsis.[10,12]

Microsatellite and insertion/deletion polymorphisms represent other genetic variations that may be used to characterize an individual's risk for disease and response to therapy. Microsatellite polymorphisms are tracts of repetitive DNA in which certain DNA motifs (ranging in length from 1–6 or more base pairs) are repeated, typically between 5 and 50 times. Microsatellites occur at thousands of locations within an organism's genome and have a higher mutation rate than other areas of DNA, leading to high genetic diversity. Insertion/deletion polymorphisms are characterized by the presence or absence of a single base in some cases or a longer fragment in others. Microsatellite and insertion/deletion polymorphisms are generally considered to be markers for other functional variants and are not themselves functional, but in some cases they may directly alter gene activity.[13,14] Typically, they occur in nonfunctional regions or in gene regulatory regions and not in coding regions because they would likely lead to a nonfunctional protein. Although translating knowledge obtained from SNPs and microsatellite data directly to the patient's bedside may seem an abstract concept, it is hoped that these studies will continue to contribute to the understanding of the biology of disease and facilitate characterizing individual patient risk, treatment response, and clinical outcome.

Many important advances in genomic analysis have been made using genome-wide association studies (GWAS) and, more recently, next-generation sequencing (NGS), which have revolutionized genomic research.[15] In a GWAS, hundreds of thousands of SNPs are genotyped and analyzed for association with a particular clinical phenotype. NGS can be used to sequence entire genomes or be constrained to specific areas of interest, including all 22,000 coding genes (whole exome) or small numbers of individual genes. Usually, this is accomplished by fragmenting the genome into small pieces, randomly sampling for a fragment, and sequencing it using one of a variety of technologies. Sequencing of an entire genome is often possible within a day because multiple fragments are sequenced at once (giving it the name *massively parallel sequencing*) in a highly automated process. This methodology has been used recently in injured patients to identify candidate SNPs, as well as gene expression patterns of peripheral leukocytes associated with persistent organ dysfunction and mortality.[16-18] The sheer amount of data gathered from a GWAS, however, can present significant statistical problems.[19] Whole-exome sequencing, as the term implies, involves sequencing the protein-coding genes of the genome.[20,21] Exome sequencing will identify rare variants directly. These rare variants are typically missed by GWAS, which rely on relatively common haplotype-tagging SNPs to capture variability across the genome. Therefore, NGS exome sequencing holds promise for digging more deeply into the genome of critically ill injured and surgical patients.

An emerging area of genome-based pathology is the role of microRNAs (miRNAs) in modulating gene expression. miRNAs are short, single-stranded RNA fragments that downregulate gene expression when bound to mRNAs by base pairing with the 3′ untranslated region of target gene

mRNAs to inhibit protein translation. Gene expression modulation via circulating miRNAs has been identified as a potential biomarker and possibly a compensatory mechanism, but also likely a direct contributor to several disease processes including many cancers, cardiovascular disease, and spinal cord injury.[22-24] Particularly relevant to acute care surgery, up to 69 unique and differentially expressed miRNAs have been identified in the plasma of severely injured trauma patients.[25] Further investigation is needed because it is possible that miRNAs play a key role in the modulation of shock-related genes and pathways, including cell surface signaling receptors (Toll-like receptors), inflammatory intracellular signaling (MyD88), and endothelial cell function (VCAM-1).[25,26]

THE "GENOMIC STORM," MULTIPLE ORGAN FAILURE, AND CHRONIC CRITICAL ILLNESS

The advent of intensive care units (ICUs) in the early 1970s facilitated the survival of patients with single organ failure; concurrently, multiple organ failure (MOF) emerged as a highly lethal syndrome (with mortality >80%). Since then, MOF has plagued ICUs for more than four decades, and its epidemiology has evolved as advances in critical care have allowed patients to survive previously lethal insults.[27] Through the years, various predominant clinical presentations of MOF have come and gone (eg, abdominal compartment syndrome, acute respiratory distress syndrome), all having consumed tremendous health care resources with associated prolonged ICU stays and high mortality. Investigators then recognized that both infectious and noninfectious insults could induce a similar, overwhelming, destructive systemic inflammatory response syndrome (SIRS). Epidemiologic studies revealed that MOF was subsequently evolving into a bimodal phenomenon with decreasing early and increasing late mortality. Early MOF occurred after either an initial severe insult (one-hit model) or sequential amplifying insults (two-hit model), whereas late MOF was precipitated by secondary nosocomial infections. The compensatory anti-inflammatory response syndrome (CARS) was proposed to follow SIRS and seemed to explain this increased susceptibility to infection and bimodal distribution of MOF. SIRS-induced early MOF was thought to occur because of exaggerated innate immune and inflammatory responses (ie, "cytokine storm"), whereas CARS was viewed as progressive depression in adaptive immunity resulting in secondary infections. At this point, our understanding of the mechanisms of this dysfunctional postshock immune response remained limited. Research thus shifted to determining the underlying mechanisms of this phenomenon of a postinjury dysfunctional inflammatory response to severe injury and shock.

Significant advancements in our understanding of the genomic basis for the dysfunctional inflammatory response driving MOF after hemorrhagic shock were made by the Inflammation and Host Response to Injury Collaborative Program (Trauma "Glue Grant"). Analysis of total circulating leukocyte gene expression of severely injured blunt trauma patients illustrated that a so-called "genomic storm" at the level of circulating leukocyte gene transcription occurred after injury. In addition, it was found that SIRS and CARS occurred simultaneously rather than sequentially, as previously thought.[28] Patients who exhibited a complicated clinical trajectory (defined as >14 days of persistent organ dysfunction or death) had exacerbation and prolongation of their dysfunctional transcriptomic response and failure to return to baseline expression patterns. Other acute proinflammatory insults such as burns and sepsis have been shown to have a similar pattern of early genomic inflammatory storm and persistent organ dysfunction followed by prolonged low-grade inflammation and immunosuppression.[29]

Due to ongoing advances in surgical critical care, a substantial portion of high-acuity patients with MOF now survive their initial insult and progress into a chronic critical illness (CCI) characterized by an underlying pathophysiology of persistent inflammation, immunosuppression, and catabolism (Fig. 9–2). Contrary to the initially hypothesized bimodal SIRS/CARS paradigm, inflammation co-occurs with immunosuppression and anti-inflammation after major acute events, such as severe trauma, burns, pancreatitis, and sepsis.[28,30,31] For a relatively few patients, an initial overly robust and dysfunctional inflammatory response leads to a trajectory of early MOF and fulminant death. Patients who do not succumb to early MOF follow one of two pathways as follows: (1) the patient is rapidly restored to genomic/immunologic homeostasis, or (2) immunologic dysfunction persists and leads to CCI, characterized by persistent organ dysfunction requiring critical care resources for 14 days or longer. These patients who develop CCI after trauma or sepsis have been shown to have longer hospital and ICU lengths of stay and increased utilization of health care resources, are discharged to care facilities associated with poor long-term outcomes (long-term acute care and skilled nursing facilities), and have a 1-year mortality in excess of 50%.[30,32,33] These dismal outcomes have clearly shown us that we need to think beyond initial shock resuscitation and have a deeper understanding of, and ability to predict and modify interventions for, the host response to injury and sepsis.

DIAGNOSTIC GENOMICS AND PRECISION MEDICINE

NGS expression technology with "big data" computational analyses of genomic data and data from the clinical electronic medical record continues to reveal novel insights into the biology of the response to injury and surgical sepsis.[34] For example, network-based analysis of gene expression from circulating white blood cells revealed that acute systemic inflammation causes transient alteration in numerous pathways and networks, including those involved in immunity and modulation of leukocyte translational machinery.[28,35,36] Additionally, genomic analyses have given us insight into differing host response factors to these insults, including sex and

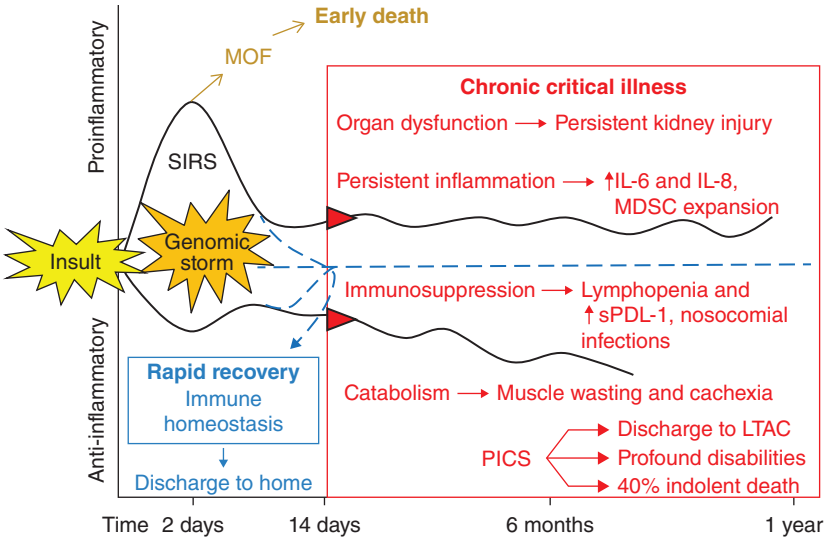

FIGURE 9-2 The "genomic storm" and its persistent downstream effects after trauma, burns, or sepsis. IL, interleukin; LTAC, long-term acute care facility; MDSC, myeloid-derived supressor cells; MOF, multiple organ failure; PICS, persistent inflammation, immunosuppression and catabolism syndrome; SIRS, systemic inflammatory response syndrome; sPDL-1, soluble programmed death ligand 1.

age, which are associated with differences in both genomic response and clinical outcomes.[37-39]

In addition to improving our understanding of pathophysiology, genomic analyses may help improve disease classification and prognostication for severely injured or septic patients.[40,41] The transcriptomic signature after severe injury and hemorrhagic shock has been shown to be highly predictive of onset, severity, and duration of MOF.[28,42] One methodology to develop a genomic metric for trauma uses a baseline or "reference" status for the average leukocyte gene expression profiles of healthy human volunteers. This is then compared to gene expression profiles from patients early after injury to compute a difference-from-reference (DFR) score for each individual.[43] A 63-gene DFR metric score within 24 hours after injury has been shown to be associated with subsequent adverse outcomes, including multiple organ dysfunction, longer length of mechanical ventilation and hospital stay, and increased infection rates. This genomic metric is highly predictive of persistent organ dysfunction (ie, CCI) or death after severe injury and hemorrhagic shock.[17] Clinical genomic metrics such as this may allow us to intervene earlier and select those likely to respond to various immunomodulatory interventions in a precision medicine diagnostic, prognostic, and therapeutic approach.

SUMMARY AND IMPLICATIONS FOR CLINICAL PRACTICE

A growing body of scientific knowledge strongly indicates that genomic data will continue to improve our understanding of acute disease processes and affect clinical care for conditions that are commonly encountered within the scope of acute care surgery, including severe trauma, burns, and surgical sepsis. These proinflammatory insults trigger a "genomic storm" within the innate immune system, leading to MOF, persistent immune dysfunction, nosocomial infections, and recurrent complications. These patients are at high risk of developing CCI and an underlying pathophysiology of persistent inflammation, immunosuppression, and catabolism, which ultimately results in dismal clinical outcomes. Rapidly evolving analytical technologies and our growing understanding of the genomic response to injury and infection are now beginning to successfully translate genomic analysis from the bench to the bedside. In the near future, this will contribute to clinically important advances in diagnosis, risk stratification, and prediction of treatment response for a precision medicine approach to severely injured and septic surgical patients.[44,45]

Prehospital Care

Donald H. Jenkins • Andrew Muck • Scott P. Zietlow

KEY POINTS

- In the United States, the Emergency Medical Services (EMS) Systems Act of 1973 (PL 93-154) resulted in federal funding for the establishment of emergency medical systems.
- The four levels of prehospital care providers described in the National EMS Education Standards of 2009 are emergency medical responder (formerly, first responder), emergency medical technician (EMT; formerly, EMT-Basic), advanced EMT (replaces both prior versions of the EMT-Intermediate), and paramedic.
- The Stop the Bleed campaign developed under the direction of Lenworth M. Jacobs, Jr., MD, at Hartford Hospital trains laypersons to evaluate for life-threatening bleeding, compress bleeding, and apply tourniquets effectively.
- Basic life support (BLS) in the field includes basic airway management, supplemental oxygen and rescue breathing, cardiopulmonary resuscitation, control of external hemorrhage, splinting, spinal immobilization, and uncomplicated childbirth.
- Advanced life support (ALS) in the field includes advanced airway management, cardiac monitoring, cardioversion and defibrillation, insertion of intravenous lines, and administration of numerous medications.
- In areas primarily covered by BLS units, a tiered response arrangement should be in place so that ALS backup is available when needed.
- By 2015, 96% of the US population lived in an area covered by an enhanced 911 phone system, but this only represents about 50% of the counties in the country.
- When caring for a critically injured patient, EMS personnel should limit on-scene time to 10 minutes or less.

INTRODUCTION

Critically injured patients must receive high-quality care from the earliest postinjury moment to have the best chance of survival. Most trauma victims first receive health care from the emergency medical services (EMS) system, which is responsible for rendering aid and transporting the trauma patient to an appropriate facility.

The practice of medicine in the prehospital setting presents numerous challenges not encountered in the hospital. Hazardous materials along with environmental and climatic conditions may pose dangers to rescuers as well as to patients. If the patient is entrapped in a mangled vehicle or a collapsed building, there must be meticulous coordination of medical and rescue teams. Communication with police may be required in the setting of an active shooter or when concerns exist regarding potential explosive devices. Providers of prehospital care are expected to deliver high-quality medical care in situations that are dynamic, dangerous, austere, and unforgiving, and, often, for prolonged periods.

The role of the EMS system is far more complex than simply transporting the trauma victim to a medical facility. In most EMS systems in the developed world, specially trained health care professionals are responsible for the initial assessment and management of the injured patient. Experience from the past several decades has shown that these paraprofessionals can safely perform many of the interventions that were previously performed only by physicians or nurses in the emergency department.

Prehospital research has helped direct best practices, influence policies, and improve outcomes. As EMS systems mature and additional prehospital care research is conducted, the question is no longer, "What *can* the emergency medical technician (EMT) do for the trauma patient in the prehospital setting?" but rather, "What *should* the EMT do?" The answer to this question can be dynamic depending on such

factors as scene safety, resources available, medical direction, transport times, and experience.

HISTORICAL PERSPECTIVE

While the roots of prehospital trauma care can be traced back to military physicians, modern civilian prehospital trauma care began several decades ago. J.D. "Deke" Farrington and Sam Banks instituted the first trauma course for ambulance personnel in 1960.[1] This course, initiated with the Chicago Committee on Trauma and the Chicago Fire Academy, marked the beginning of formal training in prehospital care of injured patients. Farrington is generally acknowledged as the father of modern EMS.[2]

In September 1966, the National Academy of Sciences and National Research Council published the landmark monograph, *Accidental Death and Disability: The Neglected Disease of Modern Society*.[3] This document argued that there were no standards for ambulances with respect to design, equipment, or training of personnel. As a direct result of this monograph, the Department of Transportation funded the development of the Emergency Medical Technician–Ambulance (EMT-A) curriculum, which was published in 1969. Continued public pressure resulted in the passage of the Emergency Medical Services (EMS) Systems Act of 1973 (PL 93-154). This act revolutionized EMS in the United States and resulted in federal funding for the establishment of EMS systems.

In the late 1950s, J. F. Pantridge, an Irish physician practicing in Belfast, developed a mobile coronary care unit that was staffed by physicians.[4] He conceived of a system in which the victim of an acute myocardial infarction was stabilized at the scene by bringing advanced life support (ALS) to the patient. The physicians worked to restore normal cardiac rhythm through medications and defibrillation at the location where the victim was stricken. This practice brought into focus the debate regarding whether to bring advanced practice to the patient versus transporting the patient as quickly as possible to higher levels of care.

It was soon recognized that physicians were not always available or necessary to provide more advanced care. In the United States, the concept of advanced prehospital care involved training EMTs to perform these lifesaving skills. The original "paramedic" programs began in Los Angeles, California; Houston, Texas; Jacksonville, Florida; and Columbus, Ohio, and were often associated with fire departments. Paramedics were trained to serve as the "eyes and ears" of the physicians in their base hospitals and provide care under their direction.

Although prehospital ALS proved beneficial for victims of cardiac emergencies, it was not until the 1980s that it became obvious that definitive care for trauma patients was fundamentally different than that for the cardiac patient. Efforts to restore circulating blood volume proved to be unsuccessful in the face of ongoing internal hemorrhage. The exsanguinating trauma patient requires operative intervention, and any action that delays the trauma patient's arrival in the operating room is ultimately detrimental to survival. During this period, significant controversy surrounded prehospital ALS for trauma patients as expert panels and editorialists debated the positive and negative impacts.[5,6] Several studies documented the detrimental effect of prolonged attempts at field stabilization on seriously injured trauma patients,[7-9] while others showed that paramedics could employ ALS measures in an expeditious manner.[10-13]

EMERGENCY MEDICAL SERVICES SYSTEM

The modern EMS system involves the integration of a number of complex components. Essential elements include the following: personnel, medications, equipment, communications, transport modalities, medical control, and an ongoing quality improvement process. Different configurations of EMS systems result when these components are integrated in varying combinations. The EMS system represents a significant component of the trauma system, described elsewhere (see Chapter 4).

The Department of Transportation, through the EMS office of the National Highway Traffic Safety Administration (NHTSA), provides federal leadership for the EMS system. With input from national stakeholder organizations, NHTSA developed the *EMS Agenda for the Future*, published in 1996.[14] This document detailed a vision for improving 14 aspects of EMS, including the following: integration of health services, EMS research, legislation and regulation, system finance, human resources, medical direction, education systems, public education, prevention, public access, communication systems, clinical care, information systems, and evaluation. Two related documents that expand on concepts addressed in the original *Agenda* are the *EMS Education Agenda for the Future: A Systems Approach* (2000) and the *National EMS Research Agenda* (2001).[15,16]

EMS Personnel

EMTs compose the vast majority of prehospital care providers employed in the United States, and only a small number of nurses and physicians deliver care in the out-of-hospital setting.

Emergency Medical Technicians

For more than a decade, the *National Emergency Medical Services Education and Practice Blueprint*, published by NHTSA in 1993, provided the basis for the levels and training of EMTs used in the United States.[17] The four levels of EMTs described in the document are the First Responder, EMT-Basic, EMT-Intermediate (EMT-I), and EMT-Paramedic. An enhanced EMT-I level was introduced in 1999, but many states retained the original 1985 curriculum. The Blueprint divided the major areas of prehospital instruction into 16 "core elements." For each core element, there are progressively increasing knowledge and skill objectives, representing

a continuum of education and practice. A National Standard Curriculum (NSC) provided lesson plans for each level.

With the publication of the *EMS Education Agenda for the Future*, the foundation was laid to replace the NSC with a system that it was hoped would standardize EMS training and certification across the country. This system is based on a medical model that includes a defined scope of practice, accredited education programs, certifying exams that ensure baseline competency, and licensure to permit one to practice. Three of the five components of this system focus on the levels and education of EMS providers, and each had input from national stakeholder organizations and the public during its development.

NATIONAL EMS CORE CONTENT

Published in 2005, this document describes the domain of prehospital care, identifying the universal body of knowledge and skills that could potentially be used by EMS providers who do not function as independent practitioners.[18]

NATIONAL EMS SCOPE OF PRACTICE MODEL

Published in 2007, this document identifies four new levels of prehospital care practitioners[19] (Table 10-1). The knowledge and skills described in the Core Content are divided among the four levels. During the development of the Scope of Practice Model, there was insufficient support in the EMS and medical communities to support the development of a fifth level of EMS provider with a scope of practice greater than that of the paramedic.

Regular updates of the National EMS Scope of Practice allow for best practices to be related to prehospital providers. The scope of practices has direct impact on trauma care delivered in the prehospital setting. In 2017, tourniquet use and wound packing were examples of practices highlighted to improve trauma care that impact the trauma care patients receive in the prehospital setting.[20]

NATIONAL EMS EDUCATION STANDARDS

Published in 2009, these standards describe the minimal, entry-level competencies that EMS personnel must achieve for each of the levels described in the Scope of Practice.[21]

TABLE 10-1: EMS Provider Levels

National EMS standard curricula	National EMS scope of practice (2007)
First Responder (FR)	Emergency Medical Responder (EMR)
Emergency Medical Technician-Basic (EMT-B)	Emergency Medical Technician (EMT)
Emergency Medical Technician-Intermediate (EMT-I)	Advanced Emergency Medical Technician (AEMT)
Emergency Medical Technician-Paramedic (EMT-Paramedic)	Paramedic

Compared to the NSC, the Education Standards allow for more diverse methods of implementation, more frequent updates of content, and some variation at the state or local level. Each level builds upon the knowledge and skills of the previous level.

The four levels of prehospital care providers described in this new system are discussed in the following sections.

Emergency Medical Responder. This level was previously termed *first responder*. After the terrorist attacks of September 11, 2001, this term now refers to those who are the initial responders to emergencies and can include law enforcement personnel or firefighters who may lack medical training. The emergency medical responder (EMR) uses a limited amount of equipment to perform initial assessment and rudimentary intervention until EMS providers with a higher level of training arrive at the scene. Skills used by the EMR include oral airways, suctioning, automated external defibrillators, cardiopulmonary resuscitation (CPR), oxygen therapy, hemorrhage control, and manual stabilization of the spine and injured extremity. New skills included at the EMR level that were not taught to the first responder include measurement of blood pressure, eye irrigation, and use of a bag-valve-mask (BVM) device and autoinjectors for self or peers.

Emergency Medical Technician. Previously termed *EMT-Basic*, the EMT has greater knowledge and skills than the first responder and holds the minimum qualifications to staff an ambulance. The EMT possesses expanded assessment skills and is trained to perform spinal immobilization and splinting, assist with uncomplicated childbirth, and use limited medications (oral glucose, sublingual nitroglycerine, and subcutaneous epinephrine). Compared to the EMT-Basic, the new EMT is trained to use more types of oxygen masks, automated transport ventilators, autoinjectors, and oral administration of aspirin.

Advanced EMT. In the current system, the EMT-I is the least well defined of all the levels of EMS providers, as training requirements and skills vary widely from state to state. The Advanced EMT (AEMT) replaces both versions of the EMT-I, although the AEMT is closer to the scope of practice of the 1999 EMT-I than to the 1985 version. Additional time is devoted to acquiring a more in-depth knowledge of pathophysiology, advanced techniques of patient assessment, and advanced skills for airway management, but not endotracheal intubation. The AEMT is trained in intravenous access and can perform fluid resuscitation with crystalloid solutions. Medications an AEMT may administer include epinephrine, glucagon, 50% dextrose, naloxone, and inhaled β-agonists and nitrous oxide.

Paramedic. In addition to the knowledge and skills of the previous levels, the paramedic is trained in the use of a wider range of medications and the performance of a greater number of advanced skills. The scope of practice of the EMT-Paramedic includes endotracheal intubation, needle

decompression of the pleural cavity, cardiac monitoring and interpretation of arrhythmias, and administration of numerous medications. The paramedic has had a major impact on the resuscitation of patients with cardiac or major medical problems and is very effective in urban areas in which response times are short. Compared to the EMT-Paramedic, the new paramedic is trained to administer continuous positive airway pressure, monitor and manage chest tubes, access indwelling venous devices, perform eye irrigation using a Morgan lens, initiate and monitor thrombolytic agents, and perform analysis of limited blood chemistry using portable devices.

EDUCATION AND CERTIFICATION OF EMS PERSONNEL

In addition to the three components of the *EMS Education Agenda for the Future* described earlier, the two additional elements that complete this system of EMS education are national certification and national accreditation of paramedic training programs.

National EMS Certification. In medical practice, certification exams serve to protect the public by ensuring that practitioners have minimal, entry-level competency on entering the workforce. Traditionally, individual states have offered certification exams for their EMS personnel, resulting in issues related to cost for test development, legal challenges, and reciprocity as EMS providers move from one state to another. The National Registry of EMTs (NREMT), a nonprofit organization founded in 1970, has emerged as the only national entity that offers certification exams for all recognized EMS levels. Through its careful test development, NREMT offers psychometrically sound, legally defensible examinations that states may use for licensure of their EMS personnel. Currently, states use the NREMT examination process.[22]

National EMS Education Program Accreditation. The Committee on Accreditation of EMS Programs (CoAEMSP), also a nonprofit corporation, is the only organization that offers accreditation of paramedic training programs on a national basis. CoAEMSP itself is accredited by the Commission on Accreditation of Allied Health Education Programs (CAAHEP). Established in 1994, this group had its origins as the Council on Medical Education of the American Medical Association. CoAEMSP uses a combination of self-assessment and peer assessment to a set of defined standards that ensure a quality educational experience for the student. One recent study demonstrated that graduates of accredited paramedic programs are more likely to successfully achieve certification by the NREMT.[23] The NREMT now requires applicants for the paramedic certification exam to have graduated from an accredited education program.

Nurses

Nurses occupy a unique position in the EMS system. They serve as prehospital providers, instructors, and proctors of quality improvement. Although nursing education imparts an excellent understanding of patient assessment, the pathophysiology of disease processes, and administration of medications, most nursing programs do not teach many of the skills necessary for prehospital care. These include splinting, spinal immobilization, and advanced airway management, so dual training is often required to function in the EMS setting. Nurses may also be employed by EMS services as on-site instructors for continuing education and may be used as field observers for quality improvement. They can provide insight to the EMTs on the smooth integration of patient care from the field to the emergency department.

GROUND NURSES

When dual trained as a nurse and an EMT, the individual can function in the field as a prehospital provider under the auspices of EMT certification. Nurses are used by many critical care transport services to assist in the care of special patients (eg, neonatal and cardiac). In this context, nurses can function to the extent of their training, abilities, and license restrictions. Most states have not developed standards for the prehospital role of nurses. Because of the paucity of trained EMTs, nurses often serve as ambulance attendants in foreign countries.

FLIGHT NURSES

Almost all air medical services in the United States use nurses in the delivery of prehospital care and transport. The composition of the flight crews varies widely, and common configurations are two nurses, a nurse and a paramedic or EMT, or a physician with either a nurse or paramedic, whereas some services fly a nurse with a respiratory therapist. The scope of practice of both the critical care nurses and the paramedics during critical care air or ground transports varies widely from state to state based on nursing law and state EMS regulations, as well as delegation of skills by authority of medical direction. Approximately two-thirds of helicopter medical services in the United States use a combination of a critical care nurse paired with a paramedic. This combination of disciplines provides a wide range of complementary knowledge and skills between the two providers in caring for both out-of-hospital scene flights, which are predominantly for victims of trauma, and the complex patients transported from one hospital to another.

Physicians

In the United States, it is unusual for physicians to directly participate in the provision of care to the injured patient in the field, although about 5% of air medical services use physicians as members of their primary flight crew. The physicians assigned to such crews are usually emergency medicine residents who rotate onto the aircraft as a formal part of their residency. Another use of physicians in the prehospital setting involves neonatologists, pediatric residents, or fellows who staff units used for interfacility transport of critically ill infants.

In Europe, Australia, New Zealand, Japan, and Central and South America, it is common for physicians to function as primary members of the EMS team. Physicians may work for an EMS service, either staffing an ambulance or responding in a separate vehicle. The standards of EMT training in the United States suggest that little is gained by employing physicians on EMS units, and this use of a valuable resource in the field is a challenging one to defend.

Physicians who happen upon the scene of a motor vehicle crash may be tempted to assume control of the patient despite the fact that they possess little experience caring for patients in the prehospital setting. In such situations, the physician should realize that the vast majority of EMTs are well trained, better equipped, and capable of performing their job and that they work under the medical direction of a licensed physician. Additionally, should the physician begin to direct care for a patient, he or she must remain with the patient until care is formally transferred over to an accepting physician, either by radio communication or by face-to-face turnover in the emergency department. Failure to do so may constitute abandonment of the patient and leave the physician exposed to serious legal repercussions.

In unique environments, physicians have been used to improve outcomes in patient transport. Longer-range air transports of critical trauma and medical patients by physicians and nursing staff has been refined by the US Air Force Critical Care Air Transport Teams (CCATT) with positive effect on morbidity and mortality.[24,25] In the setting of complex injuries, prolonged transports, and concurrent resuscitation, the presence of a critical care specialist has been deemed highly valuable.

Bystanders

Just as rapid time to defibrillation for cardiac arrest warranted placing automated defibrillators in public venues and training laypeople in their use, so too has trauma care followed a similar path in the management of hemorrhage. The Stop the Bleed campaign has been a national campaign championed by such organizations as the Department of Homeland Security and the American College of Surgeons in an effort to train laypersons to evaluate for life-threatening bleeding, compress bleeding, and effectively apply tourniquets. The campaign has been an effective opportunity for community engagement for prehospital providers, trauma surgeons, and community members.

EMS SYSTEM DESIGN

Prior to the early 1970s, EMS services in the United States were very rudimentary and focused primarily on transportation of patients. Actual medical care began only after the patient's arrival at the hospital. Today, numerous models of EMS systems exist, as the various elements of the system are combined in different ways. Community leaders design their system around the available resources in the community. An EMS service may be operated by a private company, a hospital, a fire department, a police department, or an agency funded by the government that is solely responsible for emergency medical care (a public "third service"). Regardless of which agency provides EMS, prehospital care generally fits into one of two distinct categories—basic life support (BLS) and ALS.[26]

Basic Life Support

BLS is a term used to describe a level of care that provides noninvasive emergency care and includes care rendered by personnel trained at the EMR and EMT levels. Although EMRs may drive an ambulance, the minimum level for providing patient care during transportation should be the EMT. BLS involves providing basic airway management, supplemental oxygen, and rescue breathing; CPR; control of external hemorrhage; splinting; spinal immobilization; and uncomplicated childbirth. The goal of BLS care is to maintain breathing and circulation and transport the patient without causing further harm. Many BLS services use semi-automatic external defibrillators that identify ventricular fibrillation and deliver electrical countershocks. Because of the limited equipment and training, BLS systems are less costly to establish and maintain than are more advanced levels of care.

Advanced Life Support

ALS describes care that involves the use of more advanced, invasive procedures such as those performed by personnel in an emergency department. EMS providers at the ALS level are capable of advanced airway management, cardiac monitoring, cardioversion and defibrillation, insertion of intravenous lines, and administration of numerous medications. ALS systems use individuals trained at the AEMT or paramedic level.

In contrast to BLS systems, ALS systems provide advanced therapy to the patient at the scene, rather than waiting until arrival at a hospital to institute care. ALS systems have had impressive results in the care of cardiac patients, especially when CPR is started within 4 minutes of a cardiopulmonary arrest and ALS can be initiated within 8 minutes of the arrest. These types of systems, however, are very expensive to establish and maintain, primarily because of the equipment and amount of training required. ALS systems also must invest more in continuing education for their personnel in order to maintain their skills.

Tiered Response Systems

An EMS system that is not purely BLS or ALS but a combination of both is called a *tiered response system*.[24] The goal of a tiered EMS system is to match the training level of the provider with the needs of the patient. The first level of care is typically BLS with the providers being from a public safety agency (eg, fire or police) or EMS units staffed by EMTs. In this model, BLS personnel would initiate transport if the patient did not require ALS procedures. If ALS interventions are needed, the BLS crews initiate basic care and attempt to

stabilize the patient until the ALS unit arrives. This allows ALS units to respond only when needed.

Proponents of this system argue that it functions in a more cost-effective manner, providing ALS-level care only to those patients who require it. In many communities, especially those in rural settings, a third tier composed of air medical transport may be used. This tier usually provides a slightly higher level of training and expertise, combined with the more rapid transport capabilities of the aircraft. The structure of the system will vary widely based on local geography, population density, and resources, but must be set up by local consensus in the region in conjunction with the state(s) involved.

EQUIPMENT FOR EMS UNITS

The American College of Surgeons Committee on Trauma (ACSCOT) joined with the American College of Emergency Physicians (ACEP), the National Association of EMS Physicians (NAEMSP), and other organizations to publish a document delineating the necessary equipment that should be stocked on an EMS unit.[27] This document includes separate recommendations for both BLS and ALS ambulances. More recent revisions require EMS units to include sufficient sizes of equipment to adequately care for infants and children in addition to adults. In most jurisdictions, state law mandates the equipment carried by EMS units, and administrative agencies periodically inspect ambulances to ensure that necessary equipment is present. Medical directors may also require that certain equipment or medications be added to units under their direction.

COMMUNICATIONS

Communications compose an essential component of the EMS system. The EMS dispatch center must be able to readily locate the unit closest to the incident and provide an exact location and description of the call. EMS units must also be able to communicate with other agencies that provide first responder care (ie, law enforcement and fire department) and those that serve an adjunctive role such as extrication and control of hazardous materials. EMS units must also have two-way communication with receiving facilities and with the physicians who provide medical oversight. EMS personnel may request specific orders from a physician when a patient's condition falls outside established treatment protocols. The increased availability of public safety answering points (PSAPs) and EMS dispatch centers to automatic notification of a crash information may enhance their ability to send an appropriate response to a traumatic event.[28,29]

TRANSPORT MODALITIES

Ground Units

EMS units operating on the ground may possess transport capabilities (ie, an ambulance), or they may be a "quick response" unit that contains only equipment and personnel, and a separate ambulance may be required for transport. Such quick response vehicles are common in rural areas or in tiered EMS systems. Ambulances should conform to size and performance specifications as outlined by governmental agencies and authoritative organizations and possess required equipment as described earlier.

In areas primarily covered by BLS units, a tiered response arrangement should be in place so that ALS backup by intercept is available when needed.[26] To qualify as an ALS unit, at least one member of the team must possess training beyond the EMT level. Most commonly, ALS units now are staffed by at least one paramedic, although many ALS services use units staffed by two paramedics. Additional equipment and supplies must be available on the ALS unit to support the defined scope of practice.

Rotor-Wing Aircraft

Helicopter evacuation of military casualties began during World War II, expanded in the Korean War, and matured during the Vietnam War.[30] A mandate made in 2009 by Secretary of Defense Robert Gates reduced the time between combat injury and arrival to definitive care, leading to improved survival.[31] The improvement noted in survival was largely attributed to the speed of evacuation to facilities capable of providing initial trauma care. Civilian air medical services were established in the United States as a result of the success during wartime and have proliferated throughout the industrialized world.

In the United States, helicopter EMS (HEMS) programs are most commonly operated by a private EMS service or are hospital based; however, the Coast Guard, military, law enforcement agencies, or park services may also provide helicopter transport. Crew configurations vary from service to service. The two most common combinations are two flight nurses or a flight nurse and a paramedic. Helicopters are equipped as ALS units and often function as compact intensive care units. HEMS personnel generally have an expanded scope of practice compared to ground EMS providers, including a greater variety of medications and additional skills (eg, management of an intra-aortic balloon pump, extracorporeal membrane oxygenation, complex ventilators, tube thoracostomies, rapid sequence intubation [RSI]), but only a small portion may be applicable to the care of trauma patients. Many advanced HEMS services are now carrying packed red blood cells and plasma to use with patients who have uncontrolled hemorrhage. The usual transport radius for a helicopter is 150 miles, depending on the helicopter model.

Helicopter transport appears to be beneficial for wilderness rescue and for the transport of critically injured patients from a rural facility with limited resources to a major trauma center.[32,33] Analysis in a study from the Centers for Disease Control and Prevention (CDC) of nearly 55,000 HEMS transported patients enrolled in the National Trauma Data Bank (NTDB) showed that the odds of death were 39% lower in patients transported by air versus ground.[34] An even larger study of 256,387 patients based on data from the NTDB

showed that, even though HEMS-transported patients had more severe injuries, they had lower mortality and were more likely to be discharged home.[35] A study from Nova Scotia, where HEMS and ground transport were under the same dispatch center and had the same medical oversight and the same destination medical facilities, showed that blunt trauma patients with an Injury Severity Score of greater than 12 transported by air showed significantly better outcomes than those transported by ground ambulance.[36] Loss of HEMS in one rural area was shown in one study to decrease interfacility transfers and increase transfer times and led to a fourfold increase in mortality of transferred patients.[37] A similar study in a different region of the United States showed no difference in transport times or mortality after loss of HEMS transport capability.[38] The introduction of a second helicopter to the eastern end of Long Island significantly reduced trauma mortality.[39] Unfortunately, many trauma patients transported by HEMS are not critical, and in many trauma centers, it is not unusual for up to one-third of the patients transported by HEMS to be discharged from the emergency department. It is essential that HEMS transports have strong utilization review and medical oversight. HEMS programs need to be fully integrated into the EMS and trauma systems to minimize patient discharge from the emergency department.

The benefits of on-scene HEMS response are also debatable in an urban or suburban setting when a well-trained ground EMS service is present and transport times are brief.[40,41] This is a systems issue because extenuating circumstances such as severe traffic congestion or a mass casualty incident may change HEMS utility in urban areas. A recent study by Diaz et al[42] found that ground transport is always faster than air medical transport when the distance from the scene to the trauma center is 10 miles or less, whereas helicopter transport is always faster when the scene is more than 45 miles from the trauma center. These findings are not surprising considering the time it takes to power up and power down a helicopter. Many EMS systems have the PSAP autolaunch the helicopter based on preset criteria to accelerate dispatch. This is especially true for scenes with potential serious injuries based on information obtained from callers into 911. The helicopter may launch and even land to assess the situation. The helicopter may not necessarily transport the patient, and no charge to the patient is made in that event.

There is a noteworthy element of risk associated with air medical transport, and a study by Bledsoe and Smith[43] documented a steady and marked increase in the number of crashes of medical helicopters over the decade of 1993 to 2002. This trend has continued at an alarming rate since that study was published, resulting in significant loss of life of both patients and the air medical crews. This serious problem is in the process of mitigation since HEMS safety hearings were held by the National Transportation Safety Board (NTSB) in 2009 involving all of the HEMS interested parties. Recommendations were made by the NTSB to the Federal Aviation Administration (FAA) regarding rulemaking pertaining to HEMS safety. The initial draft rules were published in 2014 and finalized in 2015[44] and include such safety items as radar altimeters, helicopter terrain and avoidance warning systems, requiring the pilot in command to maintain current instrument flight rating status, and requiring flight data monitoring systems on HEMS aircraft. All HEMS flights will be flown under the more stringent parameters of FAA Part 135. The various aspects of these rules will be phased in over several years. In addition, over 90% of programs have instituted night vision goggle usage. There has also been a marked increase in simulator training by HEMS programs. The FAA has been mandated to collect data on HEMS flights to determine if these measures increase HEMS safety or if additional measures are needed in rules such as mandating night vision goggles, actual flight data recorders, simulator training for all HEMS pilots, or autopilots for all HEMS aircraft. A recent study from the United Kingdom analyzed all HEMS accidents over the past 26 years and compared their numbers to those of Australia, Germany, and the United States. The authors considered the accident rates per 10,000 missions and the fatal accident rates per 10,000 missions to be comparable.[45] A position paper/policy statement ("Appropriate and Safe Utilization of Helicopter Emergency Medical Services")[46] was jointly developed by several organizations involved with HEMS along with a background paper.[47] Another joint paper by ACSCOT and NAEMSP on HEMS guidelines for appropriateness and safety has also been published.[48]

Fixed-Wing Aircraft

Fixed-wing aircraft are constrained by the need for a runway and, therefore, lack the versatility of rotor-wing units that can land at an accident scene or at a trauma center. With the additional time required to transport a patient to and from a local airport, fixed-wing aircraft only become more time efficient when a patient requires transfer over a distance greater than about 150 miles. Aircraft equipped for air medical transport often serve to transfer patients to regional specialized facilities such as those for burns or spinal cord injuries or to transplant centers. The equipment and supply requirements for fixed-wing aircraft are not as well defined as for ground or rotor-wing units. Fixed-wing aircraft have been used successfully by the US military with such systems as the Critical Care Air Transport Teams during Operation Iraqi Freedom and Operation Enduring Freedom.

PERFORMANCE IMPROVEMENT

Quality medical care is a vital issue in all areas of the health care system. This is attained by developing a performance improvement (PI) process. PI is an ongoing cycle of evaluation, data collection, interpretation, and modification of the system to improve patient care.[49]

An EMS service should have its own internal PI program, with strong oversight by the medical director of the service. Key aspects of this program include evaluation of the care rendered and monitoring the efficiency of the EMS system. A variety of methods are used in order to determine if care is rendered in a timely, efficient, and medically sound fashion.

Equipment must be reliable and durable in order to withstand the sometimes austere and difficult conditions associated with the delivery of prehospital care and not contribute to injury. Trauma centers should also evaluate the care of the patients transported to their facilities and provide appropriate feedback to EMS system administrators, medical directors, and field personnel.

System Efficiency

The evaluation process for any EMS system must determine the efficiency of all components involved in providing care to the patient. One method of evaluating efficiency of the system is to review notification time, response time, on-scene time, and transport time.

NOTIFICATION TIME

This represents the time interval between the injury and notification of the EMS dispatch center. In the United States, most requests for EMS arrive via the 911 phone system. By 2015, 96% of the US population lived in an area covered by enhanced 911 (E911), although that only represents about 50% of the counties in the country.[50] E911 is capable of delivering a wireless caller's number and location to the appropriate PSAP. The PSAP may still have to pass information along to the EMS dispatch center.

RESPONSE TIME

This is defined as the period that starts when an emergency call is received by the EMS dispatch center and ends with the arrival of the ambulance at the patient's side. This time frame encompasses several actions as follows: (1) the call must be physically received; (2) the dispatcher must analyze the call and decide on the appropriate response; (3) the ambulance must be contacted and dispatched; and (4) the ambulance must leave its current location and travel to the scene. The final factor, ambulance travel time, is a function of location and availability of the ambulance, weather, and traffic conditions.

The desired response time for any system directly impacts the number of ambulances that the system requires. To meet the target response times, sufficient EMS units must be available to meet the expected number of emergency calls in the coverage area. Although many urban systems have set a response time standard of 8 minutes that must be met 90% of the time, the ideal response time for trauma is unknown. A retrospective study failed to identify an association between shorter EMS response times and improved outcome in trauma patients.[51]

ON-SCENE TIME (SCENE TIME)

This is the interval from the arrival of EMS at the scene until their departure en route to the receiving facility. This time will vary according to environmental conditions, geography of the scene and location, accessibility of the patient, entrapment, injuries present, and requirements for packaging of the patient. When caring for a critically injured patient, the EMS personnel should strive to limit their on-scene time to 10 minutes or less.[52] Approximately 85% to 90% of trauma patients encountered by EMS are not critically injured and, thus, do not require rapid packaging and immediate transport. Continuous monitoring of on-scene times should be performed to ensure that time is not being lost in the performance of unnecessary procedures on patients with severe injuries.

TRANSPORT TIME

This is the length of time required to transport the patient from the scene to an appropriate facility. The factors that affect this time are distance from the facility, weather, transport modality (air vs ground), and traffic conditions, if transported via ground. The choice of a destination facility is an important decision in the care of the critical patient. The local or regional EMS system in conjunction with the trauma system must have criteria in place for appropriate transport to the appropriate facility.[53] A patient who requires emergent operative intervention to control hemorrhage should be taken to a hospital staffed and equipped to move the patient to the operating room immediately, if such a facility is available. PI reviews should address these issues in an ongoing manner.

Care Rendered

The medical director and leadership of an EMS service must be able to objectively review the care rendered by the personnel they supervise. Evaluation of medical care can be separated into prospective, concurrent, and retrospective phases.

PROSPECTIVE EVALUATION

This form of evaluation attempts to improve the level of care rendered prior to the actual delivery of the care. Evaluating continuing education programs and periodic assessment of skills are examples of prospective evaluation tools.

CONCURRENT EVALUATION

Concurrent evaluation involves direct observation of the EMS personnel during the delivery of care. The medical director or a designated member of the staff of the EMS system (eg, field training officer) accompanies the crew in order to observe the delivery of care in the field. Trauma surgeons may also evaluate the EMS personnel's assessment and care as they deliver patients to their facility. Steps can be taken immediately to correct deficiencies and improve patient care.

RETROSPECTIVE EVALUATION

Retrospective evaluation occurs after care has been delivered. This form of review is the easiest and least costly of the methods and comprises chart audits, case reviews, and debriefings to review the events of any particular EMS call. Trauma surgeons should participate in the retrospective evaluation of

TABLE 10-2: Audit Filters for Prehospital Trauma Care

Lack of adequate airway
Misplaced endotracheal tube
Hypoxia (Spo_2 <90%)
Inability to control external hemorrhage (ie, no tourniquet for extremity)
Spinal immobilization for penetrating torso trauma
Scene time <10 min for critical patient
Appropriateness of needle decompression of pleural cavity
Failure to transport critical patient to closest appropriate facility

EMS services that transport patients to their facility. Such involvement helps EMS providers gain perspective into the entire spectrum of trauma care. A noninclusive list of audit filters that may be used to evaluate prehospital care are shown in Table 10-2. Customized audit filters for specific local/regional PI initiatives should be incorporated as the PI process matures.

MEDICAL CONTROL

One of the most important relationships in EMS is that between the prehospital providers and the physician. Although state EMS offices issue licenses to prehospital care providers, EMS personnel do not function independently, and function under the auspices of their medical director. Thus, EMS personnel perform under delegated practice, which is typically described in the Medical Practice Act in state law.

Numerous terms have been applied to the association between EMS providers and the supervising or responsible physicians, including *medical control*, *medical direction*, and *medical oversight*. Medical direction of an EMS system is provided in a variety of fashions that differ from region to region. In some systems, a single physician provides medical direction, and in other circumstances, medical direction is carried out by a group of physicians acting collectively through a consensus process.

In 1986, Holroyd et al[22] recommended that the EMS medical director be a physician with the following qualifications: (1) knowledge and demonstrated ability in planning and operation of prehospital EMS systems; (2) experience in the prehospital provision of emergency care for acutely ill or injured patients; (3) experience in the training and ongoing evaluation of all levels of participants in the prehospital care system; (4) knowledge and experience in the application of medical control to an EMS system; and (5) knowledge of the administrative and legislative processes affecting regional and/or state prehospital EMS systems.

No specialty of medicine is required for being a medical director. Often, emergency medicine physicians or nontrauma physicians assume the role of medical director. The rise of EMS fellowship training programs has focused medical directorship into a trained subset of physician specialists. In more rural settings, often non-fellowship trained emergency medicine physicians fill the role of medical director. Because nontrauma surgeons may be directing much of the prehospital medical care, it is important for trauma surgeons to work closely with medical directors to ensure trauma care is cutting edge and results in best outcomes.

The medical director must be interested in and committed to the day-to-day activities of the EMS service. The role of medical director for an EMS service is not limited to emergency physicians, and trauma/critical care surgeons are well suited to function in this role once they have gained the prerequisite knowledge of how EMS systems function. The National Association of EMS Physicians has developed a workshop for EMS medical directors. EMS has now been established as a board certifiable subspecialty, with the first subspecialty board exams having been given in 2013. Further information about this process is obtainable from the American Board of Emergency Medicine.

Medical control is divided into two categories: indirect (offline/protocols) and direct (online).[54]

Indirect (Offline/Protocols)

This form of medical direction involves the development of written protocols and the review of EMT performance. The amount of time required to accomplish these administrative duties varies with the size and complexity of the particular EMS system. The medical director's review of care is a PI function and has been discussed previously.

Protocols are the overall steps in patient management that are to be followed by the prehospital provider at every patient contact. Because an accurate diagnosis is often not possible in the field, protocols are usually developed based on the patient's complaints or condition. For ease of memorization and integration with those of other conditions, many protocols are designed in an algorithmic fashion. Trauma surgeons should participate in the development of EMS protocols regarding care for injured patients in their region.

Direct (Online)

Direct or online medical control by the medical director or his or her designee is clinical in nature.[52] This form of direction involves providing radio or telephone instructions to prehospital providers for conditions that are not covered in their protocols and direct observation of individual performance.

Early in the development of EMS systems, a great deal of emphasis was given to direct medical control. Many authorities believed that direct communication between the physician and the prehospital providers would be the mainstay of good prehospital care. Despite this, several studies have demonstrated that there is no difference in survival with and without online medical control and less time is spent in the field when there is no requirement to call the hospital.[52] In cases where medical direction has developed robust guidelines or protocols, online medical control is infrequently used except in unusual circumstances. It is a duty of the medical

director to keep protocol knowledge up to date with the EMS providers.

TRAUMA EDUCATION FOR EMS PERSONNEL

Two continuing education courses have been developed to provide EMS personnel with the essential knowledge and skills to manage critically injured patients. Both courses have been promulgated nationally and internationally.

Prehospital Trauma Life Support

The Prehospital Trauma Life Support (PHTLS) program was developed by the National Association of EMTs in cooperation with ACSCOT.[52] The PHTLS course is based on the tenets of the Advanced Trauma Life Support course developed by ACSCOT, but has been modified to meet the needs of the patient in the prehospital setting.[55] The central philosophy of the PHTLS course is that EMS providers, when given an appropriate fund of knowledge, can make appropriate decisions regarding patient care. Thus, the course emphasizes "principles" of management, rather than focusing on individual preferences or protocols.

A new edition of the course is produced every 4 years, 1 year after the revised ATLS course has been released. This strategy guarantees that PHTLS continues to disseminate any changes in treatment or philosophy that have been introduced in ATLS and ensures a seamless interface between the prehospital providers and personnel in the emergency department in the initial management of the trauma patient. PHTLS is currently taught throughout the United States and in 64 foreign countries.[56]

International Trauma Life Support

About the same time that PHTLS was developed by the National Association of EMTs, the Alabama Chapter of the ACEP developed the Basic Trauma Life Support course.[57] The course was subsequently transitioned to BTLS International, a not-for-profit organization, and in 2005, the name was changed to International Trauma Life Support (ITLS). Like PHTLS, ITLS is also based on the philosophies of ATLS and is taught both in the United States and internationally.

ASSESSMENT AND MANAGEMENT

Assessment and management of the injured patient in the prehospital setting should proceed in an orderly manner, despite the fact that the EMT must frequently make rapid decisions about patient care under adverse conditions. Although the general approach is based on that taught in the ATLS course, one important modification is that the EMT first performs a "scene assessment" prior to evaluating an individual patient. Next, a "primary survey" is conducted to identify life-threatening conditions and initiate immediate therapy.

At the end of the primary survey, the EMT considers whether life-threatening or potentially life-threatening injuries have been identified. If so, the patient is expeditiously packaged and transported to the closest *appropriate* facility. Definitive care for severe, uncontrolled internal hemorrhage cannot be provided in the field, and surgery is usually required. Interventions such as direct pressure on a bleeding wound and infusion of intravenous fluids are not substitutes for rapid transportation to an appropriate facility with immediate surgical capabilities.

Assessment of the Scene

In the prehospital setting, assessment of the patient actually begins before reaching the patient's side. As an EMS crew is dispatched to a scene, they begin to consider numerous factors that may play a role in caring for the patient, as well as ensuring their safety and that of the patient. These factors include such things as mechanism of injury, environmental conditions, and hazards present at the scene. The important aspects of this assessment can be divided into the following two key categories: safety/standard precaution and situation.

SAFETY/STANDARD PRECAUTION

EMS personnel must first evaluate the safety of the scene; that is, they must not enter into a situation that puts their health and well-being at risk as this puts them in jeopardy of becoming patients as well. EMS workers are dependent on law enforcement personnel to ensure that the scene has been cleared of violent assailants and their weapons.[58] In addition to their personal safety, the EMS providers need to consider concerns that threaten the safety of the patient. The scene of a traumatic incident may include dangers such as traffic, downed power lines, hazardous materials, and harsh environmental conditions. In light of incidents of terrorism, there is heightened concern of chemical, biological, or nuclear contamination of a scene, or secondary devices planted with the intent of killing rescuers. Providers should assess for need for at-scene decontamination prior to transport.

Standard Precautions. One hazard ubiquitous to virtually all trauma scenes is blood. Blood and other body fluids may contain communicable diseases including hepatitis and human immunodeficiency viruses. In any patient encounter, health care workers are encouraged to employ measures to decrease the risk of contracting these pathogens. Standard precautions involve the use of impermeable gloves, gowns, masks, and goggles. In addition to wearing this protective gear, EMS providers must also exercise caution when handling sharp devices, such as needles that are contaminated with a patient's blood or body fluid.

SITUATION

The second component of the scene assessment is evaluation of the situation. The EMS providers should consider the

following issues: the number of patients and their ages; the need for specialized personnel or equipment (power company, heavy rescue); the need for additional EMS units, including summoning an air medical helicopter; the need for a physician at the scene to assist with triage; and the possibility that the traumatic event was triggered by a medical emergency (acute myocardial infarction or a cerebrovascular accident). Because the EMS personnel are essentially the "eyes and ears" of the emergency physician and trauma surgeon at the scene, they are in a position to observe key data about the mechanism of injury.

Kinematics. An understanding of the mechanism of injury assists in evaluating the patient for potential injuries (see Chapter 1). Certain mechanisms frequently result in specific injury patterns. Recognition of the mechanism may guide providers in the assessment of the patient. If the incident involves a motor vehicle crash, the EMS crew should evaluate the type of collision (eg, frontal, rear, or lateral impact) and note the degree of damage to the vehicles. The location of the patient at the time of the crash and the use of restraints or protective gear is also valuable information.

Mass Shooting and Terrorist Events. With the advent of frequent mass shootings as well as bombings in the civilian environment, special consideration should be considered for mass shootings. Recent years have brought about consideration for extra emphasis on the safety of the environment in which prehospital providers may find themselves, which had previously been a consideration expected more frequently in military conflicts. Training should be undertaken with police units. Communication is paramount in the dynamic setting of a mass shooting or terrorist attack, because the number of casualties and environment entered can change dramatically over time. Mass shootings may require close communication with law enforcement personnel who may be searching for active shooters or secondary explosive devices. In the case of blasts in workplace environments or bombing devices, prehospital personnel must consider their safety and the potential for further patients. Prehospital providers must be prepared to distribute large volumes of patients to different hospitals so as not to overwhelm a single hospital. Communication is paramount to ensure balance between patient stability and the ability of the closest hospital to continue to manage acute patients.

Primary Survey

After assessing the scene, EMS personnel perform a primary survey of the patient (see Chapter 13). As taught in ATLS, this survey serves to identify life-threatening or potentially life-threatening conditions. Although it is taught in a stepwise A–B–C–D–E approach, one must remember that many aspects of this evaluation can be done simultaneously. In the event of external massive hemorrhage, bleeding should be addressed first. In the event of significant danger to prehospital personnel, such as the presence of an active shooter, a consensus group has recommended a THREAT approach. This procedure consists of steps as follows: (1) threat suppression, (2) hemorrhage control, (3) rapid extrication to safety, (4) assessment by medical providers, and (5) transport to definitive care.[58] EMS personnel employ a "treat as you go" philosophy, wherein care is initiated for life-threatening conditions as they are identified. Thus, the primary survey establishes a framework for setting priorities for management.

AIRWAY MANAGEMENT

Management of the airway is given highest priority, but care must be taken not to aggravate a potential injury to the cervical spine (see Chapter 14). One EMS provider applies manual in-line stabilization to the head and neck while a coworker begins assessment and management of the airway. This stabilization of the cervical spine is continued either until the patient is completely immobilized on a long backboard or until it is determined that the patient does not require spinal immobilization.

All EMS providers, regardless of their level of training, must master the essential skills of airway management.[46] These skills include the following: manually clearing the patient's airway of foreign material; manually opening the airway using the trauma jaw thrust or trauma chin lift; suctioning the oropharynx; and inserting basic oral or nasal airways. An algorithm for prehospital management of the airway is provided in Fig. 10-1.[52]

Endotracheal Intubation. Although this has long been the gold standard for securing an airway in the hospital, its role in prehospital care has become increasingly controversial. This skill is typically limited to advanced providers, although all levels of EMTs have now been taught to safely insert endotracheal tubes. The use of this technique is almost universally accepted at the EMT-Paramedic level throughout the United States. A limited number of communities have allowed EMT-Basics to be trained in endotracheal intubation, as well. In most EMS systems, the success rate for endotracheal intubation exceeds 90%. With good medical direction and field preceptors, training in endotracheal intubation can be successfully accomplished.[59]

Because of the concern of potential fractures of the cervical spine, endotracheal intubation should be performed concurrently with in-line stabilization of the cervical spine.[60,61] Although intubation is most commonly accomplished via the orotracheal route using a laryngoscope, other techniques include digital intubation and retrograde intubation, although these are rarely used in the field.[62-64] Video laryngoscopy is becoming increasingly used in the field by ALS and HEMS personnel. It is not clear yet if this will improve the success rate with less time expended with the procedure. Success of RSI is certainly tied to concentrated experience. A study in San Diego showed that intubation of patients with traumatic brain injuries (TBI) by ground ALS crews led to increased mortality, whereas intubation by air medical crewmembers led to better survival.[65]

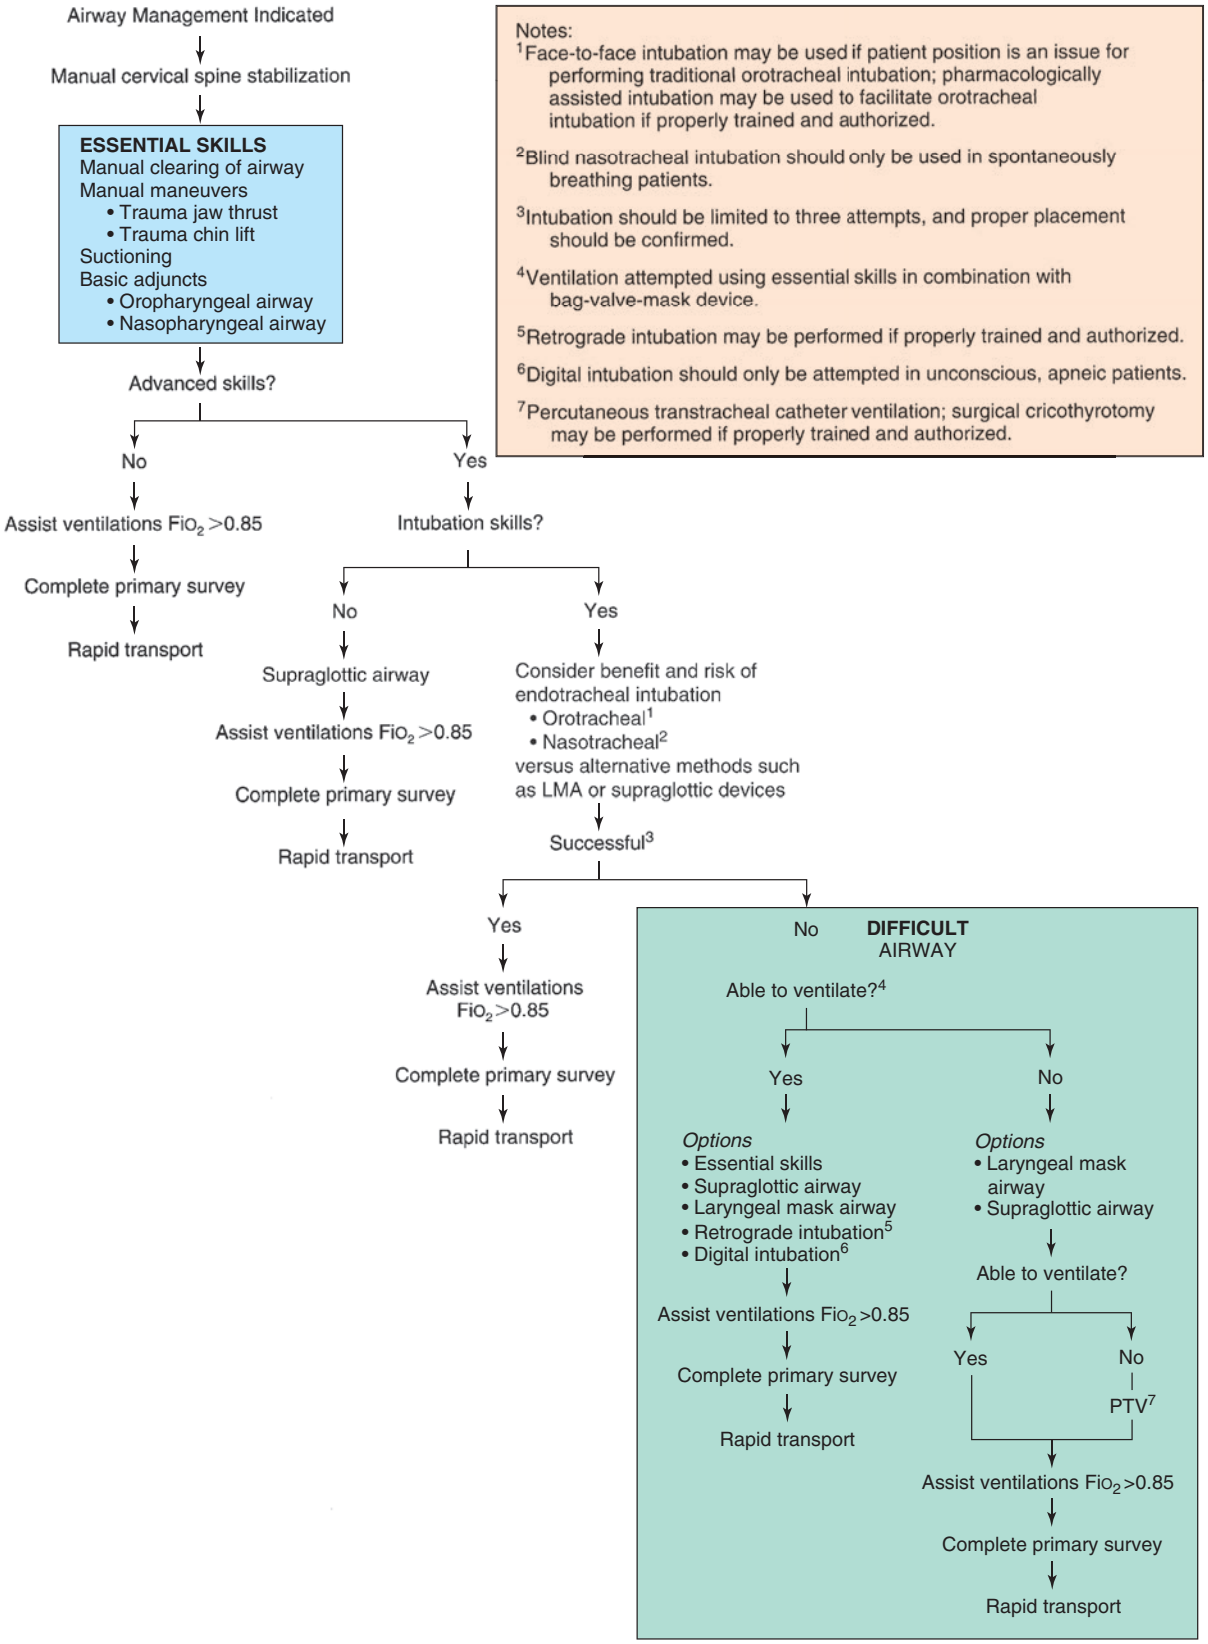

FIGURE 10-1 Airway management. LMA, laryngeal mask airway. (Reproduced with permission from Salomone JP, Pons PT, McSwain NE, eds. *PHTLS: Prehospital Trauma Life Support.* 7th ed. St. Louis, MO: Mosby; 2011:140. Copyright © Elsevier.)

Indications for endotracheal intubation in the field include the following:

- Inability of patient to maintain an airway due to altered level of consciousness (Glasgow Coma Scale [GCS] score <8)
- Need for assisted ventilations
- Threatened airway (eg, respiratory burns, expanding hematoma of the neck)

Concern has arisen that endotracheal tubes placed in the prehospital setting may be misplaced or may become dislodged more commonly than previously believed.[66] Once endotracheal intubation has been performed, care should be taken to confirm proper placement using a combination of clinical assessments and adjunctive devices. The clinical assessments include presence of bilateral breath sounds and the absence of ventilatory sounds over the epigastrium, chest rise with ventilation, and the provider watching the tube pass through the vocal cords. Adjuncts that help confirm a successful intubation include colorimetric carbon dioxide detectors, capnography, and the esophageal detector device.[67] Following intubation, the tube is carefully secured and its position checked each time the patient is moved. Continuous capnography in the prehospital setting may significantly reduce the incidence of misplaced or dislodged endotracheal tubes.[68]

A number of EMS services, especially air medical programs, permit their providers to perform RSI. This involves the administration of both a sedating agent and a neuromuscular blocking agent prior to endotracheal intubation. In skilled hands, this technique can facilitate effective airway control in patients when other methods fail or are otherwise unacceptable (eg, the patient with trismus). The role of RSI in the prehospital setting is controversial, primarily because of concerns related to the risks of losing a partially patent airway by administration of a paralytic agent and data suggesting that patient outcomes may be compromised when RSI is performed by EMS personnel.

With adequate medical control, several studies have documented that EMS personnel can safely perform this procedure.[69-71] Data from one case-control study, however, demonstrated an interesting paradox. Although paramedics using RSI had a higher success rate at performing endotracheal intubation, patients with a suspected severe TBI who were intubated with RSI had a higher mortality than did those in the control group.[72] Davis et al[73] published the findings of an expert panel on the role of prehospital RSI.

Wang and Yealy[74] reviewed the data on prehospital intubation and concluded that there is little literature to support maintaining endotracheal intubation as the standard airway of choice. More studies have documented worsened outcomes than improved outcomes. If intubation is used, the EMS systems must carefully review each intubation attempt and ensure that it is being performed safely. Most children can maintain adequate oxygenation/ventilation with BVM assistance and do not necessarily require endotracheal intubation.[75]

Supraglottic Airways. These are devices that are inserted without a laryngoscope (ie, blindly) into the hypopharynx. Although various models differ in design, properly positioned devices have openings that allow for passage of air from the device into the adjacent glottic opening to ventilate the lungs. Some devices have two ports and ventilations are then administered through the port that results in chest excursion and breath sounds (Combitube, Nellcor, Typo Healthcare, Pleasanton, CA). A similar alternative has a single ventilation port, making it even easier to use (King LT airway, King Systems, Noblesville, IN).

Another supraglottic device is the laryngeal mask airway (LMA) (LMA North America, San Diego, CA), consisting of an inflatable silicone ring attached to a silicone tube. This device is blindly inserted into the hypopharynx so that the ring seals around the glottic opening. Ventilation is then provided through the tube. This device has replaced endotracheal intubation for general anesthesia in a significant percentage of shorter operations, especially in Great Britain. LMAs have been popular in the prehospital setting in Europe and with some air medical services in the United States.[76]

The primary advantage of supraglottic airways is that minimal training is necessary to achieve competency because of their design and the blind insertion. A potential disadvantage of these devices is that the risk of aspiration is believed to be greater than with endotracheal intubation. Supraglottic devices are valuable backup ("rescue") airways when endotracheal intubation cannot be accomplished. Because of the controversies with endotracheal intubation, these airways are increasingly used as the initial airway of choice, although they can be problematic because of potential risks.[77] This is especially true in the urban setting where transport times are generally brief. It may be best to fall back on BVM if ventilation appears difficult. Use of either endotracheal intubation or a supraglottic airway is a low-volume, high-risk procedure and requires rigorous medical oversight.

Needle Jet Insufflation. This involves the insertion of a large-bore needle through the cricothyroid membrane and connecting it to high-pressure oxygen. The lungs are then insufflated periodically. This technique possesses the following advantages: it does not require paralysis, is less invasive than surgical cricothyroidotomy, affords easy access and insertion, and requires minimal education and very basic equipment. The technique has been demonstrated experimentally to be safe and effective even in the presence of complete obstruction of the airway. Although oxygenation is adequate, studies have shown that the patient may become hypercarbic.[78] Percutaneous transtracheal ventilation is indicated when an injured patient is unable to be intubated and cannot be ventilated using a BVM device or an alternative airway.

Surgical Cricothyroidotomy. This involves incising the skin and the cricothyroid membrane, followed by the insertion of a small endotracheal or tracheostomy tube. Because it is highly invasive, complications have included significant hemorrhage and injury to adjacent nerves, blood vessels, and

the larynx. Air medical crews have used surgical cricothyroidotomy in the prehospital setting for several decades with good success. Use of this procedure by out-of-hospital personnel requires strong medical oversight and intense training. It should be reserved for a situation of "can't intubate–can't ventilate."[77]

VENTILATORY SUPPORT

The patient's ventilatory status (breathing) is next examined. If the patient's ventilatory rate is 10 or lower, ventilations should be assisted with a BVM device connected to 100% oxygen. Rapid, shallow breaths indicate inadequate minute ventilation and require assistance with a BVM. Auscultation of breath sounds should be performed during the primary survey if the patient has an abnormal ventilatory rate or evidence of respiratory distress. Patients who have suffered an injury may benefit from supplemental oxygen. Pulse oximetry should be monitored and oxygen administered to maintain an Spo_2 of at least 90% if not more.

Prehospital care providers must exercise caution while providing ventilatory support, as deleterious effects may ensue. Hyperventilation by EMS personnel in one study was associated with increased mortality in patients with a suspected TBI.[79] Additionally, data from animal models suggest that hyperventilation resulted in auto-positive end-expiratory pressure that further compromised the hemodynamic status of a hypovolemic swine.[78] For an adult patient, a reasonable tidal volume of 350 to 500 mL delivered at a rate of 10 breaths/min is probably sufficient to maintain a satisfactory oxygen saturation while minimizing the risk of hyperventilation. Continuous pulse oximetry and capnography can help guide the ventilatory support. Continuous positive airway pressure ventilation and bilevel positive-pressure ventilation are increasingly frequently used in the prehospital environment with proposed benefit in thoracic trauma.[80]

CIRCULATION

Assessment of a patient's circulatory status involves examining for external hemorrhage and evaluating the adequacy of perfusion. Most life-threatening external hemorrhage can be controlled with direct pressure. If manpower is limited, a pressure dressing with gauze pads and an elastic bandage can be placed around an extremity. Should direct pressure alone not control bleeding in an extremity, a tourniquet should be applied just proximal to the site of hemorrhage and tightened until bleeding ceases. A second tourniquet may be required to obliterate the distal pulse and control bleeding. Improvised, noncommercial tourniquets have not been shown to be effective. No published data document any significant decrease in hemorrhage when a bleeding extremity is elevated, and such manipulation may result in the conversion of a closed fracture to an open one. The efficacy of applying pressure over "pressure points" in the axilla and groin has also not been studied in the prehospital setting and is labor intensive. In the operating room, arterial tourniquets have been used safely for periods of 114 to 150 minutes. Options for a tourniquet include a blood pressure cuff and the use of a readily available manufactured tourniquet.[81] If a manufactured tourniquet is used, it should be one that has been tested and recommended by the Committee on Tactical Combat Casualty Care (CoTCCC).[82]

1. Attempt to control hemorrhage with direct pressure or pressure dressing must fail.
2. A commercially manufactured tourniquet, blood pressure cuff, or "Spanish windlass" is applied to the extremity just proximal to the bleeding wound.
3. The tourniquet is tightened until hemorrhage ceases, and then it is secured in place.
4. The time of tourniquet application is written on a piece of tape and secured to the tourniquet ("TK 21:45" indicates that the tourniquet was applied at 9:45 pm).
5. The tourniquet should be left uncovered so that the site can be seen and monitored for recurrent hemorrhage. If bleeding continues after application and tightening of the initial tourniquet, a second tourniquet can be applied just above the first.
6. Pain management should be considered unless the patient is in Class III or IV shock.
7. The patient should ideally be transported to a facility that has surgical capability.

FIGURE 10-2 Protocol for tourniquet application. (Reproduced with permission from Salomone JP, Pons PT, McSwain NE, eds. *PHTLS: Prehospital Trauma Life Support*. 7th ed. St. Louis, MO: Mosby; 2011: 201. Copyright © Elsevier.)

A sample protocol for application of a tourniquet is described as follows and is shown in Fig. 10-2.

Multiple studies have looked at the outcomes of casualties who had tourniquets applied for their extremity wounds.[83-86] The data demonstrated that prehospital use of tourniquets was lifesaving and that complications were low. Less than 2% of the patients suffered transient nerve palsy at the level where the tourniquet was applied, and no limbs were sacrificed because of use of a tourniquet. In patients who had a tourniquet on for 2 hours or less, 28% required fasciotomy, whereas a slightly higher percentage (36%) required fasciotomy if the tourniquet was in place more than 2 hours.

Perfusion is assessed primarily by evaluating pulse rate and quality, skin color, temperature, and moisture. Time should not be taken in the primary survey to measure blood pressure. Even mild tachycardia (heart rate >100 bpm) should always make one consider that the injured patient is hypovolemic. Significant tachycardia (>114 bpm), weak peripheral pulses, and anxiety are associated with loss of 30% to 40% of the blood volume of an adult.[55] A new patient monitoring modality using noninvasive tissue oxygen saturation (Sto_2) shows promise as a way to determine early hemorrhagic shock.[87,88] It must be noted that even one drop in systolic blood pressure (SBP) while monitoring the patient may be enough to indicate early hemorrhagic shock.[89]

A topical hemostatic agent should be considered for significant external hemorrhage from body areas not amenable to placement of a tourniquet (neck, torso, axilla, and groin). The CoTCCC currently recommends Combat Gauze that is

impregnated with kaolin clay as the topical hemostatic agent of choice.[90] Civilian and military experience have found this agent to be safe and effective.[91,92] Other devices that have been proposed to assist with hemorrhage control include the iTClamp (Innovative Trauma Care, San Antonio, TX) and junctional tourniquets. The iTClamp has been suggested to be a fast and reliable device to stop external bleeding by closing the skin to create a temporary, contained hematoma until surgical repair.[93] Junctional tourniquets have been proposed as a means to compress arteries at the junction of the trunk and extremities. Current clinical evidence is not robust in support of the use of such junctional tourniquets; however. there is evidence to support the use based on laboratory work.[94]

Military to Civilian Translation of Trauma Care. As is the case with conflicts throughout history, advances in medical and trauma care are often made during war. An example is the resurgence of tourniquet use that was brought about through demonstrated benefit in outcomes during the wartime data of Operation Iraqi Freedom and Operation Enduring Freedom.[95] Survivability was noted to improve with the use of tourniquets on the battlefield, and despite liberal use of tourniquets, morbidity from the use of the tourniquets was very low.[85] Tourniquet use became more prominent in the civilian environment as a result of data and trauma practitioners returning from deployments.[96] Studies in civilian environments have demonstrated benefit,[97] whereas others have proposed that larger scale civilian studies ought to be conducted for a better understanding of safety and effectiveness of tourniquet use in civilian trauma settings.[98] Civilian and even bystander use of tourniquets has been championed.[99,100] The use of tourniquets has reached national attention with the launch of the Stop the Bleed campaign, a national campaign championing hemorrhage control including the use of tourniquets.[101]

Early hemostatic products, often used by the military, included powders or granules such as QuickClot and newer impregnated gauzes. Different products were found to be more appropriate for different types of wounds in the combat environment. Although much of the data regarding hemostatic agents come from animal models, human studies in the combat setting have demonstrated improvements with hemorrhage control.[102,103] Multiple police and EMS groups have since noted the benefits of hemostatic gauze and have instituted its use as a result of lessons learned in the combat environment.[104]

Traumatic Cardiopulmonary Arrest. Trauma patients who are found to be in cardiopulmonary arrest require special consideration. Unlike cardiopulmonary arrest associated with an acute myocardial infarction, most patients who suffer cessation of their vital signs prior to the arrival of EMS have exsanguinated. CPR, defibrillation, antidysrhythmic medications, and crystalloid resuscitation will not reverse this. Attempts at resuscitation are typically futile and place the EMS personnel at unnecessary risk from automobile crashes during emergency transport and exposure to blood. NAEMSP and ACSCOT have collaborated on a position paper that endorses the following guidelines[105]:

- For victims of blunt trauma, resuscitation efforts may be withheld if the patient is pulseless and apneic on the arrival of EMS.
- For victims of penetrating trauma, resuscitation efforts may be withheld if there are no signs of life (papillary reflexes, spontaneous movement, or organized cardiac rhythm on the electrocardiogram >40 bpm).
- Resuscitation efforts are not indicated when the patient has sustained an obviously fatal injury (eg, decapitation) or when evidence exists of dependent lividity, rigor mortis, or decomposition.
- Termination of resuscitation should be considered in trauma patients with an EMS-witnessed cardiopulmonary arrest and 15 minutes of unsuccessful resuscitation including CPR.
- Termination of resuscitation should be considered for a patient with traumatic cardiopulmonary arrest who would require transport of greater than 15 minutes to reach an emergency department or trauma center.
- Victims of drowning, lightning strike, or hypothermia or those in whom the mechanism of injury does not correlate with the clinical situation (suggesting a nontraumatic cause) deserve special consideration before a decision is made to withhold or terminate resuscitation.

Resuscitative Endovascular Balloon Occlusion of the Aorta (REBOA). REBOA has risen as a stabilization technique for noncompressible torso hemorrhage. Proposals from the austere combat surgery environment have proposed the use of REOBA as a lifesaving technique for patients with hemodynamic instability and noncompressible torso hemorrhage.[106] Feasibility studies have demonstrated the potential use of REBOA in both the field and en-route prehospital care.[107] Although the positive effects of REBOA have been noted, the results of current studies deserve further prospective investigation. A joint statement by the American College of Surgeons and ACEP states that an acute care surgeon must be immediately available if REBOA is to be used and also states that no current, high-grade evidence demonstrates REBOA improves outcomes of survival compared to standard treatment of severe hemorrhage.[108]

DISABILITY

During the primary survey, the EMS provider assesses neurologic function by evaluating the patient's GCS score and pupillary response. The GCS score comprises three components including eyes, verbal, and motor.[109] If a painful stimulus is required to complete the assessment, the EMT can either apply pressure to the nail bed or squeeze the axillary tissue. If the patient has an altered level of consciousness (GCS <15), pupillary response to light is assessed. Any belligerent, combative, or uncooperative patient should be considered to be

hypoxic or have a TBI until proven otherwise. In a trauma patient, a GCS score of less than or equal to 13, seizure activity, and a motor or sensory deficit are all reasons for concern. An important corollary to this assessment is to try to ascertain if the patient is anticoagulated, if possible. In some systems, AVPU, a simplification of the GCS, allows for rapid categorization using the categories of Alert, Verbal, Pain, and Unresponsive. An AVPU of anything less than A is considered an indication to get further help.

EXPOSURE AND ENVIRONMENTAL CONTROL

The final part of the primary survey involves a quick scan of the patient's body to note any other potentially life-threatening injuries. In general, this requires removal of the patient's clothes, but environmental conditions and the presence of bystanders may make this impractical. Hypothermia from failure to preserve body heat can contribute to a serious coagulopathy in the trauma patient.

Heavy, dark-colored, woolen clothing may absorb significant amounts of blood. On occasion, patients may have more than one mechanism of injury; that is, blunt trauma from a motor vehicle crash that occurred while trying to flee the assailant who had shot them. Injuries cannot be treated unless they are identified. Other easily missed features include those involving lightning strikes, snake envenomations, and blunt trauma associated with drowning.

Resuscitation

On completion of the primary survey, the EMS provider determines whether or not the patient is critical (Fig. 10-3). Because the primary survey involves a "treat as you go" philosophy, airway management, ventilatory support, and control of external hemorrhage are initiated as the problems are identified. Massive external hemorrhage takes precedence over other assessments.

When a critically injured patient is identified (Table 10-3), scene time should ideally be less than 10 minutes, unless extenuating circumstances such as entrapment or an unsafe scene preclude this. A large multicenter prospective study demonstrated no association between EMS intervals and mortality of injured patients with physiologic abnormalities in the field.[110] On-scene times is one of the most important factors to be scrutinized by medical direction in the quality control process.

If indicated, spinal immobilization should be performed expeditiously and the patient moved to the ambulance. Time is not taken to splint each individual fracture. For the critically injured patient, immobilization to the long backboard provides satisfactory immobilization of potential musculoskeletal injuries. A recent position statement from NAEMSP and ACSCOT discusses the appropriate use of spinal immobilization.[111,112]

Because definitive care cannot be provided to the critically injured patient in the field, EMS personnel must realize that initiation of transport to the closest appropriate facility demonstrates good judgment. Originally developed by ACSCOT, the Field Triage Decision Scheme was recently revised by a national expert panel convened by the CDC (Fig. 10-4).[113] The revision has been endorsed by more than 35 national EMS or trauma organizations. According to this algorithm, patients who meet specific anatomic or physiologic criteria should be transported to the highest level of care in the system, typically a Level I or II trauma center. Patients who meet mechanism of injury criteria should be transported to the closest trauma center, which need not be a Level I or II center. Protocols should be written so that EMS personnel may bypass a closer hospital in order to take a patient with life-threatening injuries to a trauma center based on state or regional guidelines.

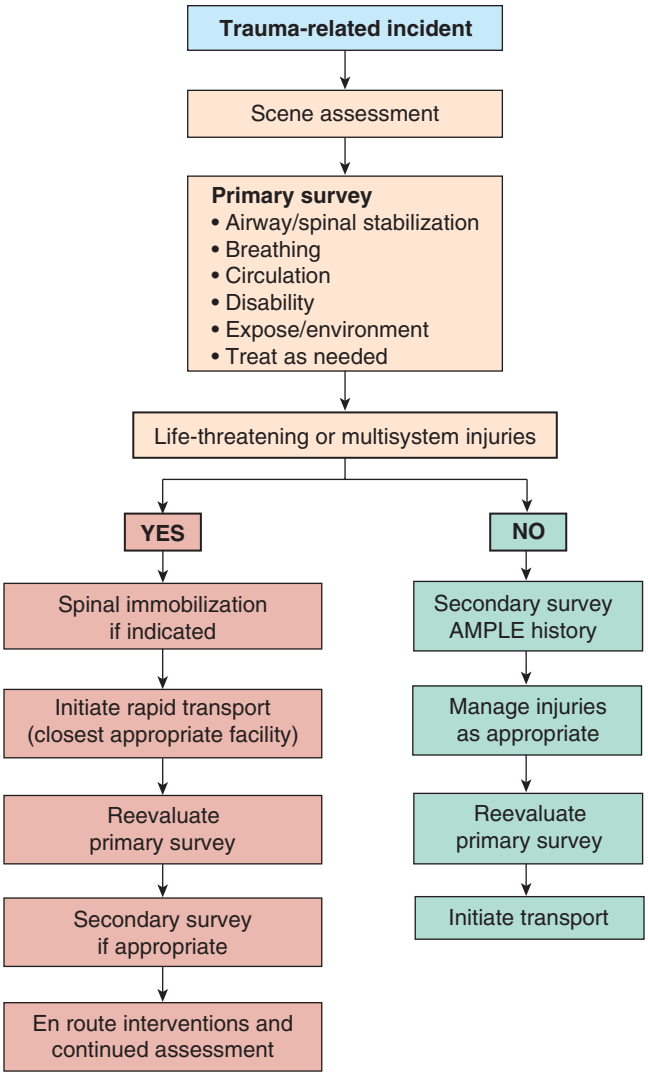

FIGURE 10-3 Prehospital care overview. AMPLE, allergies, medications, past pertinent medical history, last oral intake, events leading up to present injury. TABLE 10-3: Critical Trauma Patient

- Limit scene time to 10 min or less when any of the following life-threatening conditions are present:
  - Inadequate or threatened airway
  - Impaired ventilation as demonstrated by the following:
    - Abnormally fast or slow ventilatory rate
    - Hypoxia (SpO_2 <95% even with supplemental oxygen)
    - Dyspnea
    - Open pneumothorax or flail chest
    - Suspected pneumothorax
  - Significant external hemorrhage or suspected internal hemorrhage
  - Shock, even if compensated
  - Abnormal neurologic status
    - GCS score ≤13
    - Seizure activity
    - Sensory or motor deficit
  - Penetrating trauma to the head, neck, or torso, or proximal to the elbow and knee in the extremities
  - Amputation or near amputation proximal to the fingers or toes
  - Any trauma in the presence of the following:
    - History of serious medical conditions (eg, coronary artery disease, chronic obstructive pulmonary disease, bleeding disorder)
    - Age >55
    - Hypothermia
    - Burns
    - Pregnancy

GCS, Glasgow Coma Scale.

FLUID THERAPY AND BLOOD TRANSFUSION

Infusions of crystalloid solutions and blood transfusion are the mainstays of therapy for the in-hospital treatment of severe hypovolemic shock (see Chapter 15). Because it requires refrigeration and typing, blood is not typically available in the prehospital environment; however, packed red blood cells and plasma are becoming increasingly used by critical care air and ground services. Isotonic crystalloid solutions, such as lactated Ringer's or normal saline (0.9% sodium chloride), can be used for volume resuscitation. Although hypertonic saline (7.5% sodium chloride) initially showed promise, a meta-analysis of several studies, as well as a more recent randomized controlled trial, failed to demonstrate an improvement in survival rates compared to patients treated with isotonic solutions.[114]

En route to the receiving facility, the EMS providers should insert two large-bore (14- or 16-gauge) intravenous catheters in veins of the forearm or antecubital area or use intraosseous access. If possible, lactated Ringer's solution (or normal saline) should be warmed (102°F/38.8°C) prior to administration. Fluid resuscitation in the prehospital setting must be based on the clinical scenario.[55] If the patient has suspected uncontrolled hemorrhage in the thorax, abdomen, or retroperitoneum, fluid infusions should be titrated to maintain an SBP in the range of 80 to 90 mm Hg (mean arterial pressure of 58–65 mm Hg) in the hope of perfusing vital organs while limiting the risk of increased, uncontrollable internal hemorrhage. If the patient has a suspected injury to the central nervous system injury (TBI or injury to spinal cord), intravenous fluids should be administered at a rate sufficient to maintain the SBP at 90 mm Hg (Fig. 10-5). If the patient has identifiable shock that resulted from external hemorrhage that has been controlled, fluids are titrated to maintain a normal pulse rate and blood pressure. If the patient again becomes hypotensive, further intravenous fluids should be titrated to maintain SBP in the range of 80 to 90 mm Hg.

Controversy exists regarding the role of therapy with intravenous fluids in the prehospital setting. No published study has ever demonstrated an improvement in survival resulting from the prehospital administration of fluids. An analysis of almost 777,000 patients from the NTDB showed that administration of intravenous crystalloids by EMS personnel increased mortality.[115]

Although further studies will be needed to clarify this issue, EMS providers should never delay transport simply to initiate intravenous therapy. In one sense, the most important fluid in the prehospital care of critically injured patients is *fuel*—to transport patients rapidly to the closest appropriate facility.

Blood transfusion in the prehospital environment is a source of debate as to benefit compared to the logistical obstacles of storing and administering blood products. Given the logistical challenges involved in prehospital blood product transport and administration, some have argued that standard use is not an effective use of resources.[116] Others have demonstrated effective application of prehospital, low-titer, cold-stored whole blood.[117] In a retrospective massive transfusion protocol analysis, the risk of isoimmunization was very low and the benefit of increased resources for the early administration of balanced resuscitation high, and it was found that the utilization of low-titer, cold-stored, O RhD-positive whole blood is safe and beneficial.

In cases where obstacles exist to blood transfusion, some have proposed the use of prothrombin complex concentrate (PCC).[118] The concept of remote damage control resuscitation begins with a prehospital evaluation for potential use for PCC or tranexamic acid (TXA). Of note, some have suggested using prehospital coagulation or thromboelastogram monitoring of resuscitation with point-of-care devices to guide prehospital or guide preparation for in-hospital resuscitation with more data upon arrival.[119]

TRANEXAMIC ACID

TXA has been proposed as an inexpensive and useful adjunct to patients with hemorrhagic shock.[120] Early prehospital administration of TXA has been suggested to improve clot stabilization and reduce fibrinolytic activity.[121] TXA has been recognized as offering potential benefits in civilian trauma

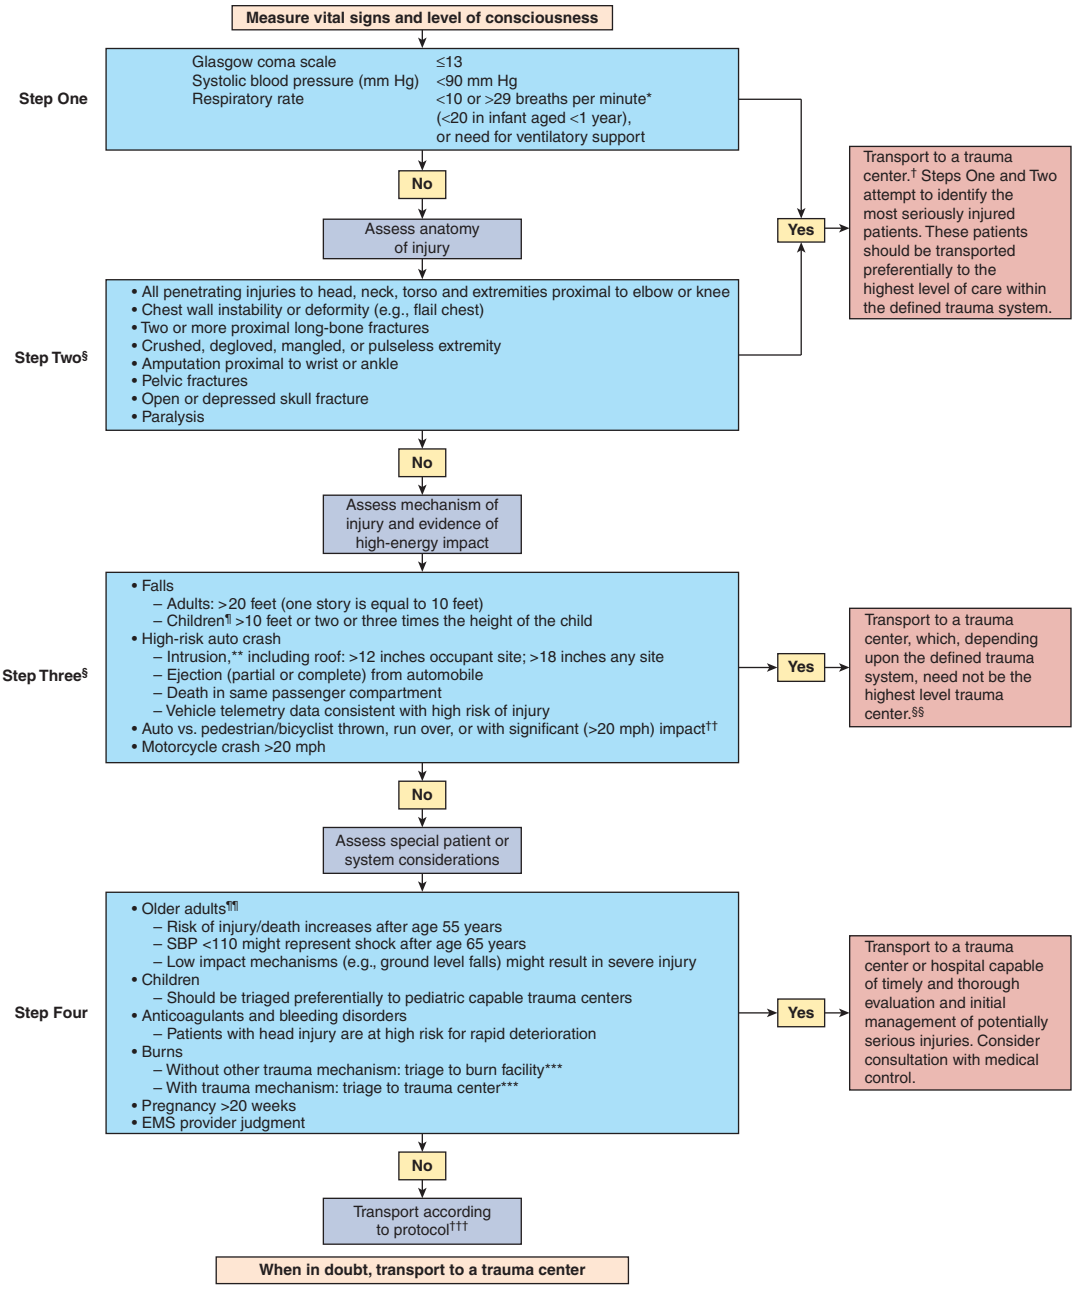

FIGURE 10-4 Field Triage Decision Scheme. EMS, emergency medical services. (Reproduced from Sasser SM, Hunt RC, Sullivent EE, et al. Guidelines for field triage of injured patients: recommendations of the national expert panel on field triage. *MMWR Recomm Rep*. 2009;58[RR-1]:1-35. *The upper limit of respiratory rate in infants is 0.29 breaths per minute to maintain a higher level of overtriage for infants.

†Trauma centers are designated Level I to IV. A Level I center has the greatest amount of resources and personnel for care of the injured patient and provides regional leadership in education, research, and prevention programs. A Level II facility offers similar resources to a Level I facility, possibly differing only in continuous availability of certain subspecialties or sufficient prevention, education, and research activities for Level I designation; Level II facilities are not required to be resident or fellow education centers. A Level III center is capable of assessment, resuscitation, and emergency surgery, with severely injured patients being transferred to a Level I or II facility. A Level IV trauma center is capable of providing 24-hour physician coverage, resuscitation, and stabilization to injured patients before transfer to a facility that provides a higher level of trauma care.

§Any injury noted in step two or mechanism identified in step three triggers a "yes" response.

¶Age <15 years.

**Intrusion refers to interior compartment intrusion, as opposed to deformation, which refers to exterior damage.

††Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact of 0.20 mph with a motor vehicle.

§§Local or regional protocols should be used to determine the most appropriate level of trauma center within the defined trauma system; need not be the highest level trauma center.

¶¶Age >55 years.

***Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.

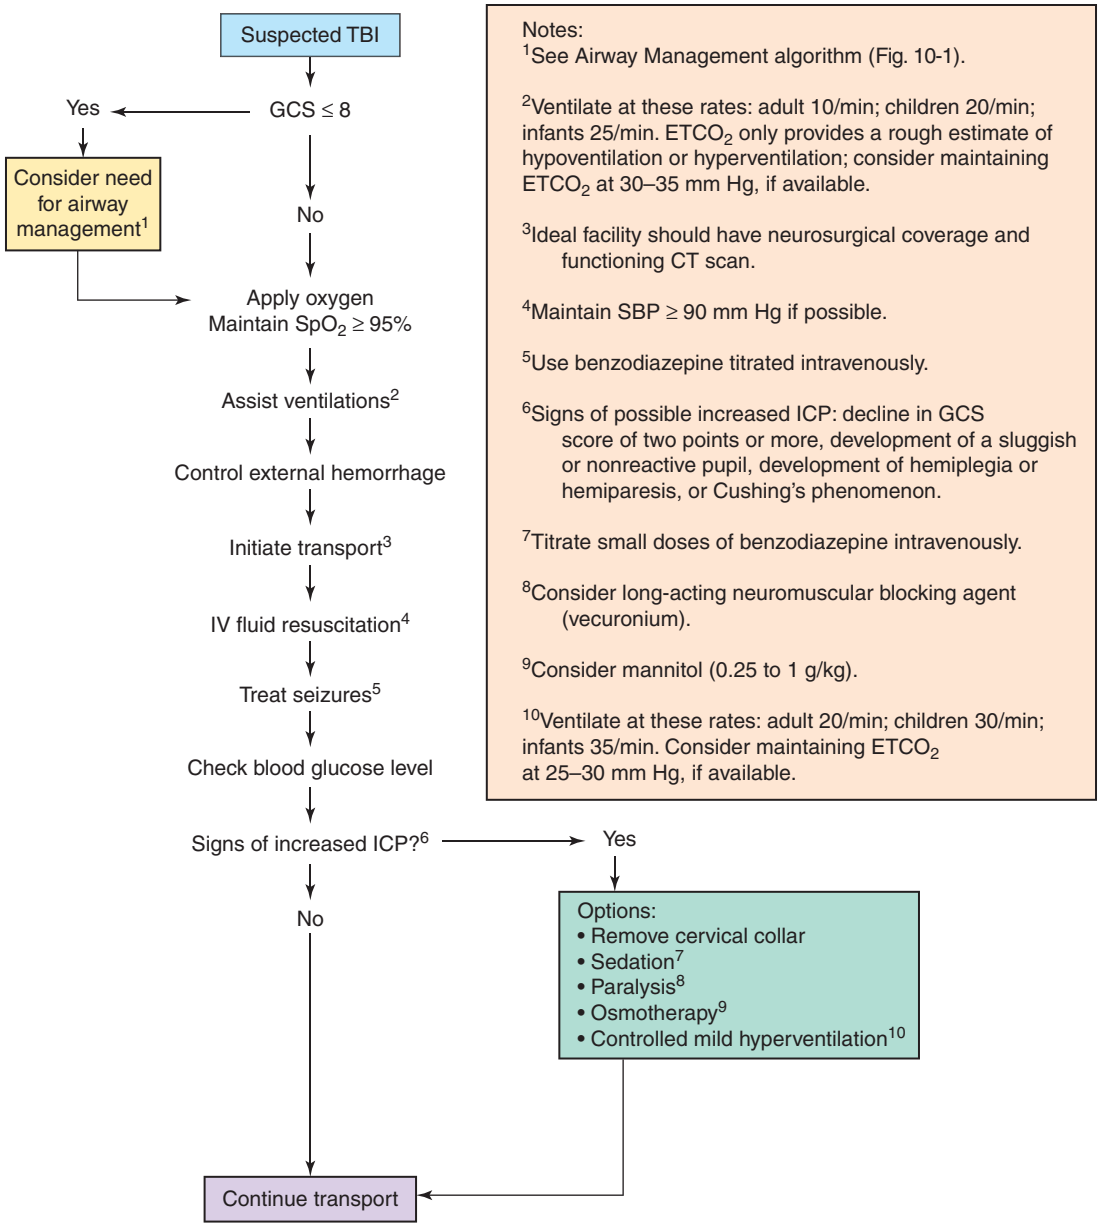

FIGURE 10-5 Algorithm for the prehospital management of traumatic brain injury (TBI). CT, computed tomography; $ETCO_2$, end-tidal carbon dioxide; GCS, Glasgow Coma Scale; ICP, intracranial pressure; SBP, systolic blood pressure. systems for severely injured shock patients.[122] Data from larger civilian studies found no significant adverse events and an associated decreased use of blood products. Of note, it appeared to be feasible for paramedics both to identify appropriate patients to receive TXA and to safely administer TXA.[123] The current data have caused the US military to advance TXA, as it has been added to the Joint Theater Trauma System Damage Control Resuscitation Clinical Practice Guideline. However, preliminary data demonstrate a risk of TXA use in patients with thrombolytic shutdown resulting in venous thromboembolism.[124] Further research will be necessary before definite recommendations on TXA can be made.

Secondary Survey

Secondary survey refers to a more thorough history and physical examination. For the patient with life-threatening conditions identified in the primary survey, the EMS provider performs the secondary survey when those conditions have been addressed and are stable or improving and the patient is being transported. If the primary survey fails to indicate that

the injured patient is critical, then the provider proceeds on to the secondary survey.

AMPLE HISTORY

This brief history from the patient or family includes the following:

- Allergies to medications
- Prescription or over-the-counter medications
- Pertinent past medical history
- Last eaten
- Recall of events leading up to the injury

HEAD-TO-TOE SURVEY

This complete physical examination begins with obtaining a complete set of vital signs. Injuries to the head, neck, chest, abdomen, pelvis, and extremities are noted. The patient is then turned using the log roll maneuver if a spinal injury is suspected, and the patient's back is examined. Finally, a neurologic examination that involves reassessing the GCS score, pupillary reaction, and motor and sensory functions in the extremities is completed.

Specific Conditions

SCALP WOUNDS

Because of the high concentration of blood vessels in the skin and soft tissues of the scalp, face, and neck, even a small wound can result in serious external hemorrhage. EMS providers and other health care workers often fail to appreciate that patients with a complex scalp wound may bleed sufficiently to develop shock. A compression dressing created with gauze pads and an elastic bandage often provides satisfactory control of hemorrhage. Hemostatic dressings can also be useful for uncontrolled scalp bleeding.

TRAUMATIC BRAIN INJURY

TBI remains one of the leading causes of mortality in injured patients. Secondary brain injury refers to the extension of the original injury and may result from numerous causes. These include hypoxia, hypocapnia and hypercapnia, anemia, hypotension, hypoglycemia and hyperglycemia, seizures, and intracranial hypertension as the result of edema or mass effect. Optimal prehospital care of the patient with a TBI involves preventing secondary brain injury, maintaining cerebral perfusion pressure (mean arterial pressure minus intracranial pressure), and expeditious transfer to a facility capable of caring for the injury.

A patient with a severe TBI may be unable to control his or her airway, and endotracheal intubation should be considered for patients with a GCS score of 8 or less, although an alternative airway device may provide a satisfactory airway. Ventilatory support should be administered, and the patient maintained eucapnic as prophylactic hyperventilation is no longer indicated.[125,126] Data from patients with TBI indicate that those who arrive in the emergency department with either hypocapnia (arterial Pco_2 <30 mm Hg) or hypercapnia (Pco_2 >45 mm Hg) have poorer outcomes compared to those who arrive in a eucapnic condition.[127] As indicated earlier, providers with greater experience and the availability of continuous end-tidal capnography led to better survival of patients with a TBI who had RSI performed by HEMS providers than by ALS paramedics in San Diego.[65] Targeted oxygen therapy has been noted to be of importance, as hyperoxia has been found to have deleterious effects in the critically ill, including traumatic head injured patients.[128]

Blood loss should be minimized by controlling external sources and splinting fractures as appropriate. Because of the risk of an associated injury to the spine, patients with a suspected TBI should undergo spinal immobilization. Intravenous fluids should be initiated en route to the receiving facility with a goal of maintaining the SBP at 90 mm Hg. During prolonged transport, blood glucose can be monitored and dextrose administered if the patient is hypoglycemic. Benzodiazepines are appropriate for control of seizures, but they should be carefully titrated intravenously because of the risk of hypotension and respiratory depression.

Intracranial hypertension may cause cerebral herniation and brain death, but it cannot be measured in the prehospital setting. Signs of possible intracranial hypertension include the following: a decline in the GCS score of 2 points or more, development of a sluggish or nonreactive pupil, development of hemiplegia or hemiparesis, or Cushing phenomena (bradycardia associated with arterial hypertension).

THORACIC TRAUMA

Flail Chest and Pulmonary Contusion. In the prehospital setting, the administration of oxygen and ventilatory support are the primary therapies for a flail chest and suspected pulmonary contusion (see Chapters 27–30). Oxygen saturation should be kept at 95% or higher by applying supplemental oxygen. If these measures fail to provide adequate oxygenation, ventilations should be assisted and endotracheal intubation considered if the patient's tidal volume appears inadequate.

Tension Pneumothorax. Tension pneumothorax should be suspected whenever the following three criteria are identified: increasing respiratory distress or difficulty ventilating with a BVM device, decreased or absent breath sounds, and hemodynamic compromise. Needle decompression of the pleural space can be lifesaving.[52,129] An intravenous catheter at least 12 gauge in diameter should be used and should be left in place. There is no need to create a one-way ("flutter") valve because any air exchange through the catheter is clinically insignificant. Recent data suggest that a catheter length of at least 8 cm is necessary to reach and decompress the pleural space.[130]

Open Pneumothorax. An open pneumothorax should be sealed with an occlusive dressing. One of the four sides of the dressing may be left untaped so that air can decompress

from the pleural space as needed. After an occlusive dressing has been applied to an open pneumothorax, any signs of a developing tension pneumothorax should prompt the EMS worker to remove the dressing. If this does not result in improvement of the patient's status, needle decompression should be considered.

Pericardial Tamponade. Pericardial tamponade is generally encountered following penetrating trauma to the heart; however, it may be a complication of a blunt cardiac rupture. In the prehospital setting, the classic symptoms of Beck triad (elevated venous pressure, muffled heart tones, and hemodynamic compromise) may be difficult to identify. Although some EMS systems permit ALS personnel to perform pericardiocentesis if pericardial tamponade is suspected, the emphasis should be placed on transporting that patient with a suspected tamponade to a facility that has immediate surgical capabilities.

ABDOMINAL TRAUMA

Intra-Abdominal Hemorrhage. In the absence of an obvious sign such as a bullet wound, intra-abdominal hemorrhage is difficult to identify in the prehospital setting, especially in the unconscious trauma patient (see Chapters 31–38). Unexplained hypovolemic shock should lead the EMS provider to suspect this condition. Management involves rapid transport to a facility that offers immediate operative intervention. A FAST (focused assessment for the sonographic evaluation of the trauma patient) examination is becoming increasingly available in air and ground EMS units and can help with triage.

Pelvic Fractures. The presence of a severe pelvic fracture may be suspected if the EMS provider finds instability on examination of the pelvis, especially if the patient has evidence of hypovolemic shock (see Chapter 39). Pelvic binders, which are often placed on hypotensive trauma patients with proven pelvic fractures in the hospital, have limited utility in the field. EMS providers may not be able to identify a fractured pelvis on physical examination alone, and the pelvic binders are costly. These binders may be useful in the setting of a hypotensive trauma patient with a known pelvic fracture who requires interfacility transport.

Pregnancy. Prehospital management of the injured pregnant patient focuses on adequately resuscitating the mother, especially if shock is present (see Chapter 41). In the third trimester, pregnant individuals may exhibit hypotension while lying supine due to compression of the inferior vena cava by the uterus. Supine hypotension is treated by gently rolling the mother into the left lateral decubitus position or, if immobilized on a long backboard, placing sufficient padding under the right side of the board to elevate it 30° or so. If hypotension does not correct with this measure, hemorrhagic shock should be suspected. Oxygen should be administered and the patient transported to a facility that has both trauma and obstetrical capabilities.

SPINAL TRAUMA

An algorithm has been developed that details the indications for spinal immobilization in the prehospital setting (see Chapter 26) (Fig. 10-6).[52,130] Patients with penetrating trauma to the torso almost never have an unstable vertebral column.[131] A recent analysis of data from the NTDB showed that victims of penetrating trauma who received prehospital spinal immobilization had a higher risk of death compared to those who did not.[132] Therefore, spinal immobilization is indicated in the setting of penetrating trauma only when the patient has a neurologic complaint or finding. In patients with blunt trauma, spinal immobilization should be performed if the patient has an altered level of consciousness (GCS score <15) or if spinal pain or tenderness, a neurologic deficit or complaint, or an anatomic deformity of the spine is present. In the absence of these findings, the mechanism of injury should be evaluated. If the mechanism is considered to be concerning, the patient should be evaluated for evidence of alcohol or drug intoxication, presence of a distracting injury, or the inability to communicate. If any of these are present, spinal immobilization should be performed. In their absence, spinal immobilization is not indicated.

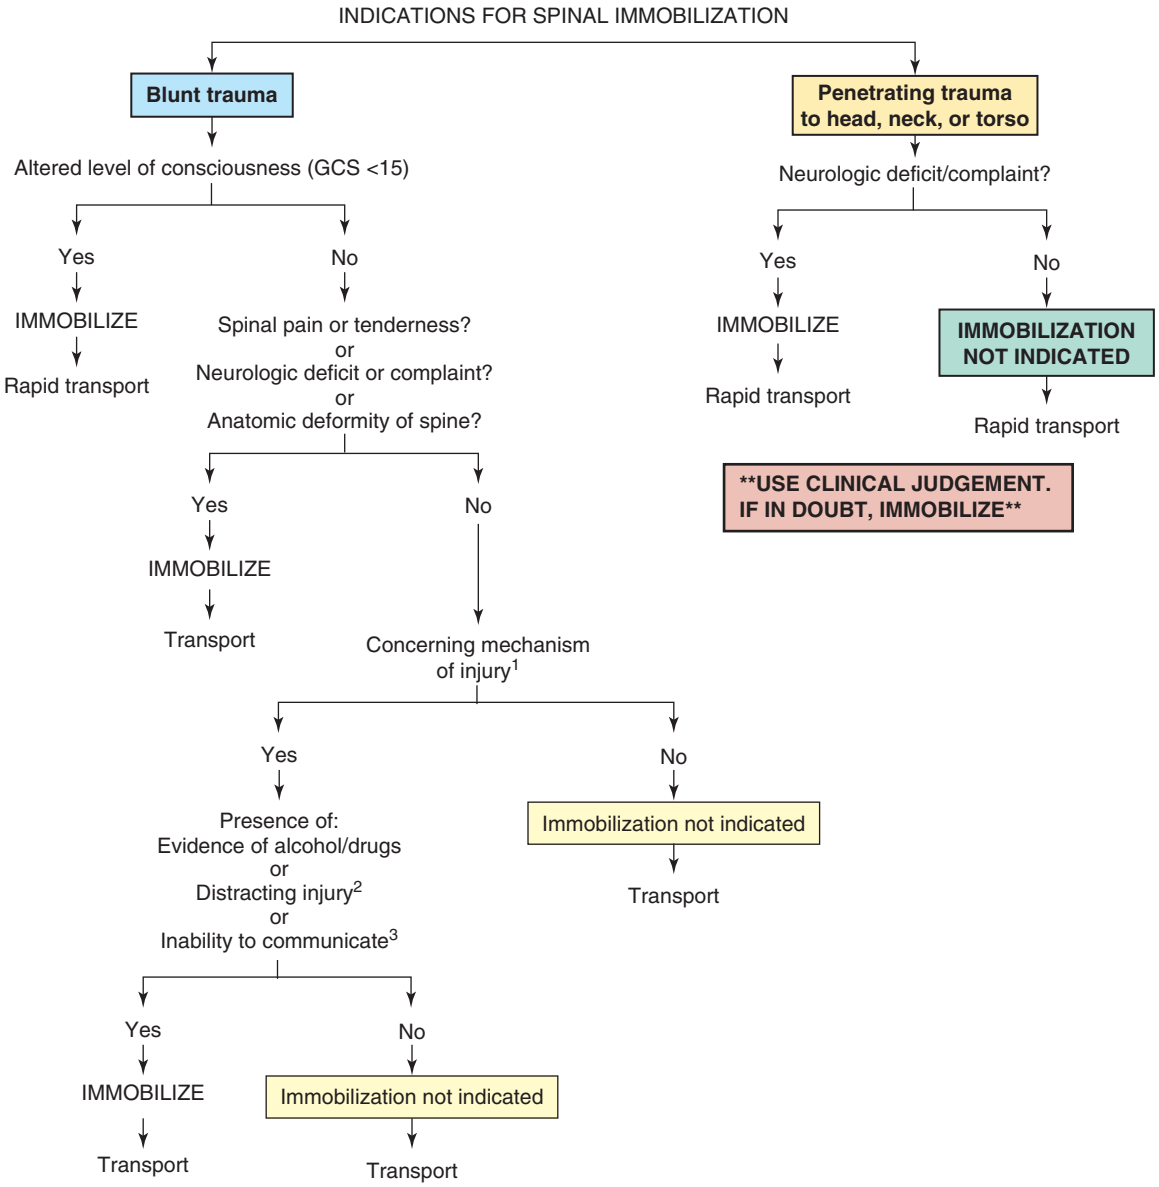
MUSCULOSKELETAL TRAUMA

Splinting. Hemorrhage is the only immediately life-threatening condition associated with trauma to an extremity (see Chapters 43–45). External hemorrhage should be controlled with direct pressure or a pressure dressing, followed by a tourniquet if these measures fail. Internal hemorrhage is best managed in the field by immobilization of the extremity. In the critically injured patient, immobilization to a long backboard is sufficient stabilization. If the patient does not have life-threatening injuries, time can be taken to splint each suspected fracture individually. A traction splint provides reasonable pain control and will stabilize a suspected fracture of the femur.

Amputation. ACSCOT has published guidelines for the management of amputated parts.[133] These include the following:

- Cleansing the amputated part by gentle rinsing with lactated Ringer's solution.
- Wrapping the part in sterile gauze moistened with lactated Ringer's solution and placing it in a plastic bag.
- Labeling the bag or container and placing it in an outer container filled with crushed ice.
- The part should not be allowed to freeze, and it should be transported along with the patient to the closest appropriate facility.

Pain Control. In the prehospital setting, analgesics are indicated for an isolated injury to an extremity, but not in a patient with multisystem trauma.[52,134] After appropriately splinting



Notes:
[1]Concerning mechanisms of injury
- Any mechanism that produced a violent impact to the head, neck, torso, or pelvis (e.g., assault, entrapment in structural collapse, etc.)
- Incidents producing sudden acceleration, deceleration, or lateral bending forces to the neck or torso (e.g., moderate- to high-speed MVC, pedestrian struck, involvement in an explosion, etc.)
- Any fall, especially in elderly persons
- Ejection or fall from any motorized or otherwise-powered transportation device (e.g., scooters, skateboards, bicycles, motor vehicles, motorcycles, or recreational vehicles)
- Victim of shallow-water diving incident

[2]Distracting injury
Any injury that may have the potential to impair the patient's ability to appreciate other injuries. Examples of distracting injuries include a) long bone fracture; b) a visceral injury requiring surgical consultation; c) a large laceration, degloving injury, or crush injury; d) large burns, or e) any other injury producing acute functional impairment.
(Adapted from Hoffman JR, Wolfson AB, Todd K, Mower WR: Selective cervical spine radiography in blunt trauma: methodology of the National Emergency X-Radiography Utilization Study [NEXUS], *Ann Emerg Med*. 1998 Oct;32(4):461–9.)

[3]Inability to communicate. Any patient who, for reasons not specified above, cannot clearly communicate so as to actively participate in their assessment. Examples: speech or hearing impaired, those who only speak a foreign language, and small children.

FIGURE 10-6 Indications for spinal immobilization. GCS, Glasgow Coma Scale; MVC, motor vehicle crash. (Reproduced with permission from Salomone JP, Pons PT, McSwain NE, eds. *PHTLS: Prehospital Trauma Life Support*. 7th ed. St. Louis, MO: Mosby; 2011:257. Copyright © Elsevier.)

the extremity, small doses of narcotics titrated intravenously may help relieve pain. The patient should be observed for side effects including hypotension and respiratory depression. Narcotics should not be administered in the trauma patient who exhibits signs of shock or when the patient appears to be under the influence of drugs and alcohol.

Medications other than narcotics have become commonplace for pain control in the prehospital environment. Ketamine has achieved a higher level of use as a result of benefits of sedation, pain control, and decreased posttraumatic stress disorder (PTSD) after traumatic events. Ketamine as a pain medication has been appreciated for its ease of use, efficacy, and multiple routes of administration, including intranasally.[135-137] Proposals that ketamine reduces rates of PTSD highlight a future area of study for its use in prehospital traumatic injuries.[138]

TRIAGE

Disasters may be the result of natural phenomena, such as tornadoes, hurricanes, and earthquakes, or manmade in the case of a building collapse or terrorist event. When situations such as these occur, the EMS and health care systems must try to match their resources with the needs of the community. A *multiple-patient incident* refers to a situation where numerous individuals may be injured but the EMS system possesses the ability to provide adequate care. In a *mass casualty incident*, the number of injured patients overwhelms the resources of the community, and additional aid from other locations is required. The number of patients involved in each of these circumstances may vary, depending on the size of the EMS system and the resources of the community.

In either situation, EMS personnel and health care workers must employ the principles of triage so that the most seriously injured patients receive care before those with minor injuries. Simple Triage and Rapid Treatment (START) is an easily taught, simple triage system that is widely used by EMS providers when faced with numerous injured patients.[52,129,139] A national expert panel, assembled by the CDC, reviewed all available triage schemes ("SALT" [*s*ort, *a*ssess, *l*ifesaving interventions, *t*reatment/*t*ransport]) and proposed a new method composed of the best components of the others.[140] A more comprehensive discussion of disaster care is presented in Chapter 12.

HAND-OFF AND TRANSITION OF CARE TO HOSPITAL

It is imperative for EMS personnel to give a clearly communicated, concise, and thorough report to personnel at the trauma center. The hand-off or report about the patient from EMS to the hospital is a potentially dangerous situation with implications for mistreatment of the patient if the prehospital interventions are not understood at the receiving facility. Every effort should be made to transmit what previous care was rendered. A system-wide standardized hand-off method is encouraged to promote exchange of vital information. This should include, but not be limited to, any abnormal vital signs, mechanisms of injury, care provided, and, especially, medications that may alter the patient's sensorium.

PREHOSPITAL RESEARCH

Over the past decade, the entire health care field has seen a growing trend toward evidence-based medicine. EMS, in general, and prehospital trauma care, specifically, require high-quality research to separate sound medical practice from conjecture. Management of the airway and fluid therapy are two areas that deserve intensive investigation in the prehospital setting. Far too few treatment protocols in EMS are based on high-quality data. More commonly, protocols are written that include the biases of the authors and extrapolations from in-hospital care.

Several major obstacles to the development of quality EMS research exist.[14] Funding is woefully inadequate, and integrated information systems are needed to link data on patient care with information on outcome. Few academic institutions possess a long-term commitment to EMS research. Governmental regulations regarding informed consent inhibit the conduct of research in the emergency situation, as well. As these challenges are overcome, new research will lead us to better care for our patients. NHTSA has published a document detailing numerous issues in prehospital care that are awaiting investigation.[16]

SUMMARY AND KEY POINTS

Prehospital management of the injured patient is in a state of transition. Few experts recommend a return to a mere "scoop and run" approach in which EMS personnel would leave the patient without support of vital functions during the transport to the hospital. Conversely, delays on the scene to perform unnecessary interventions are associated with increased mortality.[141] A recent publication compared trauma mortality before and after the implementation of a province-wide ALS program and found no significant change in survival between the two periods.[142] Although these findings could be the result of inexperienced ALS providers or inappropriate ALS protocols, it remains unclear which, if any, ALS procedures improve survival.

A more moderate approach that focuses on limited, key field interventions as taught in the PHTLS program is as follows:

- Rapid assessment to identify life-threatening injuries is critical.
- Key field interventions include management of the airway, ventilatory support with administration of oxygen, and control of external hemorrhage, among others.
- Rapid transport to the closest appropriate facility is essential.
- Prehospital trauma care must be part of an integrated regional trauma and EMS system (Table 10-4).
- High-quality research is desperately required in the field of prehospital trauma care.

TABLE 10-4: Golden Principles of Prehospital Trauma Care

1. Ensure the safety of the prehospital care providers and the patient.
2. Assess the scene situation to determine the need for additional resources.
3. Recognize the kinematics that produced the injuries.
4. Use the primary survey approach to identify life-threatening conditions.
5. Provide appropriate airway management while maintaining cervical spine stabilization.
6. Support ventilation and deliver oxygen to maintain an Spo_2 ≥95%.
7. Control any significant external hemorrhage.
8. Provide basic shock therapy, including appropriately splinting musculoskeletal injuries and restoring and maintaining normal body temperature.
9. Maintain manual spine stabilization until the patient is immobilized on a long backboard.
10. For critically injured trauma patients, initiate transport to the closest appropriate facility within 10 min of arrival on scene.
11. Initiate warmed, intravenous fluid replacement en route to the receiving facility.
12. Ascertain the patient's medical history and perform a secondary survey when life-threatening conditions have been satisfactorily managed or have been ruled out.
13. Provide thorough and accurate communication regarding the patient and the circumstances of the injury to the receiving facility.
14. Above all, do no further harm.

Rural Trauma

Juan C. Duchesne • John P. Hunt • Alan B. Marr

KEY POINTS

- By the World Bank's calculation, 45.7% of the world's population still lives in a rural area.
- In the United States, at least 31% of rural residents live more than an hour from a Level I to III trauma center.
- In one study in a rural area, patients transported directly to the Level I trauma center from the field arrived 1.6 hours after injury, compared to 5.3 hours when patients were first sent to a local hospital that was not a trauma center.
- Recruiting and retaining emergency medical personnel in rural areas is difficult because of low wages, lack of training opportunities, and the need to cover a broad geographic region.
- The Rural Trauma Team Development Course of the American College of Surgeons is aimed at small hospitals without surgical capability and only nonsurgical personnel to treat the occasional injured patient.
- According to the National Highway Traffic Safety Administration, rural fatal crashes account for 61% of all traffic fatalities but only 39% of vehicle miles traveled.
- Many of the most dangerous occupations are found in rural areas, most notably mining and agriculture.
- The percentage of homes that experience a fire and have a working smoke alarm is 41.8% in urban areas but only 20.8% in rural areas.

HISTORICAL PERSPECTIVE

Injury continues to be a leading cause of death and disability throughout the United States; however, there are significant differences between injuries that occur in rural versus urban settings. Rural environments account for over 85% of the North American land mass and roughly 62.5 million people live in rural areas. Although less than one-fourth of the population lives in rural areas, the population in these regions accounts for a disproportionate number of trauma-related deaths.[1-4]

There are some key factor differences to consider when dealing with trauma patients in rural locations. They are typically older, less severely injured, and more likely to die at the scene than urban patients. The majority of trauma in rural settings is blunt injury, with fewer penetrating injuries, whereas the reverse is true in some urban locations. Similarly, the fatal crash rate is more than two times higher in rural than urban areas, with a rural rate of approximately 2.4 deaths per 100 million vehicle miles traveled.[5-7] The factors leading to these higher injury mortality rates include a lower rate of use of protective devices, greater severity of crashes due to higher speeds, and prolonged discovery time.[8-11]

Another important geographic disparity in these vulnerable populations is access to rural trauma care.[12] Rural may be defined in accordance with census data based on metropolitan areas, in terms of geography and distance, or by virtue of limited resources. In an analysis of the general surgery workforce, Thompson et al[13] identified significant differences between communities with a population between 10,000 and 50,000 (large rural) and those with 2500 to 10,000 residents. Large rural towns are far more likely to have the necessary resources such as general surgery, medical and surgical subspecialties, advanced life support ambulance services, and essential equipment to provide prompt and sophisticated trauma care.

In addition to longer distances to appropriate health care, health services in rural areas differ from those in urban areas, with fewer physicians and specialists per capita to furnish comprehensive trauma care. As a result, implementation of a systematic inclusive trauma system with outreach trauma education that focuses on injury prevention can potentially lower the incidence of rural trauma and improve outcomes in rural trauma hospitals.[14-18]

Although efforts in injury prevention might reduce the frequency or severity of injury in rural environments, it is

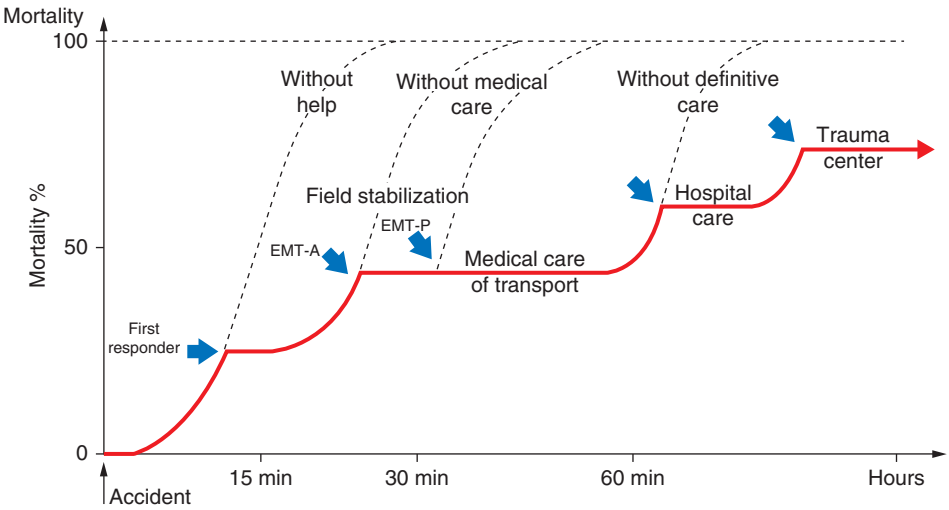

FIGURE 11-1 Mortality of trauma against time with field resuscitation and definitive care. EMT-A, emergency medical technician-advanced; EMT-P, emergency medical technician-paramedic. (Reproduced with permission from Boyd DR. Trauma: a controllable disease in the 1980s [Fourth Annual Stone Lecture, American Trauma Society]. *J Trauma.* 1980;20:14-24.)

evident that hospital-based interventions directed to improve injury care among rural trauma patients play a significant role in reducing mortality. As a result, the American College of Surgeons Committee on Trauma has designated trauma centers into Levels I to IV, with Level I or II trauma centers having the most comprehensive resources required to provide high-level trauma care in addition to trauma education and outreach. Trauma care at a Level I center has been shown to reduce risk of mortality in the severely injured by 25%.[8] Unfortunately, most advanced trauma centers are not distributed evenly across the nation, and approximately 45 million Americans do not live within 1 hour of the highest level of trauma care. This creates a marked rural-urban time-dependent disparity in access, with at least 31% of rural residents living more than an hour from a Level I to III trauma center compared to only 12% of urban residents.[19,20]

Rural trauma outcomes are time dependent. With approximately 500 verified or designated Level I and Level II trauma centers created for definitive trauma care and 1045 rotary-wing helicopters currently stationed at 879 bases in hospitals or airports to transport scene patients to trauma centers,[21,22] the key and still immediate determinant in rural trauma care survival is place of injury (Fig. 11-1).[23] In addition, there needs to be an established mechanism for fast patient transport with interfacility agreements developed by a regional inclusive trauma system.

The biggest benefit of an inclusive regional trauma system is to ease the transfer of injured patients from non–trauma center hospitals to higher echelon levels of care. Statewide inclusive regional trauma systems have demonstrated improvement in injury-related mortality as compared to states with less developed trauma systems. Currently, 9 states and districts lack a statewide trauma system and, of the remaining 42 states, only 24 have state-funded trauma systems. In this chapter, we will provide a current description of today's rural trauma care with suggested improvements, evidence of persistent disparities between urban and rural systems, and future improvements in education in an inclusive trauma system.[24,25]

DEFINING RURAL

Assessing the needs of rural populations is exceedingly difficult because of the lack of a uniform and internationally accepted definition of the term *rural*. Most international organizations rely on definitions set by nation states. By the World Bank's calculation, using United Nations data available in 2017, 45.7% of the world's population still lives in a rural area[26]; however, as demonstrated globally in Fig. 11-2,[27] enormous amounts of land still have very low population densities. In 2005, one study demonstrated that only 3% of the earth's land mass would be considered urban, although it contained nearly half of the planet's population.[28] By any definition, there are large numbers of people who live in rural areas worldwide, and these areas cover vast expanses.

There are numerous ways to determine whether a place is urban or rural. The most rudimentary is probably the simple calculation of population density. This requires determining a population for a given area of land. In the United States, the typical unit of area is the square mile, and the population for each area is counted every 10 years in the national census. Areas of similar population densities are aggregated to produce a map reflective of population densities of larger areas within the country (Fig. 11-3).[29] This representation clearly shows that there are still large areas of the country that are sparsely populated. Although most are in the Midwest and West, there are still large regions of the South and even areas of the Northeast that are rural.

Although useful, the crude population density mapping technique lacks some detail that may be useful in planning for delivery of medical and other services vital to a modern community. Although the Census Bureau and its

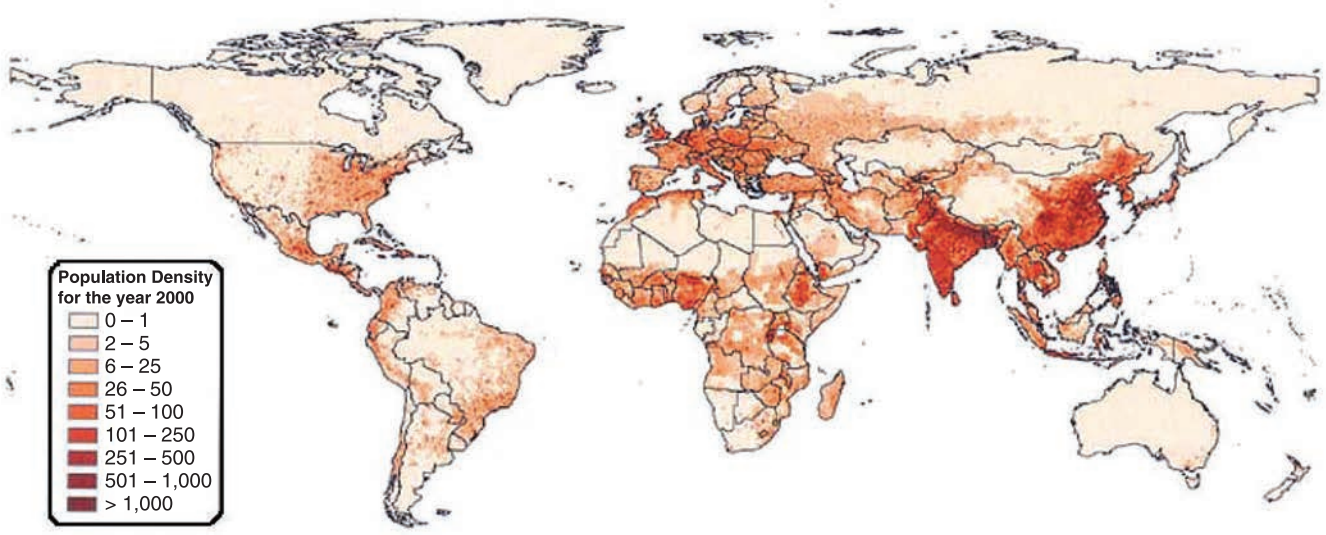

FIGURE 11-2 Map demonstrating population density for the year 2000. (Reproduced with permission from Food and Agriculture Organization of the United Nations [FAO]. Salvatore M, Pozzi F, Ataman E et al. *Mapping Global Urban and Rural Population Distributions.* Rome: FAO; 2005.)

forerunners were originally charged with the population count for the purposes of assigning the number of representatives to Congress,[30] over the course of 225 years, their data collecting has been expanded and used for other governmental functions. Historically, the US Census Bureau has never actually defined what "rural" is, other than all the land that is not classified as urban. Although the definition of urban has changed over time to include more people and land, the definition of rural remains all "territory, persons, and housing units not defined as urban."[31]

In 2000, the Census Bureau expanded the classification of urban regions. This included "urbanized areas," which contain over 50,000 persons, and "urban clusters," which are areas with at least 2500 but fewer than 50,000 people.

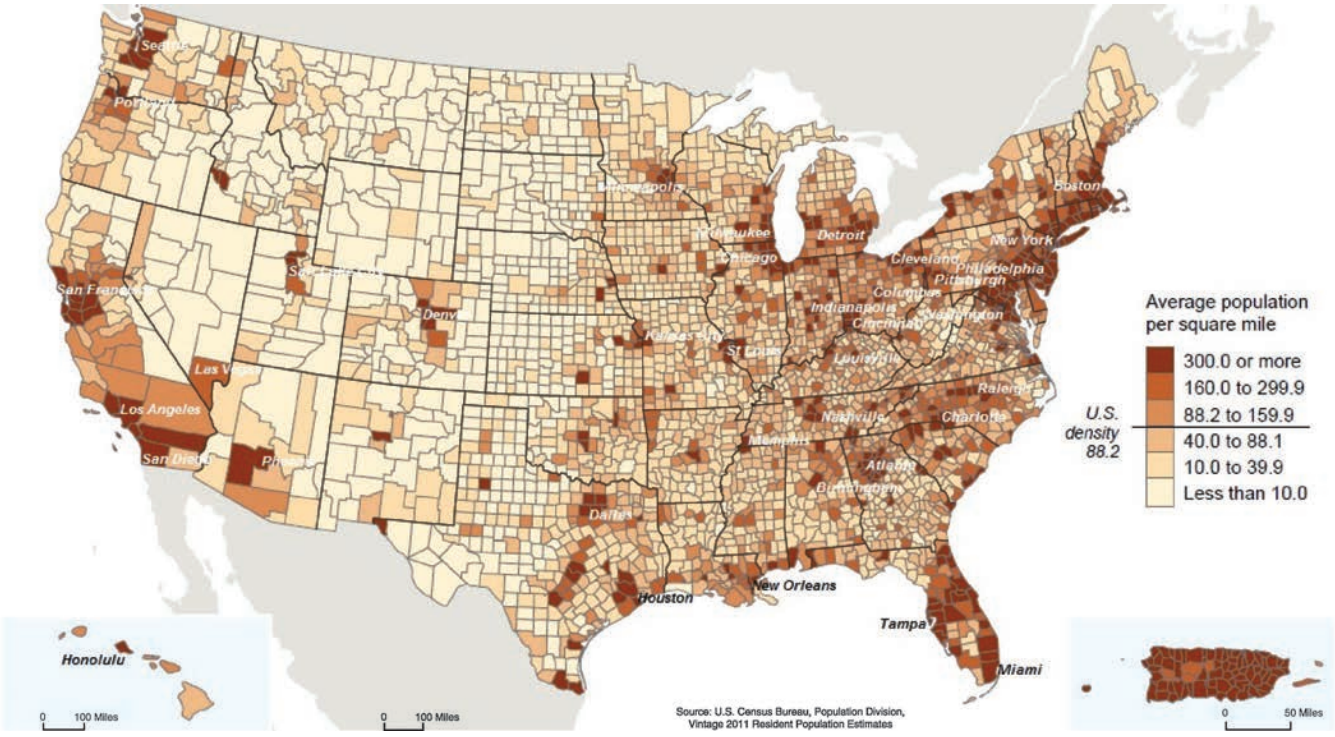

FIGURE 11-3 Map describing average population per square mile. Large sparsely populated areas remain in the Midwest and West, as well as the South and even areas of the Northeast. (US Census Bureau. Maps. Retrieved from https://www.census.gov/history/www/reference/maps/.)

Other factors such as population density, land use, and distance between urban clusters are also used to define the new urban area classifications.[32] In 2010, there were 486 urbanized areas and 3087 urban clusters in the United States.[33] This representation (Fig. 11-4)[34] provides more detail and may be useful in the planning of parts of trauma systems that may be integral to providing trauma care to rural areas.

Urban clusters are uniquely placed to be points of care to the sparsely populated regions of the country. They may not have the population to support larger tertiary care centers able to provide definitive care. They will, however, be indispensable in providing the initial phases of the continuum of trauma care. They could include a population center that can support a cadre of prehospital providers, a nontrauma hospital that can provide stabilizing care prior to transport to a trauma center, or in some cases, even Level III trauma centers that can provide definitive care to certain trauma patients. All of these elements are essential in bringing state-of-the-art trauma care to rural populations.

The challenges to bringing the best trauma care to rural citizens are not just related to the great distances between patients and definitive care. Rural areas are frequently starved of resources. Due to economies of scale, it is often difficult to bring more expensive care and technology to a smaller number of people. This is compounded by the fact that rural households, on average, earn almost 5% less than their urban counterparts.[35] Rural areas are frequently sites of inhospitable climates, which interfere with effective retrieval and transport. In addition, they often have geographic features such as mountains, which hamper radio communications and air travel, or bodies of water that will require special equipment for rescue and marine transport.

The challenge will be varied, and the solutions will depend on the environment and the resources available. It is imperative that attention and funds be applied to trauma care for the

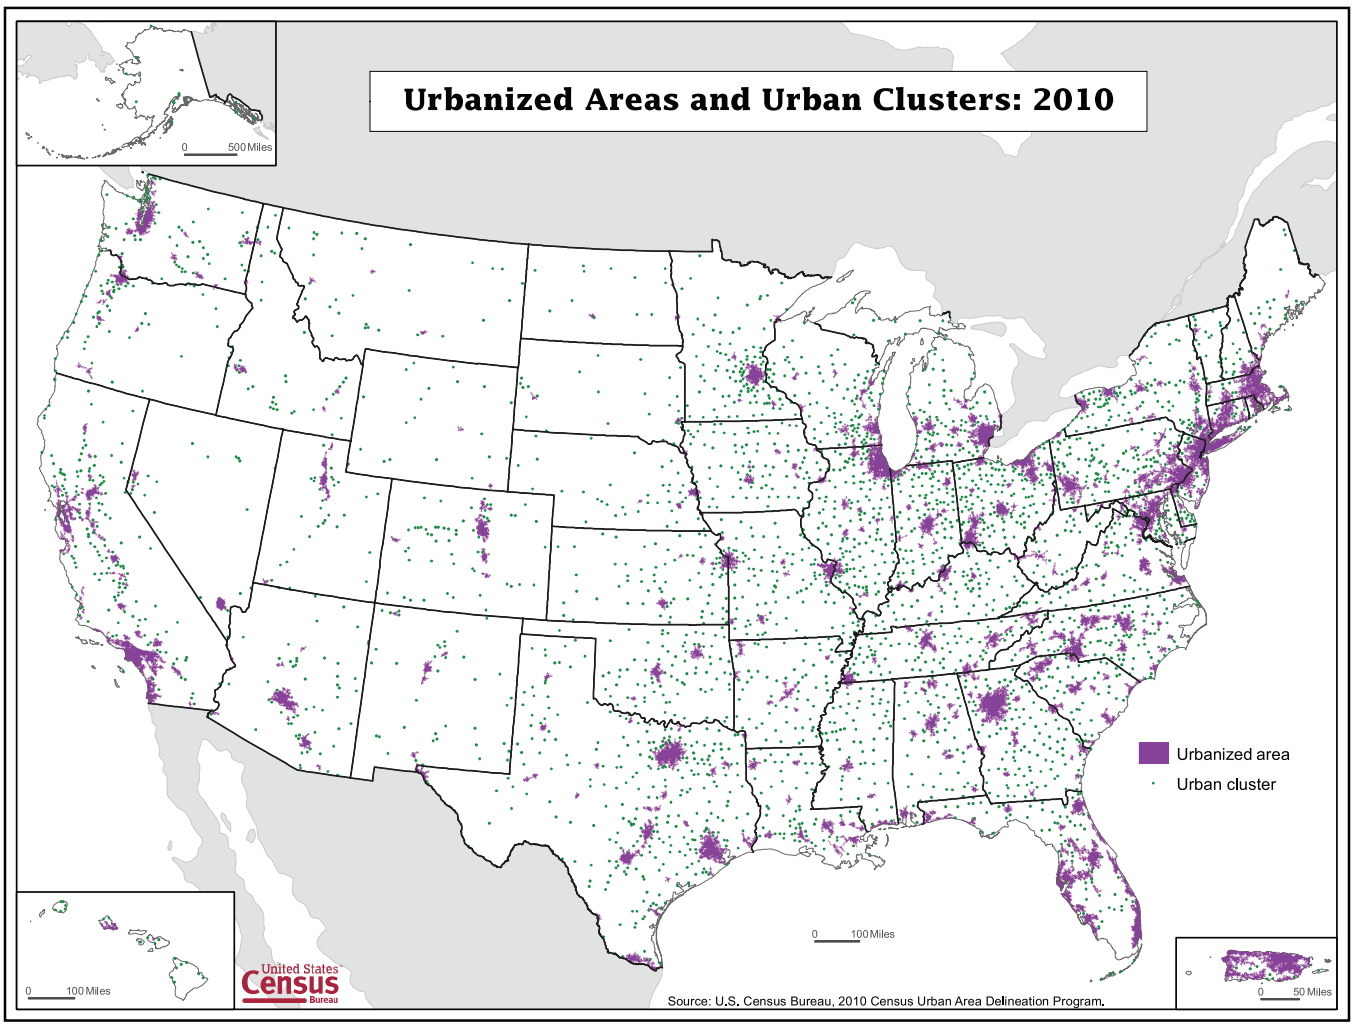

FIGURE 11-4 Understanding urbanized areas and urban clusters can be useful in the planning of trauma systems in rural areas. (US Census Bureau. Defining rural at the U.S. Census Bureau. Retrieved from https://www2.census.gov/geo/pdfs/reference/ua/Defining_Rural.pdf.)

rural population. In 2016, John H. Thompson, the Census Bureau Director, stated, "Rural areas cover 97 percent of the nation's land area and contain nearly 20 percent of the population."[36] That is approximately 60 million Americans.

THE NEED FOR REGIONAL INCLUSIVE TRAUMA SYSTEMS

As noted earlier, numerous challenges confront officials trying to render state-of-the-art trauma care to rural populations.[37] All of these factors can contribute to worse outcomes in the rural trauma patient. In one study in Ontario, Canada, deaths in the field were twice as frequent in rural areas of the province, and there was a threefold increase in the mortality rate for patients who had limited access to trauma center care.[38] This is notable in some particularly at-risk patient populations. For example, geriatric trauma patients admitted to rural hospitals have a significantly increased mortality when compared to their urban counterparts.[39]

In addition, it has been effectively demonstrated that trauma patients with an increased transport time have a higher rate of complications and length of stay.[40] Rural transport times are by definition longer when compared to those of urban cohorts. One study of Scottish trauma patients demonstrated increases in prehospital times in rural regions when compared to urban areas. This is true of response time, scene time, and transport time.[41] In one statewide study in the United States, the mean emergency medical services (EMS) response time was 13.9 minutes in the rural areas compared to 6.8 minutes in urban settings. This, in turn, corresponds to an average 10.5-mile response distance in rural settings versus a 7.7-mile distance in urban settings. This creates a twofold increase in mortality for rural trauma patients when compared to the urban trauma patient population and has been observed in other rural and urban comparisons.[42]

In addition to distance, the environment itself contributes to less favorable outcomes. In one rural Level I trauma center over a 5-year period, 1490 (15.7%) of 9482 adult patients admitted were hypothermic. Hypothermia was associated with a nearly twofold risk for mortality and significantly increased hospital days.[43] The only means to bring effective care to patients in rural regions in the face of the burden imposed by the frequently austere environments, geographic obstacles, distances involved, and a relative lack of resources is a well-functioning and orderly trauma system. The American College of Surgeons defines a *trauma system* as a trauma care delivery structure that addresses all aspects along the continuum of trauma care.[44] This includes all components of EMS notification, dispatch, prehospital instruction, and transport. It also involves initial hospital care and interfacility transport and then trauma center care and rehabilitation.

In the severely injured, definitive care will often be carried out in a trauma center away from the rural environment. It is the support of the rural medical community, through education, provision of resources, and a seamless integration with centers that can provide a higher level of care, that makes the trauma system essential for improved outcomes in the rural trauma patient. In numerous rural communities across the globe, the implementation of a trauma system has yielded clinical benefits. The introduction of a trauma system in rural Victoria, Australia, resulted in a marked decrease in preventable and potentially preventable deaths.[45] A similar implementation of the Iowa Trauma System noted a significant decrease in the mortality of patients with traumatic brain injuries treated at receiving Level I or II trauma centers.[46]

Benefits are realized through a variety of mechanisms that improve quality of care and streamline access to definitive care in the initial care of the critically injured. At the prehospital and first-responder levels, education is frequently provided through the trauma system. Emergency medical technician (EMT) and paramedic courses are often provided in urban centers and attended by providers from more rural areas. The effectiveness of trained prehospital providers in the United States is often overlooked and taken for granted because they have been in place for a long period. In similar fashion, new prehospital efforts in developing countries yield results from prehospital provider education that are impressive. In the developing regions of Kurdistan, Iraq, and rural Cambodia, a program that enlisted lay persons trained in basic first aid and paramedics trained in Advanced Trauma Life Support (ATLS) made appreciable strides in outcomes. They were able to reduce the mortality from landmine injuries from 23.9% to 8.8% over a 5-year period.[47]

In a similar environment in Iraq, a low-tech prehospital system was developed that decreased time to first treatment from 2.4 hours to 0.6 hour, and the system was durable, as demonstrated by continued proficiency as the mechanism of injury changed from largely penetrating to mixed penetrating and blunt.[48] Another prehospital system consisting of 135 paramedics and 7000 layperson first responders was set up in the mine and war zones in Iraq, where prehospital evacuation times are long. The mortality rate significantly dropped from 15.6% to 9.8% among patients initially managed in the field by first responders compared to patients without first-responder support.[49] In addition, prehospital personnel in the United States trained in the use of tourniquets and application of hemostatic combat gauze have been noted to use the technique and product with demonstrable effectiveness.[50]

Another mechanism by which trauma systems help prehospital personnel is with the coordination of care. The institution of standard and simplified triage tools, developed by the military, that rely on easily collected variables such as respiratory rate and abbreviated mental status evaluations, has been shown to be reliable in identifying critically injured patients.[51] One advantage of the trauma system is that there is an accurate accounting of what services can be provided by which hospitals. Prehospital providers can then be directed toward the right receiving center for the injuries noted at the scene. In one study of rural trauma patients, half of whom were transported directly to the Level I trauma center and half of whom were taken to a local hospital, prehospital transport costs were significantly greater for patients transported to a rural hospital first. In addition, many severely injured patients were initially transported to a rural hospital rather

than directly to the trauma center. At both the scene and rural hospital, consistent use of triage criteria appeared to be lacking in determining the severity of injury, appropriate destination, and mode of transport for trauma patients.[52]

The system provides an infrastructure for standardized field triage protocols and direction of patients to appropriate hospitals. Louisiana was able to demonstrate a sixfold reduction in the secondary transfer rate when a statewide call center implemented a system with standard field triage criteria and real-time data on resources available at the state's hospitals.[53] With this information, a central command center could appropriately assign ground, helicopter, or fixed-wing units to respond. Using global positioning and mapping technology to compare one-way road transfer times with two-way helicopter retrievals in 171 helicopter fights in rural Australia, air transport was significantly faster beyond 100 km, with a mean difference of 48 minutes. The average calculated distance flown was 160.4 nautical miles.[54] Fixed-wing transports are typically used for distances greater than 250 miles. With on-the-ground knowledge of patient status and real-time information on hospital resources, the system can better assign the mode of transport to avoid delay. A 4-year retrospective review of pediatric trauma helicopter transports to area trauma centers, including 130 rural and 419 urban pediatric patients, showed greater total mileage, flight times, and scene times for rural flights. The rural times, however, would have been extraordinary if ground transport was used.[55]

The system can also provide assistance at the physician level. Academic centers are frequently the teachers of physician-level courses, such as the American College of Surgeons ATLS course, which educates physicians in the rudiments of initial trauma care. In a 5-year study of nearly 5000 patients initially treated at rural Level III trauma centers in a single state, several components of the ATLS program were found to confer a mortality advantage. These included patients needing blood products in the emergency department for a systolic blood pressure less than 90 mm Hg, patients needing transfer to higher level of care with an Injury Severity Score (ISS) greater than 20, and patients with traumatic brain injuries.[56] Seriously injured patients treated at nine rural Level III and Level IV hospitals were studied before and after implementation of Oregon's trauma system. The system mandated ATLS training for emergency physicians. Twenty diagnostic and therapeutic interventions, taught in the ATLS course, were evaluated before and after ATLS was mandated. Processes of care for seriously injured patients significantly improved after categorization of rural trauma centers in Oregon.[57]

The uniform training of these emergency physicians also translates into fewer delays in care and a more efficient and rapid movement to definitive care. In one study, nearly half of the referring physicians obtained unwarranted imaging because they felt it was a requirement or because of fear of liability. Physicians trained in ATLS are significantly less likely to obtain unneeded imaging that delays transfer to definitive care.[58] In another study of rural trauma patients requiring transfer, 75% of trauma patients had computed tomography (CT) scans at outside referring hospitals. Of those, 58% transferred to a higher level of care had to have repeat imaging.[59] Undertriage can also create serious delays to definitive care. In one study at a Level I trauma center, all patients who were treated at two hospitals prior to arriving at the trauma center were evaluated. Patients were mostly transferred to the Level I trauma center for nonspine orthopedic injuries (28%), followed by spine injuries (14%) and traumatic brain injuries (13%). These patients had serious or complex injuries and took longer to evaluate. A system-directed refining of transfer protocols concerning specialty care and a central command aware of where these services are available have the potential to decrease secondary transfers and shorten the time to definitive care.[60] When Oregon initiated the state trauma system and mandated ATLS for all emergency physicians, transfers from Level IV rural trauma centers to a higher level of care increased by fourfold.[61]

The balance that must be maintained for the rural hospital is to recognize limitations and when transfer to a higher level of care is needed. Considerations always revolve around appropriate care, but also must take into account inappropriate transfers. These can take patients a distance from their families and overtax the trauma center with patients who could have been taken care of at a local facility. In one study, injury-adjusted mortality rates were significantly lower in patients treated at rural hospital emergency departments and transferred to Level I and II trauma centers than those who were admitted and treated at rural hospitals.[62] In another study, direct transport to higher level trauma centers had a beneficial impact on mortality when compared to patients who were treated at lower level facilities and transferred to a higher level of care.[63]

Transfers after initial assessment can be time consuming. In one study in rural Pennsylvania, patients transported directly to the Level I trauma center from the field arrived 1.6 hours after injury, compared to 5.3 hours after injury when patients were first sent to a local hospital that was not a trauma center.[64] Another study in a rural Vermont Level I trauma center also compared trauma patients admitted directly with those initially stabilized at an outlying hospital. Transfer patients spent an average of just over 3 hours at the outlying hospital and 72 minutes in transport to the trauma center. The transfer population was more severely injured than the trauma patients admitted directly and may have been better served by being brought directly to the trauma center.[65] These delays may be responsible for poorer outcomes and should always be minimized when possible. Most systems will have organized triage protocols and preexisting destination protocols to limit the variability that leads to these delays.

Another important system function is trauma center development and the promulgation of an inclusive system. Level I and II centers often naturally develop in cities and in population centers that will support tertiary care in general. It is frequently in the smaller rural cities, towns, and even villages where it is most difficult to get appropriate hospital resources marshalled toward the smaller volume of trauma patients. Community size, hospital size, and resources and

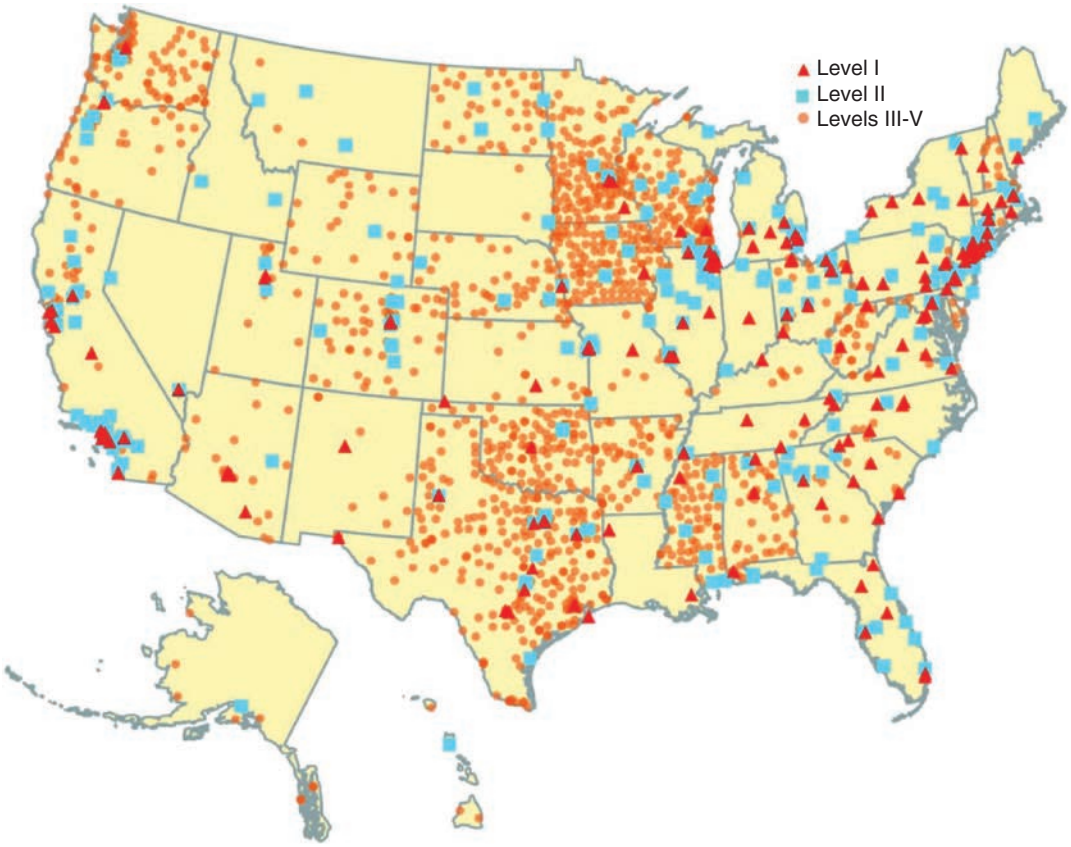

FIGURE 11-5 Distribution of recognized trauma centers is not uniform and clearly follows the population density. (Reproduced with permission from Eastman AB, MacKenzie EJ, Nathens AB. personnel available will dictate the role of each acute care hospital.

The current distribution of recognized trauma centers is not uniform and clearly follows the population density discussed previously (Fig. 11-5). Most Level I and II centers are in the major metropolitan areas and large towns. Level III through V centers are much more randomly dispersed but clearly clustered in certain states. The systems in these states have been active in development and verification of lower level trauma centers; however, this may not be necessary at the Level III to V hospitals. In a study comparing two western states, Washington and Oregon, there was no improvement in outcomes between Level III, IV, and V trauma centers that were formally categorized or verified and those that were not.[66] Inclusion and active participation may be all that is required and may be attractive to hospitals that do not want to have the cost of verification. Preexisting structures, whether they are at the hospital corporation level or at a higher level such as the critical access hospital system (Fig. 11-6), may also be used to develop a trauma system that is inclusive of even the smallest hospitals and helpful to rural communities. The state of Kansas, a largely rural state, has used the existing Medicare-supported critical access hospital system and its referral pattern to support a trauma system that covers the entire state. Ten in- and out-of-state support hospitals and six designated trauma centers support the 83 critical access hospitals.[67] There may, however, be limitations to this system. In a nationwide study over 5 years of patients hospitalized with moderate to major traumatic injury in nonfederal, short-stay rural hospitals with annual discharges of 1500 or fewer patients, in-hospital death was more likely among patients treated at the nondesignated hospitals with fewer than 500 discharges per year than among patients treated at similar trauma-designated hospitals.[68]

The role any given hospital will play is individualized to personnel and resources available and is likely to be variable across the region. In the 14 rural hospitals in New South Wales, Australia, general and orthopedic surgeons provided trauma care. Resident subspecialty surgeons were available in 43%, and half of hospitals had a formal hospital trauma team. In hospitals without a team, 86% stated that there was a lack of personnel to provide 24-hour coverage. In 71% of the hospitals, there was only a single doctor available after hours. The majority of hospitals had plain x-ray equipment, blood products, ultrasound, and CT, although always on an on-call basis after hours. All hospitals had the capability to maintain ventilated patients, averaging two ventilated beds per hospital. An average of two trauma patients per hospital per month were transferred to a larger institution.[69] The variability of this largely rural area could lead to gaps in care for the trauma

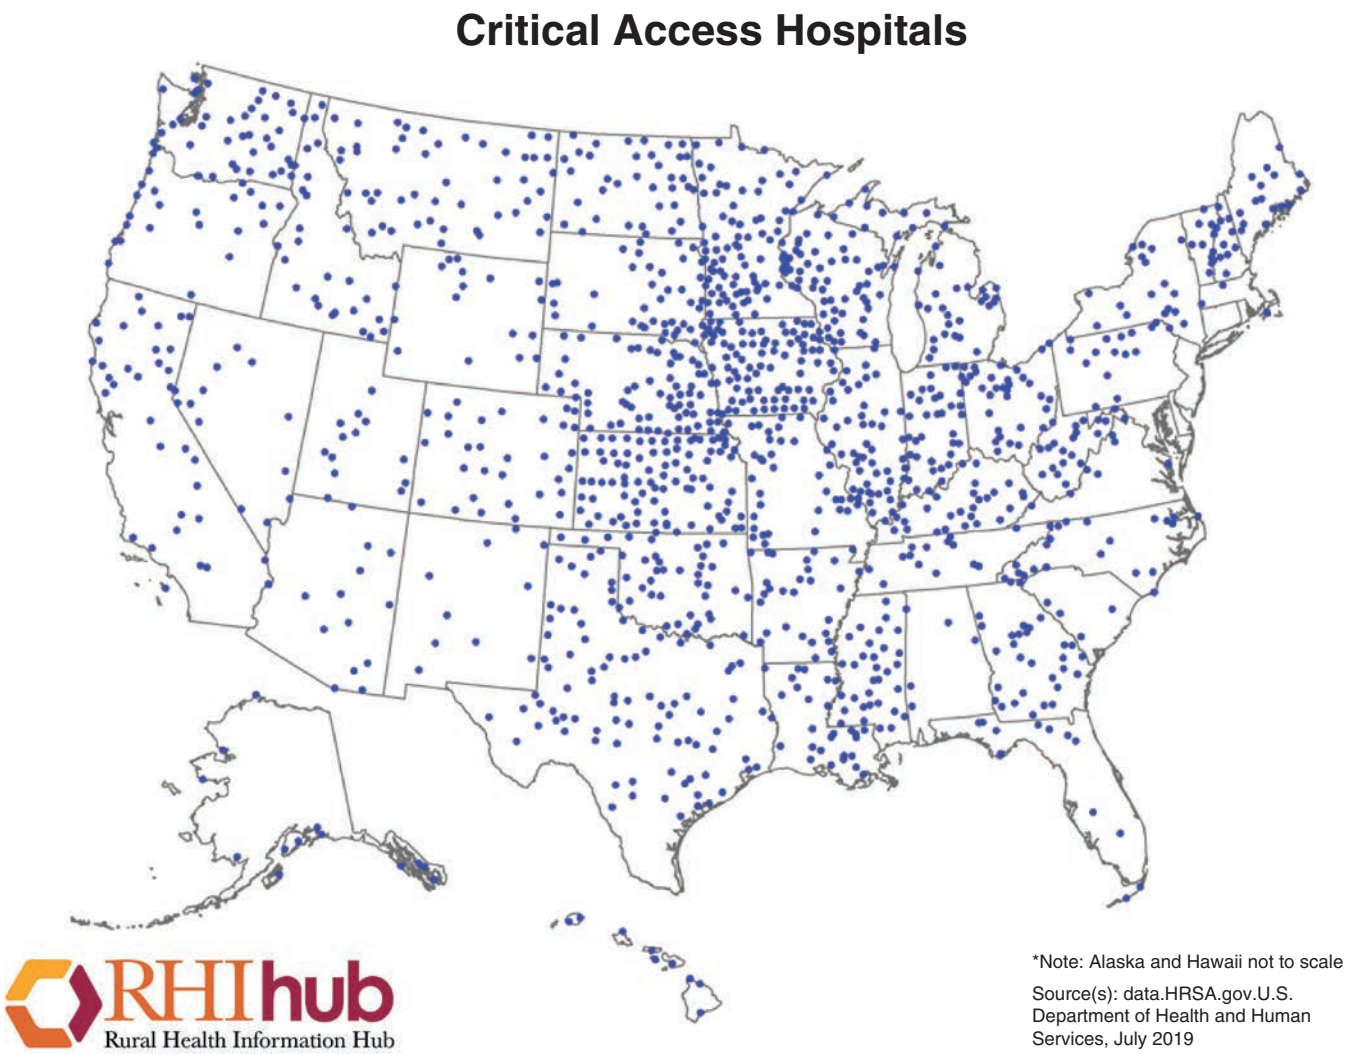

FIGURE 11-6 Critical access hospital system may also be employed to develop a trauma system that is inclusive of even the smallest hospitals. (HRSA Data Warehouse, US Department of Health and Human Services, November 2017. Reproduced with permission from the Rural Health Information Hub.)

patient. This is best managed by a system that has extensive knowledge of the resources across the system and can facilitate communication across the spectrum of prehospital and hospital care.

The spectrum of care that can be provided at lower level centers is subject to variation from hospital to hospital as well as within any given hospital. Whereas most operative procedures at rural Level III trauma centers will be orthopedic, the general surgeon may be called on to carry out lifesaving damage control procedures in patients who will be transferred on to a higher level of care. A study of the Missouri Trauma System showed that this could be performed safely.[70] Some hospitals with appropriate staffing and monitoring capabilities may also be employed to decrease unwarranted and costly transfers of patients who may be served better closer to home and family. In one study, patients with traumatic brain injuries admitted to a rural hospital without neurosurgical capability over a 2-year period had the scan reviewed via teleradiology at the regional neurosurgical referral center. The neurosurgeon on call and the trauma surgeon in the rural hospital then decided whether to transfer the patient to the neurosurgical referral center. Of 209 trauma victims with neurosurgical pathology in need of hospitalization, 126 (60.2%) were immediately transferred, whereas 83 of the patients (39.7%) were hospitalized in the rural Level II trauma center for observation. Only two patients (2.4%) failed the intent to treat locally and required transfer to the regional center later.[71]

Another function of the lower level center in the rural community could be to prevent overutilization of a single Level I or II center by avoiding the unnecessary transfer of trauma patients with relatively minor injuries. Rural patients can also suffer from a poorly integrated system because of an increased reliance on the rural trauma center. One such center in rural Iowa saw a twofold increase (11.8% to 21.2%) in the operative care of routine fractures in patients with Medicaid that could have been taken care of at a closer hospital. Of interest, the average distance traveled by patients with

simple injuries increased over time from 35.2 to 51 miles, and the distance was greater for Medicaid patients (59.7 vs 42.6 miles).[72]

One of the difficulties for personnel in lower trauma volume hospitals is the maintenance of proficiency. There have been several new efforts at addressing this problem. In one study, trauma providers from the same hospital always trained together as a team, consisting of one to three surgeons, two to three operating room nurses, an anesthesiologist, and one to two nurse anesthetists. The 19-hour course consisted of two interactive scenario-based lecture modules integrated with a hands-on operative experience on a live porcine model. Participants in the course reported improvement in proficiency with damage control procedures.[73] This method seems applicable to the Level III center, but the same issue exists at the lower level hospitals that do not even provide operative services.

The American College of Surgeons developed the Rural Trauma Team Development Course (RTTDC) for these institutions. This course is aimed at small hospitals without surgical capability and only nonsurgical personnel to treat the occasional trauma patient. It focuses on stabilization and transfer to definitive care. In one study, over 100 nurses trained in the RTTDC course found the course helpful. Over 95% felt the course increased their trauma knowledge, and there was a significant improvement in 13 of the 19 knowledge items tested. The RTTDC education intervention was an independent predictor in reducing time to transfer in the emergency department by 28 minutes. This was sustained at 6 months, with the emergency department time being 29 minutes less than the baseline.[74]

In another cohort, rural Level III and IV centers that used the RTTDC course were able to decrease the time from arrival to decision to transfer from 114 minutes to 95 minutes and the decision time to transfer to squad arrival time from 75 minutes to 65 minutes. This was further improved with the addition of training in effective communication techniques, trimming the arrival to decision time to 77 minutes and the decision to squad arrival time to 31 minutes.[75]

The RTTDC course can be taught by anyone with ATLS training and is a useful bridge for Level I and II centers to build ties with their rural counterparts. In one nonprofit hospital system in Colorado, a hub trauma center developed a trauma outreach team consisting of a systemwide medical director, a service line director, and a trauma nurse coordinator. They worked with a rural trauma program manager to facilitate integration of the rural center into the system. These efforts included consultation and support, education, connectivity, and expanded services and referrals. A total of 18 rural hospitals were initiated after 62 interventions/meetings.[76] This educationally based spoke-and-hub relationship has also been shown to improve communication within the system. A Level I trauma center in middle Tennessee taught the RTTDC course to six surrounding rural hospitals. The RTTDC group experienced an overall 61-minute reduction in length of stay in the referring hospital emergency department compared with the control group. The RTTDC group also showed a 41-minute reduction in time to call for transfer compared with control hospitals that did not participate in the course.[77]

As rural areas expand, distances lengthen, and resources become sparser, it becomes more difficult to maintain integration of a system. This is where the central command structure becomes essential. Knowing the strengths and weaknesses of the components of the system serving the rural population and integrating this with knowledge of weather, terrain, and limitations of available equipment are tested most in the rural environment. These are not constants across regions and systems. In one study over 2 years in adults with an ISS of 12 or greater who were transported to a Level I trauma center, air ambulance was faster than ground transport, with helicopters overall superior to fixed-wing aircraft, but limited by a 225-km (140-mile) range.[78] This may not be true, however, in another region with another set of circumstances. Over a 6-year period in Western Australia, a total of 1275 major trauma patients were treated at the Royal Perth Hospital, of whom 566 (44%) were from rural areas. For rural patients, the Royal Flying Doctor Service was responsible for 440 transfers (79%), of which 83% had a doctor and a nurse escort. A total of 450 rural patients (93%) were transferred within 24 hours of trauma, although the mean transfer time was over 9 hours.[79] However, what is possible in this fairly flat, arid region of a wealthy country may not be applicable or useful in a mountainous, poor region like Nepal.

An example of complicated and multifaceted trauma system coordination and patient flow would be the state of Hawaii. The only island state in the United States presents a challenge that the state system planners have met successfully. A patient with multisystem trauma, injured on the mountainous north coast of Kauai, would be met by local EMS personnel trained in mountain and water rescue and transported by ground to a predetermined rendezvous point. The patient would then be transferred to a helicopter transport team. Helicopter transport is necessary to get to the island's major city in a timely fashion. The single coast road is circuitous because it must traverse the island's perimeter and is frequently congested, whereas the island's interior is impassable due to its mountainous character. Once there, the patient would receive definitive or stabilizing treatment at the island's Level III trauma center depending on specific injuries. If the patient required specialty care such as neurosurgical intervention or consultation, he or she would be flown to the state's only Level II trauma center in Honolulu, Oahu, by a fixed-wing aircraft (Fig. 11-7).[80]

EPIDEMIOLOGY

Rural Disparities in Injury Rates

The National Center for Health Statistics published county-level injury rates in the 2001 *Urban and Rural Health Chartbook*, in which counties were classified according to their urbanization level (Fig. 11-8). The unintentional injury mortality rate for the most rural counties was 54.1 per 100,000 population, a rate almost two times higher than that observed in large metropolitan counties.

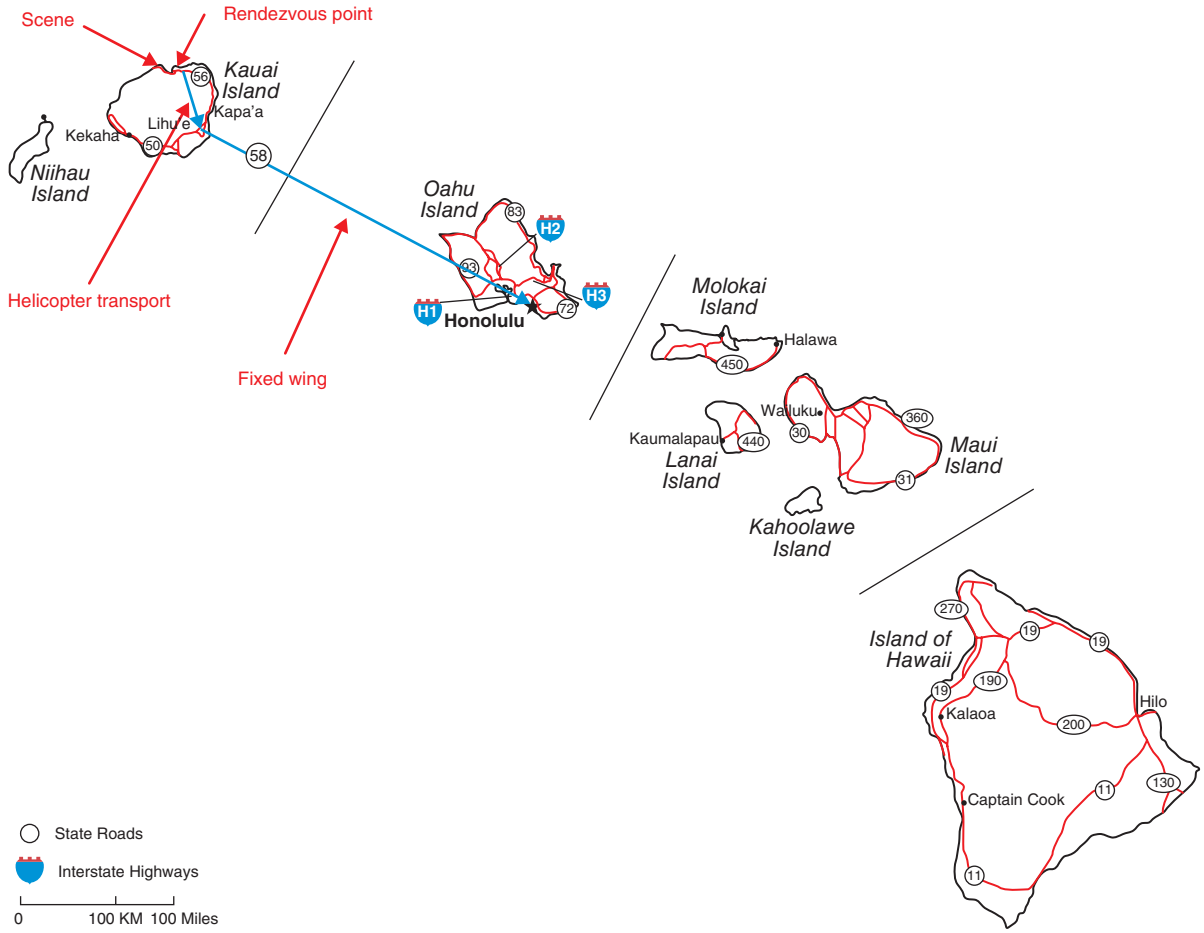

FIGURE 11-7 Hawaii islands trauma system.

The *Urban and Rural Health Chartbook* revealed similar trends in suicide deaths (Fig. 11-9). Relative to large fringe metropolitan counties, suicide death rates were 31% and 43% higher, respectively, in nonmetropolitan counties adjacent and not adjacent to small cities. Disparities were greatest among male residents of the western United States, whose suicide rate was 80% higher in rural areas than in metropolitan areas.[81]

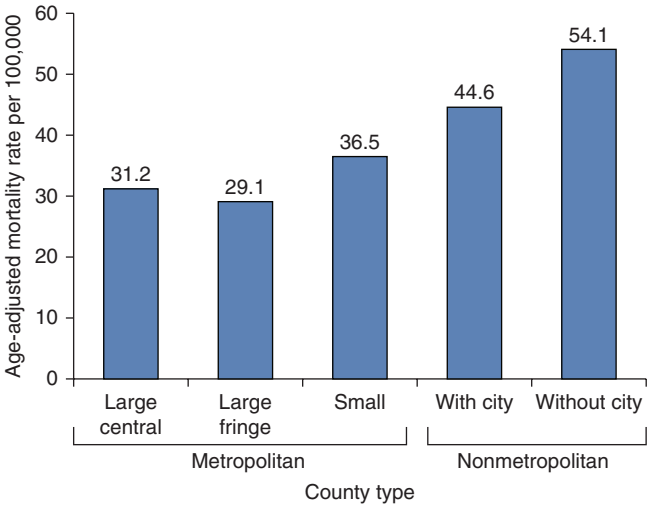

FIGURE 11-8 Unintentional traumatic injury death rates by urbanization level, 1996 to 1998.

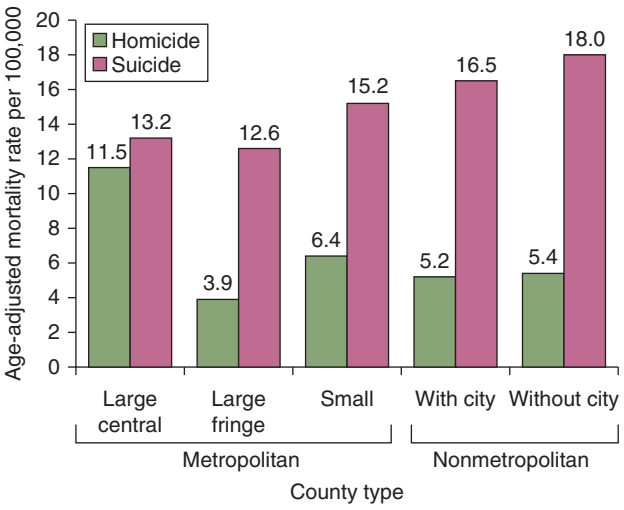

FIGURE 11-9 Homicide and suicide death rates by urbanization level, 1996 to 1998.

Although rates of both violent and property crime decreased from 1993 to 1998, this decrease occurred at a greater rate in urban and suburban areas than in rural areas.[82] This trend could indicate that prevention programs designed for urban populations have not been applied or have not been effective in rural areas.

Individual studies examining different types and mechanisms of nonfatal injury provide some information regarding rural disparities. An analysis of data from the Colorado Behavioral Risk Factor Surveillance System showed that the odds of a self-reported nonfatal injury were 30% higher among rural than among urban residents.[83] In the case of rural residents living in remote areas, the odds increased to 64%. Rates of traumatic brain injuries were shown to be higher in rural than in urban populations.[84] However, other studies that examined types of injuries, including overall fractures and hip fractures, showed rates to be lower in rural than in urban populations.[85,86] Studies have indicated that overall rates of serious firearm injuries are consistently higher in urban areas[87,88] but that unintentional firearm injury rates are higher among rural populations, perhaps driven by higher proportions of gun ownership.[89] At least one study has shown that safe storage of firearms in the home does not differ according to urban/rural status.[90]

Rural Disparities in Selected Mechanism of Injury

MOTOR VEHICLE INJURIES

Much of the increase in rural injury death rates is related to motor vehicle crashes. According to the National Highway Traffic Safety Administration, rural fatal crashes account for 61% of all traffic fatalities but only 39% of vehicle miles traveled, and the rural-urban difference is increasing over time. Crash-related mortality is inversely associated with population density and per-capita income. Analyses of motor vehicle crashes in several states have shown that fatality rates in the most rural counties are almost double those observed in urban counties.[91-97]

Certain types of crashes, such as those involving motor vehicle collisions with farm machinery, are unique to rural environments.[98] These crashes most frequently involve slow-moving tractors and are exacerbated by the high speeds at which vehicles often travel on rural roadways. In addition, other types of crashes, such as those involving all-terrain vehicles and snowmobiles, are more common in rural areas.

Roadmap Anatomy. Many factors may contribute to the increased fatality rates after motor vehicle crashes. Unlike interstate roads, rural highways are typically composed of two narrow lanes and do not have crash reduction features such as divided traffic streams, controlled vehicle entrances and exits, graded curves, skid-reducing surfaces, large lane and median widths, and lighted traffic signs. Head-on collisions, which most frequently occur when traffic streams are not separated and which are the most likely of all crash types to cause fatality and severe injury, account for 17% of fatal rural crashes and 9% of fatal urban crashes.[99]

Need for More Injury Prevention. Behavioral factors also differ according to population density. Rural residents are less likely than urban residents to wear seat belts or to use child safety seats,[91,94,95] and they are more likely to consume alcohol.[100] In addition, enforcement of traffic safety laws, such as laws against drunk driving and speeding, may be limited in some rural areas because of the reduced density of traffic enforcement officials.

WORK-RELATED INJURIES

Occupational fatality rates after trauma are higher among rural than urban populations. For example, in comparison with the national average, injury mortality rates in the construction industry are 40% higher in predominantly rural states.[101] Many of the most dangerous occupations are found in rural areas, most notably mining and agriculture.[102-105] In 2002, the mining industry had the highest occupational fatality rate, 29.1 per 100,000 workers, followed by agriculture, at 21.0.[106] Mining workers suffered approximately 10,000 disabling injuries, and agricultural workers experienced approximately 150,000 such injuries. Each year, approximately 10% of farmers are injured while working.[107,108]

Agricultural Injuries. Major initiatives established by the National Institute for Occupational Safety and Health have identified agricultural risks and potential approaches to prevention.[109,110] Research on agricultural injuries indicates that major injury risks are linked to working with animals and machinery, especially tractors.[111-114] Injuries are often multiple and severe, resulting in substantial disability, and compensation is less available for farm injuries than for non–farm-related occupational injuries.[115-117]

In addition to agricultural work, farms involve hazards for the entire family, because work areas and work tasks are so closely tied to living and play areas. Farm injury risks are similar among men and women when number of hours of exposure to farm tasks is controlled, and children and elderly farm residents are at especially high risk for farm-related injuries.[118-122] Occupational hazards on farms, such as animals and machinery, pose risks to children whether they are working or playing. In 2003, the National Children's Center for Agricultural Health and Safety led an effort to establish consensus development initiatives and generate work guidelines.

FIRE INJURIES

Fire death rates per capita are 36% higher in rural than in urban areas. Residential fires may be more common in rural homes because of older home construction and use of more risky heating sources. Heating is the leading cause (36%) of rural home fires, followed by cooking (13%). In urban areas, the situation is reversed, with cooking the leading cause of home fires (25%) and heating the second leading cause (16%).[123]

Residents of rural areas may be less likely to escape from a fire once it has started because of poor home fire protection. Smoke alarms reduce the risk of dying in a fire by half and reduce the risk of having a reportable fire by 75%.[124,125] Unfortunately, 73% of rural home fires occur in homes without operational smoke detectors. In the United States, the percentage of urban homes with smoke detectors is 92.9%, whereas the corresponding percentage of rural homes is 85.8%. Furthermore, the percentage of homes that experience a fire and have a working smoke alarm is 41.8% in urban areas, but only 20.8% in rural areas. The isolation of rural homes may also cause delayed detection and longer response times on the part of fire and emergency service personnel.[126]

TREATMENT INTERVENTIONS IN RURAL TRAUMA CENTERS

Definitive Surgery

Under most circumstances, a stabilizing procedure can be conducted and completed in conventional fashion such that no further treatment will be required for that particular problem.

Hemorrhage Damage Control

Key components during this phase of care must focus on hemorrhage control and preservation of blood volume. This involves a balance between effective low-volume hemostatic resuscitation with use of blood or plasma in combination with maneuvers that will preserve blood volume using hemorrhage control for compressible and noncompressible hemorrhage. For volume preservation in compressible hemorrhage, tourniquets, hemostatic dressings, pelvic binders, and junctional tourniquets have a great impact on survival when applied early before transfer of the patient. For patients with noncompressible hemorrhage, data are currently lacking for use of retrograde endovascular balloon occlusion of the aorta catheters, experimental ResQ foam (Arsenal Medical, Watertown, MA), preperitoneal packing, and Abdominal Aortic and Junctional Tourniquets. Because of these limitations, a potential solution in rural noncompressible hemorrhage control is the adaptation of an echelon system of care. This is where rural damage control interventions, as described earlier, can be incorporated as a bridge in care.

Damage control (see Chapter 42) is a strategy for the staged management of severe trauma using a modified operative sequence of rapid lifesaving maneuvers followed by physiologic stabilization and planned reoperation for definitive repair. Introduced in the early 1980s, damage control has gained wide acceptance in the past two decades as the "great equalizer" of trauma surgery, allowing surgeons with limited experience or resources to tackle severe truncal trauma in both military and rural settings. The wide applicability of the damage control approach has led to the development of several operative trauma courses, such as the Definitive Surgical Trauma Care Course (International Association for Trauma Surgery and Intensive Care) and Advanced Trauma Operative Management (American College of Surgeons). Even though a damage control operation involves the entire operating room team, the previously mentioned courses focus on operative techniques for the individual surgeon that can make a difference in rural trauma care.[127]

Damage control operations followed by temporary closure of the abdomen have been described for a variety of truncal injuries with an emphasis on limiting time in the operating room and limiting the triad of acidosis, hypothermia, and coagulopathy.[128-130] Candidates for these desperate measures typically have an overwhelming constellation of injuries. Rural surgeons caring for such patients can apply the same principles. Occasional patients will have such complex injuries that definitive management exceeds the technical abilities or resources of the local surgeon and hospital, but may be amenable to temporizing maneuvers, followed by rapid transfer in an aircraft equipped as an airborne intensive care unit.[131] Examples include packing of the liver for complex hepatic injuries; peritoneal cleansing, hemorrhage control, and stapling or rapid suture of multiple bowel perforations; temporary abdominal closure; and abbreviated thoracotomy, hemorrhage control, and temporary chest closure for patients with extensive pulmonary and thoracic vascular injuries.[132] If interventional radiology is not available locally, patients with unstable pelvic fractures may benefit from application of external fixators prior to transfer.

Neurosurgical Damage Control

Injury to the brain remains the single greatest source of morbidity and mortality for trauma victims. Many patients sustain their closed head injuries far from the nearest neurosurgeon, and time becomes the enemy. Under most circumstances, the only option is to minimize secondary brain injury with appropriate ventilatory and pharmacologic maneuvers and expedite transfer.[133,134] A small proportion of these patients, however, will have lesions amenable to surgical drainage. While rural hospitals generally lack neurosurgical services, most hospitals in the United States now have CT scanners. General surgeons can be trained to perform burr holes and/or limited craniotomy for decompression and hemorrhage control in patients with epidural or subdural hematomas noted on a CT scan.[135,136] When a patient with an injury to the brain shows signs of rapid deterioration and a delay of more than 90 minutes to definitive neurosurgical care is anticipated, consideration should be given to emergency decompression of the hematoma.[137] Refer to Tables 11-1 and 11-2 for appropriate operative skills for general surgeons and indications and performance of limited craniotomy by rural surgeon.

Damage Control Resuscitation

Hemorrhage is responsible for one-third of all traumatic deaths. Recent research has identified the coagulopathy of trauma as a significant component and risk factor for

TABLE 11-1: Appropriate Operative Skills for General Surgeons[a]

Establish surgical airway
Closure of evisceration
Splenectomy or splenorrhaphy
Hepatic resection/debridement; insertion of perihepatic packs
Closure of injuries to gastrointestinal tract
Shunting of truncal and extremity vascular injuries or repair
Control of hemorrhage from open extermity fractures with or without mangling
Reduction of dislocation of joint

[a]Options may be limited depending on anesthesia, blood bank, availability of surgical assistant, and availability of intensive care unit.

hemorrhagic death. Current treatment priorities include minimization of the use of crystalloid-based resuscitation in favor of early blood component–based resuscitation that includes plasma and platelets in equal ratios with packed red cells. These in-hospital practices, termed *damage control resuscitation*, are widely used for both battlefield and civilian resuscitation after traumatic injury. Initiation of the tenets of damage control resuscitation in the rural environment has the potential to reduce downstream complications attributable to hemorrhage by intervening close to the time of injury, before the development of coagulopathy, irreversible shock, and the ensuing inflammatory response.[138-141]

Recent studies have evaluated the use of tranexamic acid (TXA) in the trauma patient to treat hyperfibrinolysis. The CRASH-2 study was an international, randomized, placebo-controlled study investigating the effects of TXA on civilian trauma patients. All-cause mortality was reduced by 1.5% within the TXA group, as was the risk of bleeding-specific deaths. Follow-up studies found that this mortality effect was only present when TXA was administered within 3 hours of injury. Patients receiving TXA beyond 3 hours from injury had an increase in mortality. Additional support for the use of TXA was provided by the Military Application of Tranexamic Acid in Trauma Emergency Resuscitation (MATTERs) study. From this study, TXA was contraindicated if the time since injury was greater than 3 hours or in the case of an isolated traumatic brain injury.[142-147]

When analyzing its use in rural trauma, Bardes et al[148] demonstrated no benefit of TXA use mostly due to prolonged transport times. Of the 400 patients who were evaluated, 54% met indications for TXA, and 14% of these received TXA. In those with an indication for TXA, 30.4% were ineligible due to arrival beyond 3 hours from time of injury. There was no difference in TXA indications between the 265 patients arriving from the scene and the 135 patients who were transfers (73 vs 144, $P = 1$). As expected, transfers were more likely to arrive beyond the 3-hour window (59 vs 7, $P = .001$). Mortality for patients treated with TXA was 12.5%, and this was not significantly different from the 19% mortality rate in patients not treated with TXA.[148]

TABLE 11-2: Indications and Performance of Limited Craniotomy by Rural Surgeon

A general surgeon trained in indications for and technique of burr holes with limited craniotomy
Traumatic brain injury with lateralization signs and *threatened herniation*
Surgical lesion present on CT scan
Consultation with, and patient acceptance by, a neurosurgeon at the receiving trauma center
Limited craniotomy for decompression and hemorrhage control
Immediate transfer to definitive care

CT, computed tomography.

LIMITATIONS OF RURAL RESOURCES AND BENEFIT OF EVOLVING TECHNOLOGIES

Prehospital Limitations

An effective EMS program is vital for proper trauma care. In rural areas, the configuration of such systems varies and may include fire department–based, hospital-based, or freestanding entities. Personnel may be volunteers, salaried, or partially subsidized. Most are trained to the EMT-Basic level, which permits noninvasive interventions to reduce the morbidity and mortality associated with acute, out-of-hospital medical and trauma emergencies. Fewer emergency medical personnel have advanced training (prehospital trauma life support, paramedic), which is often difficult to maintain because individual EMS personnel see relatively few trauma patients per year. Additionally, recruiting and retaining emergency medical personnel in rural areas are difficult because of low wages, lack of training opportunities, and the need to cover a broad geographic region.[149–154]

The difficult terrain in rural areas combined with a scarcity of emergency medical personnel contributes to higher mortality rates and longer transport times to a care facility.[149–152] In addition, response times, scene times, and transport times have been shown to be significantly longer in rural areas.[150,151,153,155] Numerous studies have confirmed that rural death rates after motor vehicle collisions are twice as high as those occurring in urban environments.[150,156,157]

Communications

A number of improvements in communication between prehospital providers and health care facilities have been made in recent years. Upgrades to UHF and VHF radios and the addition of the 800-MHz bandwidth have allowed communications between multiple first-responder agencies. Despite improvements in radio communications, EMS providers often find themselves out of contact with the medical director, emergency department personnel, or the dispatcher because of challenging terrain rendering the radios unusable.

Cellular technology has improved prehospital provider communication in many areas; however, this, too, is limited in mountainous terrain.[149]

CONCLUSION

Many of the problems discussed in this chapter can be diminished with proper training, triage, and the development of trauma systems.[158] Esposito et al[159] evaluated preventable death rates and the nature and degree of inappropriate care before and after the implementation of a voluntary trauma system in a rural state. Preventable death rates decreased from 13% to 8% after implementation of a trauma system.

Having a regionalized trauma system potentiates appropriate transfers from the nontertiary hospital to the trauma centers. A study of 42 rural nontertiary hospitals in Oregon demonstrated that early transfer of patients to a tertiary center was associated with a lower mortality. The authors concluded that recognition and early transfer of at-risk rural trauma patients improve survival in a regionalized trauma system.[160] Developing a regionalized system with coordinated care and predetermined referral patterns facilitates interfacility transfers, contributes to improved outcomes, and improves efficiency. Developing these relationships promotes bidirectional communication that can be augmented with newer technology such as shared health information systems, back-transfer agreements, and telemedicine.[161]

The relationships developed in a regionalized trauma system also become a foundation for educating the providers in a rural hospital or prehospital environment. Some states have mandated that all prehospital providers will meet the standards of paramedics and be trained in Prehospital Trauma Life Support (National Association of Emergency Medical Technicians/American College of Surgeons).[149] In-hospital providers who are often family physicians, internists, or advanced practice providers can also benefit from these educational relationships.

New technology has the potential to increase education and improve communication between the rural hospitals and their tertiary referral centers. Telemedicine has the potential to aid in the decision to transfer critically ill patients and allow the rural provider to obtain advice on patient management.

In one study of six rural hospitals in upstate New York and Vermont, 80% of referring emergency physicians found direct telemedicine communications with a trauma surgeon at a distant Level I trauma center to be helpful. It was thought to facilitate care and transfer and, in almost 10% of cases, felt to be lifesaving.[162] The implementation of a telemedicine system with multiple rural hospitals feeding into a Level I trauma center decreased transfer time to definitive care from 13 hours to 1.7 hours.[163]

Telemedicine can be beneficial for prehospital providers, as well. In a simulated scenario, telemedicine to a moving ambulance was associated with better process measurements. Recognition rates for key signs, processes, and interventions were significantly higher in ambulances guided by physicians via telemedicine versus those that previously were not.[164]

Telemedicine has the ability to enhance the care of trauma patients in austere environments by bringing advanced skill and experience to injured patients who will have delays in transport to definitive care.[165] After the institution of a telemedicine program with a Level I trauma center, both providers at the rural hospitals and at the Level I trauma center receiving patients thought the quality of care was improved. Of the 41 consults over 30 months, three were felt to be lifesaving.[166]

Because of the extensive distances patients often must travel, follow-up can be difficult for trauma patients. In one study of 11 rural counties surrounding a Level I trauma center in Kentucky, patients were examined via telemedicine using an electronic stethoscope and a close-up imaging instrument. They were interviewed with the assistance of a nurse and x-rays performed at the site and viewed via a secure high-resolution internet connection. Patient and physician surveys indicated a high degree of satisfaction with the telemedicine clinic visit. In 15 of 22 patients, no further clinical follow-up was arranged. The differences in travel distances and times for an appointment at the tele-trauma clinic versus an appointment at a Level I trauma center were significant. The average and median durations of the appointments were both 14 minutes.[167]

As cellular technology has become more ubiquitous, expensive telemedicine systems may no longer be needed to communicate between facilities. In a study from Arizona, trauma surgeons were able to increase the number of tele-trauma consultations by providing secure smart phones to rural emergency departments. They concluded that smart phones may be an answer to meeting both the educational and clinical needs of rural facilities. Smart phones may replace the older stationary telemedicine technology.[168]

GENERALIZED APPROACHES TO THE TRAUMATIZED PATIENT

12

Disaster and Multiple/ Mass Casualties

Susan M. Briggs

KEY POINTS

- The objective of disaster medical care is the "greatest good for the greatest number of victims."
- The Incident Command System/Incident Management System is the accepted disaster management system for all disasters, regardless of size or etiology.
- Disaster management teams are based on functional capabilities, not titles.
- The goal of disaster response is to reduce the number of survivors from the disaster who subsequently die (critical mortality rate).

INTRODUCTION

The prehospital and hospital management of the medical effects of contemporary disasters, whether natural or human-made, is one of the most significant challenges facing trauma providers today. No one can predict the time, location, or complexity of the next disaster. The demands of disaster care have changed over the past decade in the types of threats, the scope of care, and the field of operations (Fig. 12-1). Many of today's disasters occur or result in austere environments. Access, transport, resources, and other aspects of the physical, social, political, or economic environments may impose severe constraints on the adequacy of immediate care to victims of the disaster.[1-3]

Trauma providers must be prepared to respond to both mass casualty incidents and multiple casualty events.[1,4] **Mass casualty incidents (MCIs)** are events causing numbers of casualties large enough to disrupt the health care services in the affected community or region. *Demand* for resources always *exceeds the supply* of available resources in an MCI. This is in contrast to **multiple casualty events (MCEs)** in which medical resources are strained (prehospital and/or hospital resources) but not overwhelmed. Disasters involving weapons of mass destruction (WMD; biological, chemical, and radioactive), accidental or intentional (terrorism), are increasing in frequency and present unique challenges in the delivery of care to victims by trauma providers.[1,5,6] Active shooter incidents resulting in multiple casualties have been on the rise throughout the world, significantly increasing the challenges for trauma providers and trauma centers.[7-10]

Disaster trauma care is *not* the same as conventional trauma care. Disaster care requires a fundamental change (**crisis management care**) in the care of disaster victims to achieve the objective of providing the "**greatest good for the greatest number of victims**."[1-3]

EPIDEMIOLOGY OF DISASTERS

Natural disasters may be classified as sudden-impact (acute) disasters or chronic-onset (slow) disasters.[1,11] Sudden-impact natural disasters generally cause significant mortality and morbidity immediately as a direct result of the primary event (eg, earthquakes). Traumatic injuries such as crush injuries and burns are common injuries in sudden-impact disasters. Chronic-onset disasters (eg, droughts) cause mortality and morbidity through prolonged secondary effects such as infectious disease outbreaks, dehydration, and malnutrition.

Disasters involving WMD, whether accidental or intentional (terrorism), are a significant challenge for medical providers for several reasons[1,5,6]:

- WMD have the potential to produce casualties in numbers large enough to overwhelm health care systems, including surgical capabilities.
- WMD may produce large numbers of **expectant** victims (victims not expected to survive).
- WMD may produce a **contaminated** environment. Trauma providers must be able to perform triage, initial stabilization, and possible definitive surgical care outside traditional health care facilities.

FIGURE 12-1 Haiti earthquake, 2011.

- WMD produce significant numbers of **psychogenic** casualties, greatly complicating rescue and triage efforts.

The spectrum of agents used by terrorists is limitless and includes conventional weapons, explosives, and WMD.[12-16] Over 70% of terrorist attacks involve the use of explosive weapons. Improvised explosive devices (IEDs) are a particular concern for trauma providers. Such incidents present a significant challenge due to the complexity of injuries (primary, secondary, tertiary, and quaternary blast injuries) (Fig. 12-2). Responders must also be aware of the potential for secondary strikes directed at harming medical personnel. Terrorists do not have to kill people to achieve their goals. They just have to create a climate of fear and panic to overwhelm the health care system (examples: Sarin/anthrax attacks).

DISASTER PREPAREDNESS

Disaster preparedness is the key to an effective disaster response. Preparedness is the responsibility of every health professional regardless of specialty and all health care facilities. A key concept in disaster management is the **all hazards** approach to disaster preparedness. The all hazards approach is based on a single plan for all disasters regardless of etiology. The plan then has branch points that address specific risks.[1,4,17]

FIGURE 12-2 Improvised explosive device.

Disaster planning, whether at the local, regional, national, or international level, involves a wide range of individuals and resources. All disaster plans should involve key medical and public health organizations as well as public safety officials (eg, fire, police). Disaster plans must take into account special needs populations (children, the elderly, long-term care facilities, the disabled [both physically and mentally], the poor, and the homeless). These groups are often neglected in disaster planning.

Disaster preparedness activities consist of making an organization aware of possible disaster situations, training personnel, and purchasing equipment to support their response activities. It is important to determine the balance between what is needed in disasters versus what is available in terms of personnel and equipment in a specific organization or facility before a disaster occurs. Disaster preparedness must include practical drills, not just tabletop exercises, to ascertain the true magnitude of system problems.

Hospital preparedness involves the activities a hospital undertakes to identify specific environmental and physical risks to their facility and the necessary resources and personnel to respond to both internal or external disasters. It is important for hospitals to determine their own thresholds, recognizing that their disaster plans must address both MCIs and MCEs. Hospitals should be able to care for an increase in patient volume higher than normal (estimated to be 10%–20%). It is important to distinguish *surge capacity* (resources such as beds, ventilators) from *surge capability* (qualified personnel to staff the additional resources). All disaster plans must include training in disaster response appropriate to the skills of the individuals being trained and to the specific functions they will perform in a disaster. Cross-training of functional capabilities is important in hospital disaster preparedness. Hospital preparedness should include the following[1,4,17]:

- Security plans, including hospital lockdown if necessary
- Designation of triage and decontamination sites outside the hospital
- Designation of a site for the Incident Command Center separate from the emergency department
- Procedure for initiating hospital Incident Command System
- Procedure for activating the hospital disaster plan, including procedures for notifying off-duty personnel
- Establishment of redundant communication systems in the event of loss of telephone landlines and cellular circuits
- Storage for equipment, supplies, or special resources that may be necessary based on local hazards (sufficient to sustain hospital operations for a minimum of 72 hours)
- Plan to ensure unidirectional flow of patients from the emergency department to the operating room, intensive care unit (ICU), and inpatient units
- Development of predisaster agreements for transporting victims or inpatients to other facilities if necessary

- Training in nonmedical and medical aspects of disaster management for medical providers
- Designation of a site for patients with minor or no medical conditions and equipped with appropriate supplies/equipment
- Designation of a public information center to provide timely briefings to press, hospital personnel, and families

KEY PRINCIPLES OF DISASTER RESPONSE

Lessons from previous disasters are important in distinguishing myths (misconceptions) from facts (evidence-based data). Key principles of disaster response are the same regardless of the location of the disaster (prehospital and hospital).[18-22]

Principle 1

Medical providers cannot use traditional command structures when participating in disaster response. The Incident Command System (ICS)/Incident Management System is a modular/adaptable system for all prehospital and hospital incidents and facilities and is the accepted standard for all disaster response.[1,4,17] The Hospital Incident Command System (HICS) is an adaptation of the ICS for hospital use, allowing effective coordination in disaster preparedness and response activities with prehospital, public safety, and other response organizations. The trauma system and trauma centers are important components of the ICS.

Functional requirements, not titles, determine the ICS hierarchy (Fig. 12-3). The organizational structure of the ICS is built around five major management activities (incident command, operations, planning, logistics, and finance/administration).[1,4,17] Key activities of the five categories are listed in Table 12-1.

The structure of the ICS is the same regardless of the nature of the disaster. The difference is in the particular expertise of key personnel depending on the etiology of the disaster. An important part of disaster planning is the identification of the incident commander and other key positions *before* a disaster occurs (24 hours a day, 7 days a week). Each person within the command structure should supervise *only* three to seven persons. This is quite different from conventional prehospital/hospital command structures. All medical providers must adhere to the structure of the ICS in order to integrate successfully into the disaster response team and avoid many negative consequences including:

- Death of medical personnel due to lack of safety and training
- Lack of adequate medical supplies to provide care
- Staff working beyond their training or certification
- Lack of coordination

FIGURE 12-3 Incident Command System.

TABLE 12-1: Organizational Structure of the Incident Command System

- **Incident Command (IC):** Maintains overall responsibility for the disaster response and sets objectives and priorities for the disaster response.
- **Operations Section:** Directs the activities of all organizations responding to the disaster, including medical personnel.
- **Logistics Section:** Provides resources and logistical support to meet disaster needs.
- **Planning Section:** Develops the incident action plan (plan to carry out the objectives of the disaster response), monitors progress, and makes recommendations for further operational response.
- **Finance/Administration Section:** Monitors costs, manages legal affairs, and maintains personnel records.
- The incident commander is assisted by **liaison officer**, **safety officer**, and **public information officer**.

Principle 2

All disasters are *not* different. Disaster response includes basic concerns (similar to the ABCs [airway, breathing, circulation] of trauma care) that are the same in all disasters (Table 12-2). The difference in disasters is the degree of disruption of medical and public health infrastructures and the amount of outside assistance (regional, national, international) that is needed to meet the needs of disaster victims. Rapid assessment by experienced disaster personnel will determine which functional capabilities (public health and medical) are needed to meet the demands of the *acute* phase of the disasters.

Principle 3

Effective surge capability is not based on well-intentioned and readily available volunteers. Disaster responders must understand the basic principles of disaster response (ICS, disaster triage, gross decontamination) to be effective members of the disaster teams. All providers involved in disaster response must ensure their personal safety by obtaining vaccinations

TABLE 12-2: Rapid Needs Assessment in Disasters

Public health concerns
- Water

- Sanitation
- Security/safety
- Transportation
- Communication
- Endemic/epidemic diseases

Medical concerns
- Search and rescue
- Triage
- Definitive care
- Evacuation

appropriate to their roles in disaster response (local, national, international) before a disaster occurs.

Principle 4

Trauma care in disasters is not the same as conventional trauma care.[1,3,4] Disaster care of traumatic injuries requires a fundamental change in the approach to the care of victims (crisis management care). The objective of conventional trauma care is the **greatest good for the individual patient**. *Severity of injury/disease* is the major determinant of medical care. The objective of disaster trauma care is the **greatest good for the greatest number of victims**. Determinants of care are *severity of injuries, likelihood of survival, and available resources* (personnel, logistics, evacuation assets).

MEDICAL RESPONSE TO DISASTERS

Trauma providers are uniquely qualified to participate in all four aspects of disaster medical response (search and rescue, triage, definitive care, and evacuation) given their expertise in rapid decision making, resuscitation, damage control surgery, and critical care.

Search and Rescue

Many countries, including the United States, have developed specialized search and rescue teams as an integral part of their national disaster plans (Fig. 12-4).[1,3,4] Members of these teams, who receive specialized training in confined-space environments, include the following:

- A cadre of trauma specialists
- Technical specialists knowledgeable in hazardous materials, structural engineering, heavy equipment operation, and technical search and rescue methodology
- Trained canines and their handlers

FIGURE 12-4 Search and rescue teams.

Trauma centers must be prepared to deploy additional personnel as needed to the scene of a disaster with appropriate equipment (eg, amputation kits, tourniquets, hemostatic agents).

Triage

Triage is a *dynamic* decision-making process of matching patients' needs with available resources. Triage is the most important and psychologically challenging aspect of disaster medical response, both in the prehospital and hospital phases of disaster response. Disaster triage is significantly different from conventional trauma triage.[1,3,4] The major objective and challenge of disaster triage is to identify the *small minority* of critically injured patients who require urgent lifesaving treatments, including damage control surgery, from the *larger majority* of noncritical casualties. **Critical patients who have the greatest chance of survival with the least expenditure of time and resources are prioritized to be treated first.** Review of the literature from major disasters estimates that 15% to 25% of victims are critically injured, and the remainder of victims are noncritical casualties.

TRIAGE ERRORS

Triage errors, in the form of undertriage and overtriage, are always present in the chaos of mass casualty events. *Undertriage* is the assignment of critically injured casualties requiring immediate care to a "delayed" category. Undertriage leads to treatment delays with increased mortality and morbidity. *Overtriage* is the assignment of noncritical survivors with no life-threatening injuries to immediate urgent care. The higher the incidence of overtriage, the more the medical system is overwhelmed with increased mortality and morbidity. The level of acceptable over- and undertriage in an MCI and the best method for evaluation of triage effectiveness in an MCI are controversial.[1,4,22]

LEVELS OF TRIAGE

Three levels of disaster medical triage have been defined. **The level of disaster triage used at any phase of the disaster will**

FIGURE 12-5 Crush injury to face.

depend on the ratio of casualties to capabilities.[1,3,4] Many MCIs/MCEs will have multiple levels of triage as trauma patients move from the disaster scene to definitive medical care.

Field triage (level 1) is the rapid categorization of victims potentially needing immediate medical care "where they are lying" or at a casualty collection center. Victims are designated as acute or nonacute. Color coding may be used.

Medical triage (level 2) is the rapid categorization of victims by experienced medical providers at a casualty collection site or fixed/mobile medical facility.[15,17] Victims are classified into the following categories:

- **Red (urgent)**—Lifesaving interventions (airway, breathing, circulation) are required.
- **Yellow (delayed)**—Immediate lifesaving interventions not required (Fig. 12-5).
- **Green (minor)**—Minimal or no medical care or psychogenic casualties.
- **Black**—Deceased victims.

Initial triage should be conducted outside of hospitals or casualty collection sites. Green category of victims (minor or no medical care) should be triaged to a separate designated site. At the hospital, this site should be separate from the emergency department. Many institutions perform additional triage by surgeons in the emergency department to prioritize individuals needing operative interventions.

EXPECTANT (PALLIATIVE) CATEGORY OF TRIAGE VICTIMS

The expectant category of victims is unique to MCIs.[1,3,4] Victims are classified as expectant if they are not expected to survive due to the severity of injuries (massive crush injuries or burns) or underlying diseases and/or limited resources. The expectant category of triage was first developed given the threat of WMD (biological, chemical, radioactive) during military conflicts but is now used in all disasters. Traditionally, this category of disaster casualties has been classified as yellow or delayed category. Currently, many triage systems classify expectant victims as a separate category with a different color designation. Classification of the expectant category of disaster victims remains controversial. Many models have been proposed based on severity of injury, age, underlying diseases, and hemodynamic stability of victims at time of rescue. Criteria that are currently used as guidelines for the expectant category are as follows:

- Cardiac arrest on scene
- Severity of comorbid diseases
- Requirement for intubation and ventilation on scene in victims with multisystem traumatic injuries and severe hemodynamic instability
- Severe head injuries
- Massive burns (>80% total body surface area)

Evacuation triage (level 3) is often a neglected area of disaster preparedness. Priorities for transfer to medical facilities are assigned to disaster victims using the same color classification as medical triage.

Definitive Medical Care

Definitive medical care refers to care that will improve, rather than simply stabilize, a casualty's condition.[1,3,4,23,24] Maximally acceptable care for all trauma patients is not possible in the early stages of the disaster given the large number of victims in an MCI. **In the initial stages of the disaster, only minimally acceptable trauma care to provide lifesaving interventions is possible.**

Damage control surgery is an important component of crisis management care. Damage control surgery limits trauma interventions to control of hemorrhage and contamination. Tourniquets and hemostatic agents have been important adjuncts in hemorrhage control. Damage control surgery was initially developed for abdominal trauma with uncontrolled hemorrhage but has expanded to all other trauma specialties in disasters. Spinal and regional anesthesia and intravenous sedation and intraosseous infusions are important adjuvants to trauma care in disasters.

Evacuation

Evacuation may be useful in a disaster to decompress the disaster area and provide specialized trauma care for specific casualties, such as those with burns and crush injuries. Trauma providers with expertise in critical care are increasingly valuable resources in disasters. Special considerations during evacuation include the following[1]:

- A decrease in cabin pressure occurs as altitude increases. Trapped gas in any body cavity can cause serious complications as it expands on ascent. Special attention must be paid to trapped gas within the thorax, cranium, eye, and gut in the presence of an ileus. Patient care appliances, such as endotracheal tube cuffs, are also susceptible.
- The partial pressure of oxygen in the ambient air decreases with increasing altitude. Monitoring with pulse oximetry is important.

- Takeoffs and landings present unique challenges, especially with head injury patients.
- Young children, burn patients, and postsurgical casualties are particularly susceptible to temperature changes during evacuation.

WEAPONS OF MASS DESTRUCTION

Biological Agents

Biological terrorism is the intentional use of microorganisms or toxins to kill or injure humans.[1,4] Exposure to biological agents may be accidental or intentional (terrorism). Agents believed to have the greatest potential as bioterrorism weapons are listed in Table 12-3.

ROUTES OF EXPOSURE

The route of exposure of most concern with biological agents is inhalation of the agent. Oral exposure to biological agents may occur directly or secondarily after an aerosol attack. Agents with the highest potential for person-to-person transmission (pneumonic plague, smallpox, and viral hemorrhagic fevers) constitute the greatest hazard. **The most effective and important protection against biological agents is physical protection.** Removal of clothing will eliminate greater than 85% of the agents. Any dermal exposure should be treated immediately by gross decontamination with soap and water.

PROPHYLAXIS AND THERAPY

Medical defenses against some biological agents are limited. Vaccines are available to protect against some biological agents (anthrax, smallpox), and antibiotics may be effective against bacterial agents such as anthrax, plague, and tularemia if given early enough. Disasters involving biological agents have a significant impact on the health care system for the following reasons:

- Terror in affected populations and medical care systems
- Overwhelming casualties and significant ICU/special medication needs
- Problems with handling dead victims

Chemical Agents

Chemical agent release may be unintentional (industrial accidents) or intentional (terrorism).[1] Many chemical agents, especially warfare agents, are liquids and must be dispersed to be maximally effective. There are three general methods of dispersion:

- Aerosolizing with an aerial sprayer
- Aerosolizing the liquid with an explosion (IED and chlorine tanker)
- Allowing the liquid to evaporate (Tokyo Sarin attacks)

Time is of the essence in the decontamination and treatment of chemical agent casualties. Treatment areas should be upwind and uphill from the contamination site. It is important that decontamination facilities be *separate* from the emergency department.

TABLE 12-3: Bioterrorism Agents

- *Bacillus anthracis* (anthrax) – Bacteria
- *Yersinia pestis* (plague) – Bacteria
- *Francisella tularensis* (tularemia) – Bacteria
- Botulism toxins (botulism) – Toxins
- *Variola major* (smallpox) – Virus
- Hemorrhagic fever viruses such as Ebola and Marburg

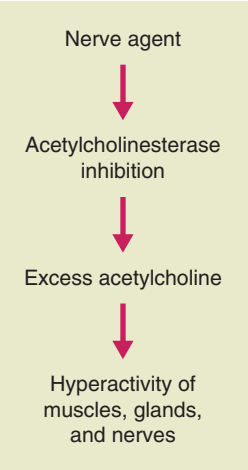

FIGURE 12-6 Mechanism of action of nerve agents.

SPECIFIC CHEMICAL AGENTS

Nerve Agents. Nerve agents are toxic relatives of organophosphate insecticides.[1,3,4] They cause effects by disrupting the normal mechanism by which nerves communicate with muscles, glands, and other nerves (Fig. 12-6). Nerve agents enter the body either percutaneously (through the skin) or by inhalation (through the lungs). Clinical effects of nerve agents are summarized in Table 12-4. The most important

TABLE 12-4: Clinical Effects of Nerve Agents

- **Eyes:** Miosis (small, pinpoint pupils)
- **Nose:** Rhinorrhea (nasal discharge)
- **Mouth:** Secretions
- **Skin:** Sweating
- **Airway:** Bronchoconstriction and bronchorrhea
- **Gastrointestinal:** Hypermotility of gastrointestinal tract (cramps, nausea, vomiting, diarrhea)
- **Genitourinary:** Involuntary urination
- **Skeletal muscles:** Fasciculations, twitching, fatigue, and flaccid paralysis
- **Cardiovascular:** Variable heart rate
- **Central nervous system:** Dose dependent (large vapor or liquid exposure: loss of consciousness, convulsions, apnea)

nerve agents are GA (Rabun), GB (Sarin), GD (Osman), GF, and VX. Treatment to counteract these agents includes the following[1,4]:

- **Atropine 2 to 6 mg intravenously (IV):** Antidote for smooth muscles and exocrine glands
- **Pralidoxime (2-PAM) 600 mg intramuscularly (IM):** Antidote for skeletal muscle sites
  - Atropine-sparing effect
  - Timing of 2-PAM administration is critical; binding of nerve agents to cholinesterase can become irreversible with time
- **Valium (diazepam):** Used as an anticonvulsant as needed (5 mg IV or 10 mg IM)

The traditional Mark 1 Kit contains two spring-loaded injectors of atropine (2 mg) and 2-PAM (600 mg). A new product, DuoDote, contains atropine (2.1 mg) and 2-PAM (600 mg) in a single autoinjector. Antidotes may be given by medical personnel in appropriate protective gear prior to decontamination.

Vesicants. Vesicants are agents that cause erythema and vesicles on the skin as well as injury to the eyes, airways, and other organs.[1,4] Key to treatment of these agents is thorough decontamination as soon as possible. Sulfur mustard has no specific antidote. Dimercaprol, also called British anti-Lewisite (BAL; 2.5–4 mg/kg IM), is the specific antidote for Lewisite.

Hydrogen Cyanide. Hydrogen cyanide has a long history as a deadly poison as it causes death within minutes of exposure.[1,4] Antidote is hydrocobalamin 5 g IV (preferred) or Cyanide Antidote Kit.

Pulmonary Agents. Pulmonary agents cause pulmonary edema, which can be exacerbated by exertion. Phosgene and chlorine are the most common agents. The pulmonary edema caused by phosgene and chlorine causes dry-land drowning to the point that the casualty can become hypoxic and apneic.

Riot Control Agents (Tear Gases or Lachrymators). Treatment is symptomatic with copious irrigation of eyes and skin with water or normal saline.

Radioactive Agents

Release of radioactive material would most likely involve the following scenarios[1,3,4]:

- Detonation of a nuclear device
- Meltdown of a nuclear reactor or melting of the nuclear fuel within a reactor with release of radioactive materials into the environment (Fukushima nuclear accident)
- Dispersal of material through use of a conventional explosive (radiologic dispersal device or "dirty bomb")
- Nonexplosive dispersal of radioactive material

Radiation types include nonionizing radiation (no tissue damage) and ionizing radiation (tissue damage). Electromagnetic radiation and particle radiation (radiation dust) are the two types of ionizing radiation seen in disasters. Radiation exposure may be external irradiation (whole body or localized) and/or contamination (radiation debris), including internal and external contamination. **Responders must assume both external and internal contamination when responding to disasters involving radiation agents.**[1,3,4]

MEDICAL EFFECTS OF IONIZING RADIATION

- Focal tissue damage and necrosis
- Acute radiation syndrome (result of whole-body exposure)
- Long-term effects (thyroid cancer, leukemia)

TREATMENT OF RADIATION CASUALTIES

- Removal of clothing in victims with external contamination eliminates more than 90% of the contamination.
- Radiation effects are delayed; trauma triage is done according to conventional trauma protocols.
- Decontamination should occur before, during, or after initial stabilization, depending on severity of injury.
- Emergency surgery, as well as closure of surgical wounds, should be performed early.
- Know the limitations of your radiation detection devices. Protect yourself until victim is free of all radiation contamination.

DECONTAMINATION

Decontamination is the removal of hazardous materials from contaminated persons or equipment without further contaminating the casualty, rescuers, or medical facilities (mobile or fixed hospitals). The basic principles in response to any hazardous material incident are the same regardless of agents involved. Removal of clothing and jewelry may reduce contamination by up to 85%. It is important for medical providers to protect themselves during decontamination with the appropriate level of personal protective equipment (PPE).

It is important to ensure that the hospital, particularly the emergency department, does not become secondarily contaminated. Failure to do so can result in contamination and quarantine of the entire facility. Local police and/or hospital security may be required to lock down a facility to prevent contaminated victims from entering the facility. The choice of decontamination technique (full decontamination vs gross decontamination) depends on the number of casualties, severity of contamination, severity of injuries, and available resources.[1,3,4]

- **Gross decontamination:** Consists of removing the patient's clothing and any jewelry and irrigating the patient's entire body with water hoses or sprays. This is the type of decontamination usually used in MCIs and MCEs.

- **Full decontamination:** Portable tents or fixed decontamination facilities.

The decontamination site is arranged in three zones:

- **Hot zone:** Area of contamination.
- **Warm zone:** Decontamination zone. The warm zone should be upwind and uphill from the hot zone. Intramuscular antidotes and simple lifesaving procedures such as control of hemorrhage can be administered to victims before decontamination by medical personnel wearing appropriate level of protective gear.
- **Cold zone:** Area where decontaminated victims receive emergency care if needed and transfer to other facilities.

SPECIFIC DISASTER INJURIES

Blast Injuries

Blast injuries are multisystem, life-threatening injuries that are caused by many types of disasters. Blast injury victims tend to sustain more traumatic injuries, varied anatomic locations of injury, and greater Injury Severity Scores (ISS) than other trauma victims. The predominant postblast injuries among survivors involve conventional penetrating and blunt trauma injuries.

MECHANISM OF INJURY

Explosives may be classified as high order or high energy or low order or low energy explosives and cause different patterns of injury. High-energy explosives (eg, C-4, Semtex, ammonium nitrite-fuel oil, TNT) **detonate** to produce a defining overpressurization shock wave. Low-energy explosives (eg, pipe bombs, Molotov cocktails) **deflagrate** to produce a subsonic explosion and lack the overpressurization shock wave.[1,4,5] An IED attack is the use of a homemade bomb and/or destructive device designed to cause death or injury. The survivability, mortality, and morbidity from a blast injury correlate significantly with whether victims are in open- or closed-space explosions. Underwater blasts are significantly more devastating because the lethal radius of an underwater explosion is about three times that of a similar explosion in air.

PRIMARY BLAST INJURY

Primary blast injuries result from the direct effect of the blast wave (traveling at supersonic speeds) on the body. Primary blast injuries affect the gas-containing organs: the lung, the ear, and the gastrointestinal tract.[1,4] The most common lung injury is a pulmonary contusion. Other pulmonary injuries range from pneumothoraces/hemothoraces to arteriovenous fistulas (source of air emboli). Abdominal blast injuries are a significant cause of mortality and morbidity. Abdominal blast injuries may be occult and difficult to diagnose and range from hemorrhage to mucosal ischemia, bowel necrosis, and perforations. The middle ear is particularly sensitive to blast injuries, and tympanic membrane (eardrum) rupture may be a useful marker for blast injury. However, isolated rupture of tympanic membranes without other symptoms is *not* a marker for high risk of associated blast injuries.

FIGURE 12-7 Secondary blast injury of extremity.

SECONDARY BLAST INJURY

Secondary blast injuries are caused by flying debris generated by the explosion. (Fig. 12-7) A favorite practice for terrorists is packing an IED with screws, bolts, nuts, and other sharp small objects. Significant soft tissue, internal, and orthopedic trauma occurs often from propelled missiles.[1,4]

TERTIARY BLAST INJURY

Tertiary blast injuries are caused by propulsion of the body by the shock wave into solid objects (eg, walls).[1,4] Tertiary blast injury casualties sustain major blunt trauma injuries, such as traumatic brain injuries, solid organ injuries, and complex orthopedic injuries. Penetrating injuries are not uncommon when the victims are impaled on objects in the environment.

QUATERNARY BLAST INJURY

Miscellaneous blast injuries encompass all other injuries caused by the blast, including burns, crush injuries, compartment syndromes, and toxic inhalations (carbon monoxide, dust, hot gases).

Crush Injury

Crush injury is defined as compression of body parts causing localized muscle and nerve damage and is seen in both natural and manmade disasters. The lower extremities are the most common site of crush injuries. Crush syndrome, first recorded in the bombings in London during World War II, is localized crush injury with systemic manifestations. The systemic manifestations are caused by traumatic rhabdomyolysis (muscle breakdown and the release of toxic muscle cell components and electrolytes into the circulatory system).

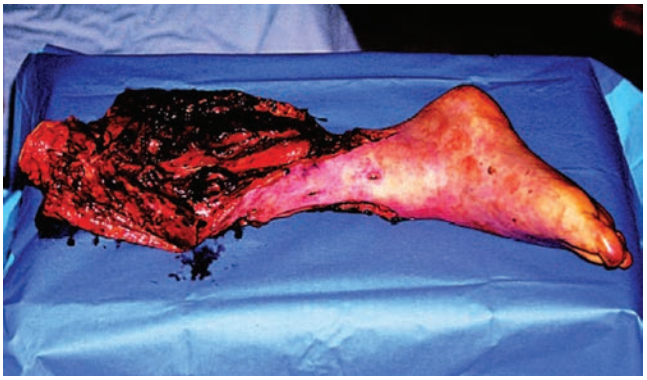

FIGURE 12-8 Field amputation.

Metabolic abnormalities include acidosis (low blood pH levels), hyperkalemia, and hypocalcemia.

Important guidelines for prehospital management of victims with crush injuries have now been established and implemented with search and rescue teams.[1,4,21,25]

- Pretreat casualties with prolonged crush (>4 hours) as well as those with abnormal neurologic or vascular exams with 1 to 2 L of normal saline *before* releasing the crushing object whenever possible.
- If not possible to pretreat, consider applying a tourniquet to crushed limbs and maintain until IV fluid administration is initiated. Risk of acute deterioration and death with sudden release of pressure on the involved extremity (reperfusion syndrome) is a significant risk. Reperfusion syndrome is manifest by acute hypovolemia and metabolic abnormalities.
- Monitor casualties for symptoms of compartment syndrome (fracture not mandatory for compartment syndrome to develop).
- Field amputation of a crushed extremity is considered as a last resort and should be as distal as possible[26-28] (Fig. 12-8).

DISASTER MANAGEMENT TEAMS

Clinical competencies, not titles, determine the roles of medical providers in disaster response. Disaster management teams are designed and trained to provide specific functional capabilities such as trauma, burns, critical care, pediatrics, and obstetrics. When the casualty load is unknown, acute care and trauma surgeons should be the first responders whether on scene or in the hospital. The complexity of today's disasters often demands civilian and military partnerships as key to effective disaster responses.

SUMMARY

A consistent approach to disasters, based on an understanding of their common features and the response expertise they require, is becoming the accepted practice throughout the world. The goal of all disaster response is to reduce the critical mortality associated with a disaster. **Critical mortality is defined as the percentage of critically injured survivors who subsequently die.**[1,4] Numerous factors influence the critical mortality including:

- Implementation of the ICS by prehospital and hospital organizations
- Triage accuracy, particularly the incidence of overtriage of victims
- Rapid movement of patients to definitive care
- Implementation of damage control procedures

Initial Assessment

Adam D. Fox • David H. Livingston

KEY POINTS

- The goal of the initial assessment is the rapid identification and treatment of life-threatening injuries.
- Structured handoffs from EMS improve communication to the trauma team.
- The resuscitation bay should contain all instruments and equipment required in a major trauma.
- Trauma team composition should have sufficient personnel to both assess and treat the severely injured.
- The team leader should be the most senior person on the team with an understanding of injury.
- Coordination of care by the team leader is crucial to successful trauma assessments and resuscitation.
- The initial assessment should follow the standard primary and secondary survey algorithms as outlined in Advanced Trauma Life Support (ATLS).
- Patients who arrive in shock require even more rapid assessment and treatment by the most senior personnel.
- Initiating the resuscitation with intraosseous access can be lifesaving in patients in shock.
- Early arterial access for subsequent resuscitative endovascular balloon occlusion of the aorta (REBOA) deployment should be considered for patients presenting with subdiaphragmatic life-threatening hemorrhage.

INTRODUCTION

The importance of the initial trauma assessment cannot be overstated. Missed or delayed identification of injuries during the initial assessment can lead to significant morbidity, complications, and even death. Although there have been multiple studies demonstrating the effectiveness of trauma center care on outcome, in reality, the optimal approach to a trauma patient should be universal regardless of the center. Prompt evaluation and treatment are cornerstones of modern trauma systems, which all starts with the initial assessment.

The initial assessment begins with an understanding of which patients need an evaluation by a trauma team. After successful field triage (see Chapter 4), the injured patient should be seen in a setting that can accommodate the necessary equipment and personnel to provide high-quality trauma care. The basic principles of Advanced Trauma Life Support (ATLS) are used with the primary goal of rapidly identifying and treating life-threatening injury. Adjunctive diagnostic modalities such as a chest radiograph or focused assessment of sonography in trauma (FAST) are often employed to help with the assessment. Finally, ongoing evaluation with feedback and training of the trauma team is needed to maintain readiness.

TRIAGE

Although trauma can be easily defined as "injury," the patient with an injury requiring the resources and expertise of a trauma team is less clear. The ability to triage or "sort" trauma patients to the appropriate level care can be examined from several different aspects. These include (1) prehospital triage (ie, does this patient require a trauma center?), (2) trauma center designation (ie, in a region where there are several levels of trauma centers, which one is most appropriate?), and finally (3) in-hospital triage tiered response (ie, who is going to see and treat the patient upon arrival?). The best outcomes will be generated by a system that is seamlessly connected.

The most recent edition of *Resources for Optimal Care of the Injured Patient* recognizes that inclusive regional trauma systems should place the right patient in the right place at the right time.[1] Ideally, the only difference between hospitals should be related to their resources and not their commitment to provide the best care for the injured patient. There are many field triage variables that have been examined to identify patients who require trauma center resources. These include anatomy, physiology, mechanism of injury, comorbidities, and field triage scores. Of these, physiologic

parameters provide the most accurate single criteria for triage, but ideally a combination of physiologic factors, anatomic factors, mechanism, and comorbidities provides better triage than any criterion taken in isolation.[2,3] Levels of trauma center designation range from I to IV, with Level I centers providing the most comprehensive trauma care and Level IV centers the least (see Chapter 4). Decisions to transport an injured patient to a specific trauma center will be based on multiple factors that are regionally dependent and ultimately depend on the severity of the patient's injuries. Finally, using a tiered response system within the hospital has been shown to be safe and cost effective and can even potentially reduce overtriage.[4-6]

ROOM AND EQUIPMENT

Although, there is no "official" standard for the amount of space needed for the evaluation and treatment of the trauma patient, understanding of the needs and composition of the team will help dictate the space required. The room and equipment should be designed to facilitate trauma team performance. A space large enough to accommodate the trauma team (see later in chapter) and ancillary staff is absolutely necessary. When considering size, one must also consider the need for monitoring and resuscitation equipment, bedside radiographic studies and ultrasound, and crowd control. In ideal situations, the room or rooms should be solely dedicated to the evaluation and initial management of the trauma patient. This dedicated room will allow the staff to become acquainted with the dynamics of the space. Having a readily available resuscitation room allows for rapid assessment and the ability to keep the appropriate equipment stocked in one easily accessible space. The room should also have telephone access for communication with the operating room, blood bank, and other important locations.

The room should have a standard set of equipment that can be used by the trauma team for all trauma patients. Personal protective equipment in the form of fluid-resistant gowns, head covering, face shield, and gloves (both sterile and nonsterile) should be readily available. Depending on how x-rays will be performed, protective lead shielding should be available. A radiographically compatible stretcher to obtain x-rays without having to move the patient is mandatory. Cardiac and vital sign monitoring equipment that includes dynamic electrocardiogram, oxygen saturation, and blood pressure should be permanently available in the room. Quantitative end-tidal carbon dioxide monitoring is a nice adjunct to have as part of the monitoring system. A manual blood pressure cuff should also be immediately available.[7] Flat panel monitors placed within the resuscitation room, which can display radiographic images and laboratory data, are an excellent adjunct that allow the team to remain at the bedside of critically injured patients. Creation of a "universal" instrument set that includes standard equipment that can be used for multiple procedures (eg, controlling hemorrhage from complex lacerations and placing tube thoracostomies) improves trauma resuscitation bay functionality. Other equipment that should be readily available in the trauma bay, presented by body region or specific need, is provided in Table 13-1.

TABLE 13-1: Necessary Ancillary Equipment for a Complete Initial Assessment

Universal tray: hemostats/clamps, retractors (ie, self-retaining, army/navy), pick-ups, needle drivers.

Head and neck: suture material for scalp wounds, intracranial pressure catheters, scopes and light sources for eye and naso-/oropharynx exam, cervical collars.

Airway: preassembled airway kit/box. These can be constructed with input from the airway team but should include endotracheal tubes (various sizes), stylets, capnography, and traditional laryngoscopes. Video laryngoscopes, difficult airway devices (bougies, intubating laryngeal mask airway) tracheostomy tubes, ventilator availability, arterial blood gas kits.

Chest: chest tubes of various sizes (pediatric through adult), chest drainage system, chest tube and thoracotomy instrument tray (see below).

Abdominal and pelvis: ultrasound, diagnostic peritoneal lavage kit, nasogastric tube, urethral catheter (temperature sensing if available), pelvic binder (commercial or homemade device).

Extremity: pneumatic tourniquet, Doppler, cast material.

Shock: intravenous pressure bags, blood and fluid warming systems, large-bore central access catheters, arterial access catheters, intraosseous devices, scalpels, thoracotomy equipment, resuscitative endovascular balloon occlusion of the aorta (REBOA) equipment.

TRAUMA TEAM

Although there are many variations in trauma team composition, there are no hard recommendations as to the optimal number and formulation of the team involved in the initial assessment. Because the primary goal of the initial assessment is to identify significant injuries and initiate lifesaving measures, the team needs to have requisite number of personnel with the appropriate skill set to accomplish this task. The initial assessment can be further divided into the immediate evaluation and management of life-threatening injuries and subsequent identification and management of non–life-threatening issues. These concepts are commonly referred to as the primary and secondary surveys. Again, the composition of the team to evaluate a trauma patient needs to include the personnel necessary to perform these tasks. Based on industrial and psychological research, team efficiency has been divided into horizontal and vertical organizations, which can be translated into horizontal and vertical resuscitations for trauma patients. A horizontal approach is preferred and is one in which each team member is carrying out his or her individual tasks simultaneously. Studies have demonstrated the effectiveness of this approach in improving resuscitation times.[8] Conversely, the less efficient approach would be a vertical resuscitation where each task is performed sequentially.

Frequently seen as the "ideal" environment, the Level I trauma center has a dedicated team for the initial evaluation of the trauma patient. This will often include a senior surgeon, residents and/or advanced practice providers, emergency medicine physicians, dedicated trauma nursing, medical students, anesthesia staff, and respiratory and radiology staff. This team is clearly not attainable in all institutions and should only be used as a template. Trauma center designation should not factor into the proper evaluation of the trauma patient. With the goal to efficiently perform evaluation and management simultaneously, the *minimum* team numbers should include personnel to perform the primary and secondary survey (one or two team members), procedures (one or two members), and a team leader (one member, usually the most experienced surgeon). The nursing staff will be working to help with intravenous access and providing medications, transfusions, and monitoring. Although not well studied, the importance of experienced and dedicated trauma nurses as part of the trauma team cannot be stressed enough.

Trauma team leader: The leader of the trauma team should be the most experienced provider in the room with an understanding of the priorities in the evaluation and care of the injured patient. In a trauma center, this should be the trauma surgeon.[1] Prenotification of a patient arrival allows the team leader to provide provide direction and assign tasks to individual team members and to focus the team *prior* to arrival of the patient. With the goal of conducting the "trauma team orchestra," they should situate themselves with a view of the entire proceedings. Although this is often best accomplished at the foot of the bed, the geography of the resuscitation room will dictate the optimal position that affords the team leader the "big view." Once the patient arrives, the team leader should keep the team on track and offer prompts as needed to bring the initial evaluation and management to an appropriate conclusion. Decisions as to the next steps in care should be made by the team leader. If trainees are present, opportunities should be made for them to be team leader under the close supervision of the attending.

Primary surveyor: This individual is responsible for the actual evaluation of the trauma patient. Based on ATLS algorithms, this individual will work through the ABCD (airway, breathing, circulation, disability)/primary survey of the evaluation and report these findings to the team. Depending on available personnel, this individual can perform the secondary survey as well.

Procedures: Depending on the severity of the trauma, the patient may require multiple simultaneous procedures or none at all. However, it is imperative for the team leader to preassign who is going to perform whatever procedures should be needed. At the very minimum, someone should be designated to provide airway care. Although in some institutions this has been traditionally performed by anesthesia personnel, no difference exists in endotracheal intubation success rates between emergency medicine and anesthesia in Level I trauma centers.[9,10] Local protocols with appropriate quality assurance should dictate control of the trauma patient's airway. All other procedures can be addressed using the most appropriate member of the team.

Ancillary team members: Because the extent and severity of a patient's injuries are often not clear at the beginning of the initial assessment, a mechanism needs to be in place for bringing ancillary staff into the team. These may include extra nursing personnel, respiratory therapists, pharmacists, and x-ray technologists. Additionally, there needs to be a method for activating operating room or interventional radiology personnel if you are in a center that will be providing this level of care. Appropriate and up-to-date contact information for relevant consultants (ie, neurosurgeons, orthopedic surgeons) will also need to be readily available.

EMERGENCY MEDICAL SERVICES HANDOFF

The communication between prehospital providers and the trauma team provides the initial information that helps report observable and potential injuries the patient has sustained. Because communication errors have been shown to be a common cause of preventable disability or death, transmission of information between emergency medical services (EMS) and the trauma team should be afforded dedicated time. The EMS report ideally begins in the prehospital environment. Mature EMS systems will have a mechanism through which the prehospital providers can notify receiving teams about the incoming patient using radio, cell phone, or landlines. Creating a centralized center for dissemination of this information is an ideal way to minimize the need for multiple steps in communication, which could otherwise lead to misinformation. The report need only be brief, containing information as it relates to age, mechanism, hemodynamics, injuries, and estimated time of arrival (ETA). Prenotification allows the trauma team to make the appropriate preparations prior to patient arrival. This can include mobilizing personnel and obtaining equipment necessary for the particular type of injuries that may be presenting.

Once in the hospital, EMS providers should be afforded dedicated time for their report. There have been multiple studies demonstrating difficulties in the handoff between prehospital providers and a receiving team.[11] The reasons for this have been shown to be multifactorial but include the different perspective between EMS and the trauma team, the real or perceived need by the trauma team to rapidly assess the patient, and multiple providers relaying fragmented bits of information.[12]

Additionally, educating EMS providers to impart concise information deemed important to the trauma team has not been a priority. Because of this disconnect, trauma teams often do not demonstrate a willingness to listen, and EMS providers either fail to give an appropriate report or continue to provide information that may not be beneficial to the trauma team. Several studies demonstrate the effectiveness of educating all the involved parties in a more "formal" handover using specific data points. At the current time, several of these exist, one of the most common being MIST (mechanism, injuries suspected, vital signs and symptoms, treatments). MIST

has been adopted by many EMS systems internationally and is also being used by the military for their handovers.[11,13] Other studies have shown that better and more timely data are transmitted when a formal handover is performed.[14] Unless the patient is in extremis, the prehospital handover should take place before or as the patient is transferred to the hospital stretcher. This allows the entire team to focus on the EMS provider without jumping into an assessment that precludes listening. The report should be prompted to start and finish by the team leader, who should be cognizant of the information being given and limit extraneous stories. Ultimately, the prehospital report should not take more than 45 seconds to 1 minute.

PRIMARY ASSESSMENT

Because the overarching goal of trauma care is to minimize mortality and improve outcomes, the primary assessment is designed to systematically allow the team to achieve this objective (Fig. 13-1). In fact, the term *primary assessment* or *survey* is somewhat a misnomer in that the goal is not only to identify (using the ABCDE moniker) potentially life-threatening injuries, but also to intervene and correct these problems as soon as they are diagnosed. With the exception of patients presenting with external or compressible life-threatening hemorrhage or those presenting in extremis for whom the circulation evaluation and treatment will come before airway (ie, CAB [circulation, airway, breathing]), the provider should follow the airway, breathing, circulation, disability, and exposure/environment (ABCDE) approach. One can rapidly obtain a general picture of the patient's condition by merely asking the patient one or two questions. Appropriate answers to "What is your name?" and "Can you tell me what happened?" will provide the team with information regarding the first four elements (ie, ABCD) of the primary survey. If the patient is not awake and alert, tactile stimulation (ie, painful stimuli) in addition to questioning may result in the patient verbalizing answers to questions. A more complete description of assessing disability and altered metal status is outlined later.

Although the importance of the physical examination is stressed continuously throughout training, what data exist following injury demonstrate that it has significant limitations and needs to occur with the appropriate adjuncts to the primary and secondary surveys. However, although the negative predictive value of physical examination may be low, positive findings are almost always secondary to serious injuries and should be acted upon.[15-18]

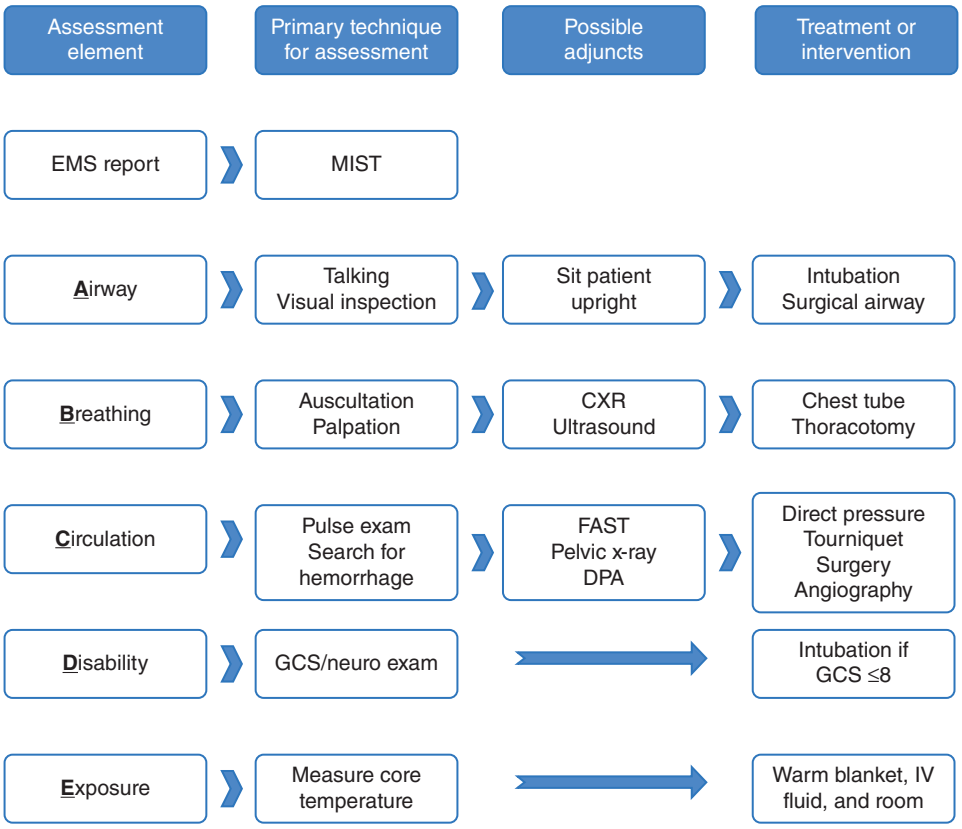

FIGURE 13-1 Overview of the elements of the primary assessment, assessment techniques, and possible treatments. CXR, chest x-ray; DPA, diagnostic peritoneal aspiration; EMS, emergency medical services; FAST, focused assessment with sonography for trauma; GCS, Glasgow Coma Scale; IV, intravenous; MIST, mechanism, injuries suspected, vital signs and symptoms, treatments.

The airway exam begins with assessment of patency. In general, a patient who is able to speak in his or her normal voice does not have airway obstruction. Significant maxillofacial bleeding into the airway or destruction in the area of the oropharynx or neck should prompt urgent airway stabilization. In the setting of penetrating trauma, where cervical spine precautions are not warranted, merely placing patients into an upright sitting position and allowing them to spit or suction the blood can turn an airway emergency into a situation that can be treated in a more controlled fashion. Airway stabilization should also be performed in the patient with a significant alteration in mental status (Glasgow Coma Scale [GCS] score ≤8). On occasion, patients who are combative either due to intoxication and/or head injury may require intubation in order to facilitate or complete their trauma assessment.[19] Once the decision is made to intubate a trauma patient, a brief but thorough neurologic exam should be performed prior to the administration of paralytics and sedation. Securing an airway will generally involve endotracheal intubation via rapid sequence intubation, but the team should always be prepared for a potentially difficult airway with other methods such as video laryngoscopy, flexible fiberoptic intubation, or surgical airway.

The assessment of a patient's breathing will depend on the severity of the injury and presentation. The rapid auscultation of each hemithorax should focus on the absence or presence of breath sounds. Although the presence of breath sounds does not rule out clinically significant pathology, the absence of breath sounds usually indicates a hemo- or pneumothorax that requires urgent treatment. A prolonged multilocation exam is never indicated at this stage in the assessment because the only goal should be to identify the presence of potentially life-threatening injuries. Continuous pulse oximetry can disclose occult hypoxemia but provides no information on the status of ventilation. In the intubated patient, absence of breath sounds, especially on the left, should prompt assessment of the depth of the endotracheal tube and the possible withdrawal of the tube a centimeter or two before other interventions. Other physical findings of chest trauma, such as significant deformity, bony crepitus, subcutaneous emphysema, tachypnea, or desaturations, should prompt further study (ie, chest radiograph) or intervention, most commonly tube thoracostomy. Expanding the FAST (extended FAST [eFAST]) exam from the traditional abdominal views to examine and screen the chest for significant pneumothoraces or pleural blood can be a useful bedside adjunct to traditional chest radiography. In the patient who presents in extremis, triage of the chest cavity needs to be more rapid and invasive. Presumptive placement of bilateral chest tubes will not only diagnose but also treat most life-threatening chest injury. Lastly, in the patient who presents in cardiac arrest, the chest can be definitively assessed via a thoracotomy (see Chapter 17).

Circulation can be rapidly assessed by looking for active hemorrhage and palpation of central and distal pulses. Although not well studied, each location is associated with a minimal threshold systolic pressure: carotid (60–70 mm Hg), femoral (70–80 mm Hg), radial (90–100 mm Hg), and pedal (>100 mm Hg) pulses. Traditionally, this is also the time the patient would be placed on a cardiac monitor. Historically, blood pressure measurement has not been part of this portion of the assessment, and as long as there is evidence of palpable radial or femoral pulses, an immediate blood pressure is not needed. If a blood pressure is to be taken, it should be done manually because the use of noninvasive blood pressure devices may be erroneous in patients in shock.[7] Simultaneously, intravenous access with large-bore catheters should be initiated. In the situation where intravenous access is not immediately obtainable, consideration should be made to perform intraosseous access (further discussed later). Treatment for active external bleeding identified through these exams should begin with direct pressure. Bleeding from wounds that is not able to be controlled by direct pressure should be treated by packing, whip-stitching, or urgent wound exploration. For extremity trauma, placement of a tourniquet can be lifesaving. Blind clamping of deep wounds is discouraged because of the proximity of nerves or the possibility of creating further trauma and hemorrhage. Adjuncts to the circulatory exam include a rapid search for intracavitary bleeding using plain chest and pelvic radiography, FAST, and diagnostic peritoneal aspiration or lavage (DPA or DPL). Identification of intrathoracic or intra-abdominal injury in unstable patients demands urgent intervention most commonly in the operating room. The treatment for pelvic fracture bleeding is beyond the scope this chapter, but a pelvic binder should be immediately placed in high-risk patients (see Chapter 39).

The disability exam focuses on the patient's neurologic status. The GCS score should be assessed immediately upon presentation and sequentially during the resuscitation. As outlined earlier, a persistent GCS less than or equal to 8 should prompt endotracheal intubation. Pupillary response and overall neurologic status (movement and sensation) should be examined and abnormalities noted for early intervention. In patients with an adequate blood pressure, presumptive osmotherapy (ie, mannitol) can be considered for lateralizing signs (see Chapter 22). It should be also remembered that generalized agitation and combativeness are also classic symptoms of class III and IV shock. Patients who present with signs of spinal cord injury should have rapid assessment of their likely injury level. A more detailed neurologic exam, including assigning an American Spinal Cord Injury Association (ASIA) level, should be performed in the secondary assessment (see Chapter 26).

The key to a full examination is appropriate exposure. All clothing should be removed to facilitate a complete 360-degree exam. This is recommended for all trauma cases as it contributes to standardization. Equally important, concern for keeping the patient warm should be paramount once the full exam has been completed. This includes the use of warm blankets, forced hot air blankets, and warm intravenous fluids.

INITIAL EVALUATION OF THE TRAUMA PATIENT IN EXTREMIS

The ideal trauma evaluation, as outlined earlier, relies on speed and efficiency to identify and treat significant injuries. The concept of the "golden hour" recognizes that time to definitive care is important to prevent unnecessary morbidity and mortality. Although this remains a useful concept and aphorism, experienced trauma surgeons realize that there is a wide spectrum of severity of injury. In reality, it is the alteration in a patient's physiology that is the greatest determinant of outcome. Even in patients with a high anatomic injury burden (ie, high Injury Severity Score), the time to evaluation and treatment (unless excessive) will play little role in outcome in those without physiologic derangement. Conversely, there are patients who present in class IV hemorrhagic shock who do not have a "platinum minute" prior to their cardiac arrest from exsanguination. Recent data have confirmed that despite improvements in trauma systems and resuscitation strategies, the mortality rate of patients presenting with a systolic blood pressure of less than 90 mm Hg who require an emergent laparotomy is greater than 40%.[20] Similar high mortality has been demonstrated in hypotensive patients requiring thoracotomy[21] or patients with pelvic fractures.[22] A recent single-center retrospective study demonstrated that patients who sustained torso gunshot wounds who arrived to the operating room in less than 10 minutes had improved survival.[23] Although the basic ABCDEs of the trauma evaluation and resuscitation should be identical from one patient to another, these data demand that patients who arrive in extremis must be considered a specific subgroup, where circulation takes precedence (ie, CABDE).

TEAM CONSIDERATION

Given the excessive mortality of these patients and the relatively thin margin to achieve a successful outcome, it is necessary to ensure the most experienced and capable providers are part of the trauma resuscitation. In addition, pulling in additional personnel may be beneficial. These are the cases where the senior surgeon/team leader will likely need to be an active participant and "lead from within" the resuscitation. Even in academic Level I trauma centers, these providers are most often not "teaching cases" during the resuscitation. Team debriefing and interactive teaching can take place following the completion of the case.

AIRWAY

Although there are no data to suggest an ideal time to secure the airway for the trauma patient in extremis, one must be thoughtful as to when endotracheal intubation (ETI) should occur. There are advantages and disadvantages to performing ETI in the trauma bay as opposed to the operating room. The clear advantages to ETI are the ability to secure an unstable airway, eliminate patient interference, and reduce metabolic demand. However, ETI takes time that the patient may not have, and it is not uncommon for ETI to precipitate physiologic collapse. In that scenario, the trauma bay is not an ideal location to begin necessary operative interventions. The team leader should be cognizant of these issues and make informed decisions as to the timing of ETI based on presumed injury, current hemodynamic status, patient level of consciousness, distance from resuscitation area to operating room, and composition of team.

INTRAOSSEOUS ACCESS

Resuscitation is not possible without access to the circulation. Although ATLS rightly stresses the importance of upper extremity large-bore intravenous accesses, the ability to find and cannulate a peripheral vein in a profoundly hypotensive patient is both challenging and time consuming. Large-bore catheters (6–8.5F) inserted in the femoral or subclavian veins have also been used to resuscitate this group of patients. Lack of circulating volume also makes placing these catheters a challenge with increased time to placement, failure of placement, or complications. For these reasons, alternative access needs to be considered to provide initial resuscitation until more traditional access can be established. Although intraosseous (IO) access was traditionally thought of as a technique restricted to field providers and pediatric patients, recent military experience has clearly demonstrated that this should not be the case,[24] especially because it has been shown that it is possible to provide all types of fluid resuscitation through an IO line. Several studies have demonstrated that the efficacy of the IO catheter and its speed and success of placement make it a possible superior initial option in patients who need rapid infusions without immediate intravenous access. Although there are several brands of IO systems and catheters on the market, we believe that trauma surgeons and emergency physicians need to be facile with the technique.[25-28]

The anatomic location for IO placement is ideally as close to the heart as possible. Although sternal access may be closest, it is often problematic in the patient in whom a possible thoracotomy or cardiopulmonary resuscitation is needed. Therefore, barring any contraindications, the humeral IO may be superior to other sites for the trauma patient. The tibia is often used as an alternative site of access (Fig. 13-2).

RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA

The traditional approach to the trauma patient in extremis or with recent cardiac arrest has been to consider emergency thoracotomy with aortic cross-clamping (see Chapter 17). Although there remain controversies regarding the risk-benefit ratio of emergency thoracotomy, for patients with suspected injuries above the diaphragm, this approach continues to remain the only option.[29-31] Although present in some form since the 1950s, catheter-based hemorrhage control using resuscitative endovascular balloon occlusion of the

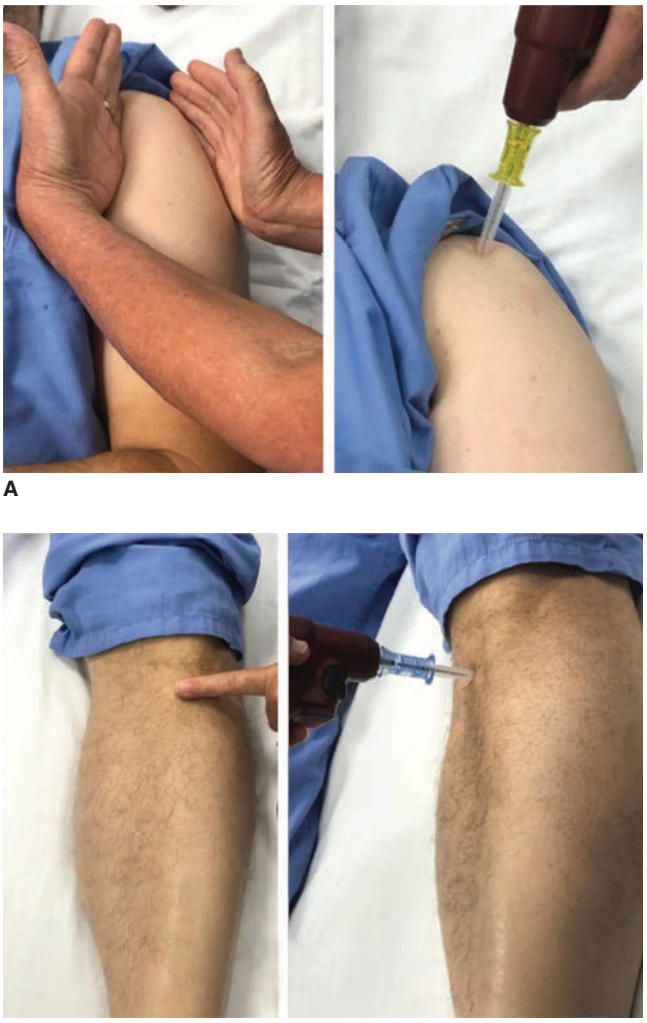

FIGURE 13-2 Landmarks for intraosseous infusion device insertion.

aorta (REBOA) has recently become a viable alternative to emergency department (ED) thoracotomy for the exsanguinating trauma patient with injuries below the diaphragm. The one clear advantage of this approach is that it does not create a wound (thoracotomy) in a previously uninjured body cavity with its attendant blood and heat loss. Preliminary results from the American Association for the Surgery of Trauma Aortic Occlusion Study Group suggested that in patients without penetrating thoracic injury undergoing aortic occlusion, mortality with REBOA was lower than in those undergoing emergency thoracotomy.[32] Conversely, a recent propensity analysis of the American College of Surgeons TQIP database found that REBOA placement was associated with increased mortality and a higher rate of acute kidney injury and amputation compared to a similar cohort of patients with no placement of REBOA.[33]

With the introduction of a small-bore (7F) wireless system, REBOA has become easier to place and its use more widespread. Although there is still a paucity of randomized prospective data and agreed upon indications, REBOA has been definitively added to the trauma surgeon's armamentarium.[34-37]

As with the adoption of all new technologies, the salient issues with its use can be broken down into the following: (1) indications (Which patient populations are candidates for REBOA?); (2) training (What, if any, training is required, and who requires it?)[38]; (3) technical considerations in usage (pitfalls in insertion and deployment); and 4) complications.[39] Until sufficient high-quality data exist, it is incumbent upon each institution to create a guideline for the use of REBOA based on their review of the literature. Once instituted, all cases should undergo robust peer review to ensure patient safety and identify areas for improvement.

Given the high mortality in patients with noncompressible torso hemorrhage, early arterial access for potential REBOA deployment should be considered in trauma patients presenting with hypotension secondary to blood loss from abdominal and pelvic trauma. Patients with concomitant thoracic trauma must be approached with caution because deploying the balloon in a patient with a great vessel injury could worsen and precipitate hemorrhage. What degree of hypotension makes a patient a candidate for REBOA remains unknown. Because the definition and breakpoint for hypotension is a systolic pressure of less than 90 mm Hg, this would seem a logical place to begin. Although many patients with that degree of hypotension will respond to early blood and plasma transfusion, some will not. Thus, it would make sense for the team to consider placing a REBOA in this population. The first hurdle to successful REBOA placement is femoral artery catheterization. The ability to palpate the femoral artery diminishes greatly at systolic blood pressures below 80 mm Hg. We strongly recommend using ultrasound for femoral arterial access because difficulties in achieving arterial access will delay deployment.[40] In patients in cardiac arrest or with profoundly low blood pressure, an arterial cutdown should be used. It would then follow that a more liberal use of femoral artery catheters for patients presenting in shock should be part of the approach to the patient in extremis. Continuous arterial blood pressure monitoring is superior to intermittent noninvasive modalities, and the indwelling arterial line can be used to follow chemical markers of shock, base excess, and lactate. Failure to respond to initial resuscitation efforts or worsening base excess identifies patients who require rapid hemorrhage control and could be seen as indications for REBOA deployment. The use of REBOA in patients presenting in cardiac arrest is also controversial. Without additional data, the indications for deploying a REBOA in this population should be identical to those in patients with nonthoracic injuries who would be candidates for ED thoracotomy.

Patient safety is paramount whenever a new technology or procedure is introduced, especially if that technique crosses specialty lines or is seen by some as just a small adjunct to a preexisting scope of practice. REBOA clearly falls into that category. Femoral arterial access is performed by multiple specialties; surgeons as well as many other practitioners have been deploying arterial lines and other intravascular catheters for decades. In an attempt to get ahead of the debate, a recent

joint statement from the American College of Surgeons Committee on Trauma and the American College of Emergency Physicians outlined their opinion as to best practice in the use of REBOA, including training in established and recognized courses.[38] Not surprisingly, this statement was followed by detractors taking issue with one aspect or another of the statement, including training. One argument for keeping REBOA primarily under the control of surgeons is that acute care or vascular surgeons are required to treat the complications that arise from REBOA. However, vascular surgeons already do so for specialists performing other catheter-based procedures. Other recent series of adoption of REBOA without specialized training have demonstrated good results and low complications.[41] These issues are complicated and clearly beyond the scope of this chapter, but the arguments should remind the astute reader of those that took place with ultrasound. Although one cannot fault additional specialized training taught by leading academic societies, local hospital credentialing dictates what a practitioner may or may not be allowed to do. However, most importantly, and to reiterate, patient safety is paramount, and we believe that no one should be performing any invasive procedure without appropriate competency.

As outlined earlier in the chapter, all necessary equipment for placement and deployment of REBOA needs to be readily accessible in the trauma bay. At the present time, there is only one commercial US Food and Drug Administration–approved small-bore REBOA catheter available. Thus, unless providers are using the older, large-bore catheters, from a technical standpoint, there is only one "system" to learn. Recent improvements have also made this catheter wireless, which eliminates a step in placement (Table 13-2). As stated earlier, the first technical consideration is femoral artery access. Once this is achieved and the decision is made that the REBOA catheter will be used, it should be deployed based on the specific location of injury. The balloon catheter may be inflated at the distal thoracic aorta (zone 1) for control of life-threatening intra-abdominal or retroperitoneal hemorrhage or those with traumatic cardiac arrest. The balloon may be also inflated at the distal abdominal aorta (zone 3) for patients with severe pelvic fracture or junctional or proximal lower extremity hemorrhage not easily amenable to external compression. What is just as important as the indication for REBOA is the time from balloon inflation to hemorrhage control and restoration of distal perfusion. This is the identical consideration that is observed with aortic cross-clamping. With the balloon inflated in zone 1, there is total visceral ischemia. The inability to restore perfusion within 30 minutes of inflation will likely result in a lethal ischemia reperfusion injury. Thus, at the present time, zone 1 inflation is only practical in those institutions and situations where the inflation to operating room time can meet that time limit. In contrast, balloon inflation in zone 3 allows a somewhat longer period of time where ischemia may be tolerated. Nonetheless, as recent military reports of deploying the balloon in a prehospital far-forward setting demonstrate, the ability to transfer to definitive care and control of hemorrhage need to be accomplished in a short time frame.[42] In addition, if REBOA is to be deployed outside of the trauma center, experienced personnel versed in REBOA insertion who can monitor the catheter in transport are mandatory to accompany the patient to definitive care.

TABLE 13-2: Steps for Resuscitative Endovascular Balloon Occlusion of the Aorta Insertion

- Obtain arterial vascular access (preferentially with ultrasound).
- Place compatible 7F sheath.
- Measure catheter using external landmarks.
- Ensure catheter balloon is deflated and pressure tubing is connected.
- Advance peel-away sheath over end of catheter.
- Flush catheter.
- Insert catheter and advance to desired depth.
- X-ray confirmation of placement is recommended.
- Inflate balloon to appropriate size but do not overinflate.
- Monitor hemodynamic response.
- Secure device.

The complications of REBOA are predominantly vascular and perfusion related and can occur anywhere along the path of the catheter. These include arterial laceration; disruption; dissection; pseudoaneurysms; hematomas; thromboemboli; visceral, renal, and extremity ischemia; perforations of the arterial system; intimal injury; and rupture of the aorta from overinflation of the balloon. These injuries may result in the need for operative repairs, organ failure, amputations, and even death. In addition to visceral ischemia, spinal cord ischemia may occur from prolonged zone 1 inflation. As with any new and emerging technology, the initial complication rates reported by those perfecting the technique will be lower than those observed over time as REBOA is used by a broad cross-section of providers. In addition to local performance improvement reviews of the use of REBOA, regional and even national anonymous registries open to all users should be created to fully identify the breadth and prevalence of complications to capture these events.

It is likely that the next decade will see further high-quality data that answer many of the questions posed earlier. It also will likely see refinements in catheter technology to allow more prolonged times between inflation and definitive control of hemorrhage. Experimental studies in porcine models have demonstrated superiority of partial occlusion of the aorta to prevent or reduce distal ischemia with pressure monitoring.[43] This concept has also been discussed in the clinical setting.[44]

SECONDARY ASSESSMENT

Once the primary assessment for life-threatening injury is completed, the team should begin a more thorough and detailed examination of each body region. This "secondary assessment" is actually a complete history and physical

examination whose aim is to identify all other injuries. After obtaining a full set of vital signs that should include pulse, respiratory rate, blood pressure, pulse oximetry, and temperature, the patient's medical history should be obtained. ATLS suggests using AMPLE (*a*llergies, *m*edications, *p*ast illnesses, *l*ast meal, *e*vents/environment/mechanism) to accomplish this. Providers should then perform and document a complete head to toe examination that should follow the standard inspection and palpation model. Specific details on the exam of each body region can be found in ATLS, and many of the issues and controversies in physical examination pertaining to specific body regions can be found in their respective chapters. The need to accurately document the findings on physical examination cannot be overemphasized. All too often later in a patient's hospitalization it is impossible to ascertain a real change in the physical examination from baseline due to poor documentation. This can lead to unnecessary testing or even delays in care.

ADJUNCTS TO INITIAL SURVEY

Although the physical examination is an important component in the initial assessment, its limitations make it necessary to use adjunctive tests to fully identify serious and potentially life-threatening injuries. Adjuncts to the primary survey should be quick and reliable, be able to be performed in the trauma resuscitation bay, and provide a high degree of specificity that positive test results are of unequivocal importance that demands attention. The primary adjuncts remain: chest and pelvic radiography, FAST or eFAST, and DPA (Fig. 13-3). Although computed tomography (CT) scanning revolutionized trauma care and is of undisputed importance in the complete identification of injuries, physiologically unstable patients should not undergo CT, and therefore, we consider it an adjunct to the secondary survey. REBOA placement with improvement in blood pressure, however, may allow for a quick CT scan. Although a complete review of all of these primary adjunctive modalities is beyond the scope of this chapter, the following outlines the major issues.

Chest Radiography

Although not yet relegated to the historical scrap heap, the role of routine chest x-ray (CXR) has been questioned.[45-47] Although chest CT is superior for the complete identification of thoracic injuries, lost in the debate is the true purpose of the plain CXR,[48] which is a screening tool to quickly evaluate a patient for life-threatening conditions. In the patient with an abnormal chest physical examination (eg, tachypnea, low oxygen saturation, significant chest deformity) or hemodynamic instability, the CXR provides a rapid means of identifying hemo- or pneumothoraces, a ruptured diaphragm, pulmonary contusions, or the suggestion of aortic injury. Additionally, pulmonary contusions or multiple rib fractures that can be seen on the screening CXR may predict later respiratory failure and the need for admission to a monitored bed for more comprehensive care.[49] Lastly, the CXR confirms placement of both endotracheal and chest tubes. Thus, although routine CXR may not be warranted in every hemodynamically stable patient with a normal physical examination, it remains an integral and invaluable part of the primary survey in patients with physiologic derangements or positive physical examination findings.

Pelvic X-Ray

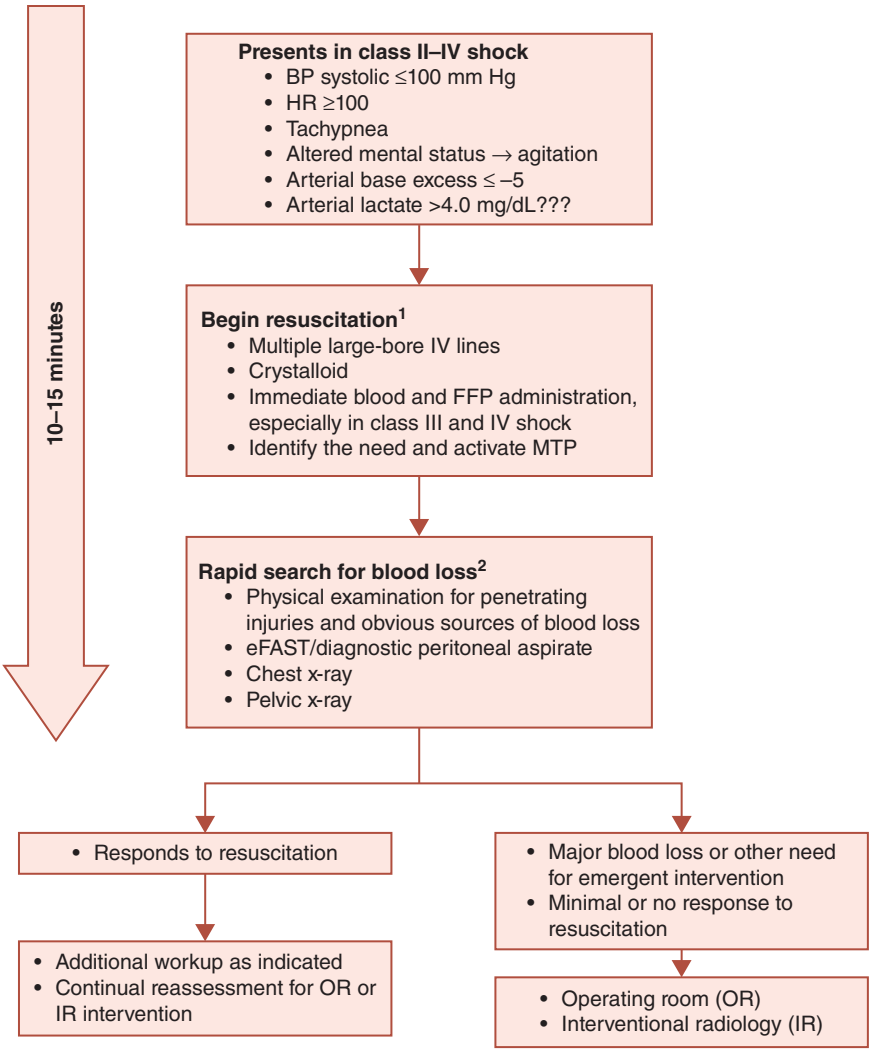
Similar to and possibly to a greater extent than the discussion on screening CXR, there are multiple studies demonstrating lack of utility for routine pelvic x-ray (PXR) as a standard adjunct to the primary survey.[50-52] This conclusion was reflected in current ATLS education, where PXR is no longer considered a mandatory adjunct to the primary survey. In our own practice, we have now focused our efforts in patients with unexplained hypotension in whom a simple intervention such as pelvic binding might be beneficial, or patients with obvious skeletal injuries in whom a hip dislocation may be considered.

Focused Assessment of Sonography in Trauma

The standard FAST exam (four views examining the pericardium, right and left upper quadrants, and the bladder) has been shown to be a useful adjunct in the hemodynamically unstable blunt trauma patient (see Chapter 18).[53-55] Its use has essentially replaced DPA/DPL as the prime adjunct for triage of the abdomen in the unstable patient. Recently, however, there have been questions as to the role this modality plays in certain subgroups such as those with penetrating trauma or the hemodynamically stable patient. Multiple studies have demonstrated that sensitivity and specificity decrease significantly in the patient who is stable or may have other injuries.[56-58] Unlike plain radiography, the reliability of the FAST exam is related to operator experience, patient's body habitus, underlying bowel gas, and the machine itself. The inability to get the critical views makes the scan unreliable, and the examination should not be considered "negative." Thus, in the hemodynamically unstable patient without external signs of bleeding and a clean CXR and PXR, a negative FAST should be interpreted with caution.

The past decade has seen an expansion in the use of ultrasound to include evaluation of the thorax for pneumothorax.[59] The eFAST has been shown in multiple studies to be equal or more reliable in detection of pneumothoraces than CXR.[60-62] Although operator experience always comes into play with ultrasound, the eFAST has the advantage of rapidity and decreased ionizing radiation. However, the true role for eFAST in the trauma patient has not yet been clearly defined. Because the eFAST can detect occult pneumothoraces that might not be found on CXR, caution should be used in making decisions about a tube thoracostomy in those patients.

In those centers with the capability, contrast-enhanced ultrasound has become a potentially viable alternative to evaluate the trauma patient with low-energy mechanisms,



[1] While standard ATLS practices begin with 2 L of crystalloid, in patients with obvious shock and the potential need for massive transfusion, early blood and plasma administration should begin prior to and even in lieu of crystalloid.

[2] While blood loss is the primary reason for shock following trauma in the vast majority of patients, it needs to be emphasized that nonhemorrhage causes of hypotension, such as neurologic, septic, and cardiogenic causes, pericardial tamponade, and tension pneumothorax, need to be identified and treated accordingly.

FIGURE 13-3 Algorithm showing a stepwise approach to a patient presenting in shock. Because time is of the essence, ideally the overall assessment and investigation should take no more than 10 to 15 minutes and should be monitored though performance improvement. Although much has been written about responders and nonresponders to resuscitation, we contend that rapid identification of patients who require emergent intervention is more meaningful. Although nonresponders fit into this group, so do patients who have responded to blood and fluid but still need emergent surgery or interventional radiology without further radiologic or investigatory delay (eg, those with pericardial tamponade, exsanguinating extremity trauma, or severe pelvic fractures). Patients who respond without obvious need for intervention may undergo complete trauma workup as needed. BP, blood pressure; eFAST, extended focused assessment of sonography in trauma; FFP, fresh frozen plasma; HR, heart rate; IV, intravenous; MTP, massive transfusion protocol.

especially in the pediatric population where it is best to avoid ionizing radiation.[63,64] Several studies have demonstrated superior sensitivity, specificity, and positive and negative predictive values as compared to standard ultrasound.

Diagnostic Peritoneal Lavage

Although DPL has been used for over 50 years in evaluation of the trauma patient with suspected intra-abdominal trauma, the adoption of FAST as a noninvasive means of evaluation has caused some to question whether it still has any role in trauma care.[65] However, as the use of FAST has become widespread, potential limitations due to patient, machine, and operator factors have become more apparent, and the role of the DPL in the hemodynamically unstable patient has reemerged.[66] We would submit that there is no longer a need for the actual lavage portion of the procedure, and as currently practiced, it is a direct aspirate of the peritoneal cavity designed to look for

gross blood in the face of hemodynamic instability. Eliminating the lavage mitigates some of the reported disadvantages to DPL, including lack of ability to repeat the study, possibility of altering/skewing CT or ultrasound results with installation of fluid, and high negative laparotomy rate due to its inherent sensitivity. We strongly believe that DPA should not be eliminated from the trauma surgeon's armamentarium. In those instances where the FAST is "negative" in a patient with unexplained hypotension, a DPA should be strongly considered as part of abdominal triage.

CT Scanning

CT scanning of the trauma patient has become a ubiquitous part of the trauma workup. As an adjunct to the secondary survey for the hemodynamically stable patient, there is no doubt that modern CT scanning provides the most accurate means of injury identification over a broad spectrum of possibilities. There is some evidence that the liberal use whole-body scanning identifies clinically significant abnormalities.[67-69] An additional advantage of the "pan-scan" is the ability to discharge patients from the ED safely when the scan is negative.[18] However, there should be some caution in liberally and routinely prescribing total-body CT scans for all trauma patients. In addition to the cumulative radiation over a patient's lifetime, there remains a debate regarding contrast-induced nephropathy, especially in the geriatric trauma patient. The provider should consider all factors, such as mechanism of injury/suspected injury, cooperation of the patient, clinical exam findings, and patient flow, when making decisions as to what scans are needed.

Laboratory

Although there are multiple studies that demonstrate a low utility for certain standard screening laboratory panels in trauma patients, there may be some tests of value depending on the nature of the trauma.[70,71] Although decisions as to appropriate testing can be made based on the severity or perceived severity of the patient, it is often useful to have a "trauma panel" that includes a complete blood count, coagulation profile, and alcohol level. Point-of-care testing should be considered because the results are more rapidly available. All patients should have a type and crossmatch sent. After that, there may be some utility in obtaining an arterial blood gas in patients meeting the highest level of trauma activation.[72,73] This should ideally be able to provide not only the standard values like pH and base deficit but lactate as well. A venous lactate may also provide similar information.[74] For those in shock, thromboelastography (TEG) and thromboelastometry have shown some promise in helping guide resuscitation.[75-77] Although a recent study demonstrated decreased mortality when TEG was used to guide a massive transfusion protocol, along with a decreased use of components, when compared with traditional means of resuscitation, there is a paucity of randomized prospective data as to its true benefit.[78,79]

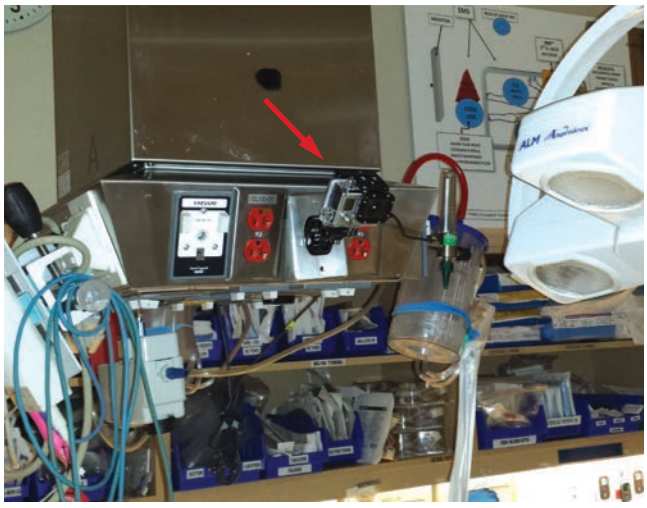


FIGURE 13-4 Small, wide-angled cameras can provide a full field of view during trauma resuscitation for later video review. These devices can be mounted unobtrusively and operated remotely such that the trauma team is unaware of their presence or operations and performs their tasks in a routine manner.

Performance Improvement

With increasing emphasis on short- and long-term outcomes, clinicians taking care of trauma patients should create performance improvement methodology that allows for a thoughtful analysis of each trauma encounter. It should include review of the team's performance during the initial assessment and management of the trauma patient and can begin with identification of appropriate triage of the trauma patient. Flow in the trauma bay, specifically evaluating times to accomplish certain tasks (eg, movement to the operating room or interventional radiology) and timely response of consultants, can also be measured. Although there is no perfect system of recording the events in the trauma bay, the backbone of most performance improvement programs is the trauma flow sheet. These should be completed in sufficient detail that allows the trauma center staff to do a thorough review of any case. Because the primary individuals responsible for charting are the trauma nursing staff, seeking their input in the creation of an institution's trauma flow sheet is invaluable.

First described in 1988, trauma video review has been used in many institutions (Fig. 13-4) and found to be an effective performance improvement tool.[80-82] Although there are medicolegal considerations to its use, trauma video review provides an opportunity to improve performance by highlighting team cooperation, error identification, and educating the entire trauma team.

SUMMARY

The importance of the initial assessment cannot be overstated because it sets the tone for the entire encounter. Recognition and treatment of life-threatening injury form the basis of the initial assessment of the trauma patient. Understanding the

multiple elements that go into the successful performance of the initial encounter with the trauma patient will result in optimal outcomes.

Management of the Airway

James M. Kempema • Marc D. Trust • Carlos V.R. Brown

KEY POINTS

- Airway obstruction can occur from excessive bleeding, expanding hematomas, direct anatomic disruption, traumatic swelling, and edema.
- Prehospital airway interventions can range from BLS airway devices, alternative or blind inserted airway devices, to endotracheal intubation.
- Capnography is the measurement of end-tidal carbon dioxide, which is typically 2 to 5 mm Hg lower than the patient's $Paco_2$.
- In the technique of RSI, laryngoscopy and intubation are facilitated by use of sedating induction agents and short-acting neuromuscular blockade.
- Etomidate and ketamine are the most appropriate induction agents in most RSI protocols.
- Adequate preoxygenation along with passive oxygenation during intubation attempts are vital in preventing hypoxia.
- Factors contributing to difficult airways include anatomic features, abnormal vital signs, and airway contamination.
- General guidelines for appropriate depth of an endotracheal tube are 21 cm for adult women and 23 cm for adult men.
- Surgical cricothyroidotomy is contraindicated in children less than 12 years old.
- A commonly used formula in children to select the appropriate size of an uncuffed endotracheal tube (ET) is ET size in mm = 4 + (age in years)/4.

INTRODUCTION

Airway is the first priority for all civilian trauma patients in the prehospital setting, emergency department, and throughout their hospitalization. In all situations, failure to oxygenate and/or ventilate due to an inadequate airway will lead to death within minutes. The airway in a trauma patient may be adequately managed with either noninvasive maneuvers or a definitive airway, most commonly orotracheal intubation. Clinicians charged with caring for trauma patients must be able to quickly recognize a trauma patient in need of an airway intervention as well as develop and sustain the skills necessary required to perform the vast array of lifesaving maneuvers designed to establish and maintain a patent airway. This chapter will present a detailed discussion regarding the assessment and management of the airway for trauma patients in the prehospital setting and emergency department.

AIRWAY EVALUATION

Airway management in trauma patients is most often an emergency intervention complicated by required cervical spine immobilization for blunt trauma patients. The emergent nature of the procedure does not allow time for a detailed and thorough airway evaluation, so every trauma patient should be considered to have a difficult airway to ensure appropriate preparation. However, a brief evaluation of the airway prior to intervention may provide insight to the possibility of a particularly challenging situation.[1,2]

If the trauma patient is conscious and able to cooperate, a brief history may elicit additional risk factors for a difficult airway including obstructive sleep apnea, arthritis, head and neck cancer or radiation, or any difficulty with previous airway interventions. In addition, history of difficult prehospital airway interventions should be a cue that the current emergency department airway management will be challenging.

Although traditional difficult airway scoring systems such as the Mallampati and LEMON (**l**ook, **e**valuate the 3-3-2 rule, **M**allampati score, **o**bstruction, and **n**eck mobility) scores are not applicable in trauma patients due to the emergent nature of the airway intervention, several physical exam findings may be useful to determine increasing difficulty with airway management. Keeping in mind that the vast majority of trauma patients will have limited neck mobility due to cervical spine immobilization and cervical collar, additional physical exam findings that portend a difficult airway include presence of a beard or facial hair, obesity, and evidence of direct injuries to the head, face, and neck.

Trauma patients may present with blunt or penetrating injuries to the head, neck, or face, which ultimately may result in airway obstruction. This obstruction can be immediate or delayed. It is imperative to manage any airway that cannot by protected by the patient or any patient unable to be adequately oxygenated or ventilated. Additionally, the provider needs to anticipate the potential for obstruction and intervene prior to ventilatory failure. Common causes of direct airway trauma include blunt or penetrating maxillofacial or neck injuries, burns, and smoke inhalation. Airway obstruction can occur from excessive bleeding, expanding hematomas (Fig. 14-1), direct anatomic disruption, and secondary traumatic swelling or edema. Smoke inhalation can directly injure the airway mucosa resulting in severe swelling and edema. Providers need to be aware that this is a dynamic process, with the potential for rapid deterioration in the patient's ability to ventilate.

FIGURE 14-1 Large neck hematoma from a gunshot wound causing potential airway obstruction.

Many patients will have obvious signs of airway compromise and need for intervention such as marked decreased level of consciousness, dyspnea, stridor, hypoventilation, or apnea. Other indirect signs include trismus, drooling, odynophagia, or evidence of direct trauma and resulting anatomic abnormalities to the head, oropharynx, or neck.

Providers need to be familiar with signs for potential impending airway compromise including severe bleeding in the oropharynx from mouth or nose, alteration in voice phonation such as hoarseness, subjective sensation of dyspnea despite supplemental oxygen, hematoma in the neck or lower face, and subcutaneous air in the neck or upper chest. Burn patients should be examined closely for evidence of inhalation injury, including singed facial hair, edema, erythema, soot, or worsening upper airway swelling. In addition, initially stable patients may benefit from early airway intervention prior to progression to a difficult airway. This includes the burn patient with signs of inhalation injury, unstable facial fractures, uncontrolled bleeding into the oropharynx, and worsening or fluctuating level of consciousness.

Patients with penetrating trauma to the face or neck may not need cervical spine immobilization unless they present with an obvious neurologic deficit attributable to a cervical spinal cord injury. If the patient is conscious and there is no evidence of cervical spinal cord injury on presentation, a patient with a penetrating injury to the face or neck should be allowed to sit up and lean forward to facilitate spontaneous respirations and removal of damaged soft tissues, blood, and secretions from the airway. The patient may receive medications for intubation while sitting up and may only be laid flat immediately prior to establishing a definitive airway. Despite the gruesome appearance of these injuries at presentation, the majority of patients will be able to have their airway controlled with rapid sequence orotracheal intubation (Fig. 14-2).

PREHOSPITAL AIRWAY MANAGEMENT

Airway management is one the most essential interventions in care of the critically ill or injured patient in the prehospital environment. It is important to recognize the differences in managing airways in the challenging environment outside the hospital versus the reasonably controlled setting of the emergency department or operating room. In-hospital care allows for a well-lit room, proper patient positioning, and access to multiple trained personnel and advanced airway equipment and interventions. Outside the hospital, patients often present with limited access to medical history or known diagnoses and have the additional challenges of the physical setting in which they are being cared. Emergency medical services (EMS) providers may have to treat patients in the dark, in the rain, or in confined environments and may have limited tools with which to work.

Prehospital Priorities

With the evolution of prehospital care, airway management of trauma patients has continued to change. Endotracheal

FIGURE 14-2 High-velocity gunshot wound to the face. Patient was managed sitting up and leaning forward and was able to maintain his own airway until immediately prior to successful rapid sequence induction and intubation.

intubation was long considered to be an essential skill for EMS personnel. Severely injured patients were considered in need of a definitive, or "secure" airway, which suggested endotracheal intubation as early as possible in the sequence of the patient's care. However, a large number of studies have demonstrated the difficulty in satisfactorily completing this procedure outside the hospital, with strong suggestions of worse patient outcomes as well as difficulties in developing and maintaining proficiency in the skill.[3,4] Patient environment, competency of the provider, access to induction and paralytic medications, and variable postintubation management have all been postulated as contributing factors to worse or adverse outcomes. Subsequently, there has been a slow shift away from endotracheal intubation as the procedure of choice in addition to the development of numerous alternative airways that may be placed more quickly and reliably by EMS providers. It is becoming apparent that maintaining appropriate oxygenation and ventilation for these patients likely results in improved outcomes rather than establishing a more definitive "protected" airway through endotracheal intubation.

Prehospital Personnel

In addition to a variety of devices, there is significant variability in the skill level of EMS providers. The extent to which they can provide airway interventions is based on their training, licensure, and their state or medical director delegated practice. In the United States, there are essentially three levels of training or licensure in paramedicine. There are first responders, often including firefighters or occasionally law enforcement personnel, who maintain basic life support (BLS) skills including minimally invasive techniques such as bag-valve-mask (BVM) ventilation, and placement of nasopharyngeal or oropharyngeal adjuncts. Some BLS providers (EMT) also have been delegated to use alternative airway devices that can be placed blindly and generally sit in the supraglottic space. Intermediate life support medics, also known as advanced emergency medical technicians (AEMTs), also are typically allowed to place these blind insertion airways and may have the benefit of giving some intravenous (IV) medications. Paramedics, or advanced life support (ALS) providers, generally maintain a skill set that includes endotracheal intubation and, in some systems, are allowed to perform drug-assisted intubations with induction and paralytic medications. Air medical providers typically maintain ALS skills at a minimum and often include respiratory therapists and flight nurses. These personnel are usually highly trained and may have access to more advanced equipment and medications, including video laryngoscopes and transport ventilators.

Prehospital Airway Options

BLS AIRWAYS

Many trauma patients can be managed initially in the prehospital setting with simple BLS techniques (Table 14-1). Oxygenation can be improved with supplemental oxygen provided via nasal cannula or simple facemask. Patients with need for a higher fraction of inspired oxygen or higher flow oxygen can be treated with a non-rebreather mask. In the event of poor respiratory effort, more significant respiratory compromise, or apnea, providers must be competent in providing active ventilatory support via BVM ventilation. Key components for BVM include a self-inflating bag, oxygen reservoir, and conforming facemask. The technique can be performed by one or two providers and includes maintaining a tight seal with the mask and the patient in a jaw-thrust position. Although a single provider can execute the procedure, it is certainly more reliable with two due to the need for good patient positioning and maintaining a firm seal while ventilating. This may be a limiting factor, especially with longer patient transports or with units that have access to only two providers. Other adjuncts used to facilitate ventilation include the oropharyngeal airway (OPA) and nasopharyngeal airway (NPA). The OPA is a rigid, curved plastic device placed into the patient's mouth. It is designed to improve

TABLE 14-1: Prehospital Airway Basic Life Support Options

Device	Oxygen flow	Fio_2
Nasal cannula	2–5 L/min	20%–40%
Oxygen mask	6–10 L/min	40%–60%
Non-rebreather mask	10–15 L/min	Near 100%

airway patency by displacing the tongue away from the posterior pharynx. The NPA is a soft, pliable plastic tube inserted into the patient's nose. One or two can be used, as it helps to lift the soft palate to facilitate air passage. During BVM, either or both of these adjuncts is recommended for use to improve both oxygenation and ventilation and can be used with simple or non-rebreather face masks as well. It should be noted, however, that placement of an OPA may induce gagging or vomiting in less obtunded patients.

ALTERNATIVE AIRWAYS

There has been significant progress in the development of alternative airways for use both in and out of the hospital. There are a number of logistical issues that arise with continued BLS management, most importantly the difficulties of performing adequate ventilation by a single provider over long transports. In addition, there are considerations with developing and maintaining competency with endotracheal intubation skills and the association with worse outcomes. Subsequently, there has been a new emphasis on airway management using devices that can be placed rapidly and reliably by EMS crews.[5] There are a number of terms used for these devices including rescue airway, failed airway device, supraglottic airway, or backup airway. However, these devices are increasingly being used as a primary device in order to minimize potential hypoxic time or other adverse events associated with repeated intubation attempts. Considering that these devices are placed without direct or indirect visualization of the glottic opening, the most appropriate descriptive term is a *blind-insertion airway device* (BIAD). The most commonly used BIADs include the King Laryngotracheal (King LT) airway, the I-gel supraglottic airway, and the laryngeal mask airway (LMA).

The **King LT** consists of a single lumen tube that is placed blindly into the patient's oropharynx and intended to enter the esophagus. A single insufflation port inflates two balloons simultaneously with the distal balloon intended to obstruct any gastric secretions and the proximal balloon intended to protect the airway from above. A ventilation port lies between the two balloons with the intention of being placed directly over the glottic opening. Often the tube will need to be adjusted by advancing or pulling back slightly to improve lung aeration once the tube is placed, and this adjustment may be necessary throughout transport or upon arrival to the emergency department. The King LT comes in multiple sizes for both adult and pediatric use, and some versions include an esophageal port allowing placement of an orogastric tube for gastric decompression. There are a number of studies demonstrating the King LT's effectiveness and ease of reliable placement; however, there are limited data suggesting trauma patients have improved outcomes with the device[6] (Fig. 14-3A and B).

The **I-gel supraglottic airway** looks similar to an LMA but has a soft, gel-like, noninflatable cuff designed to fit snugly over the laryngeal inlet (Fig. 14-4). It has a wider, oblong-shaped tube designed for stability in the patient's mouth and also functions as a bite block. Similar to the King LT, the I-gel

A

B

FIGURE 14-3 King LT airway.

FIGURE 14-4 Intersurgical I-gel airway.

has a port for an orogastric tube and comes in multiple sizes. Both the King LT and I-gel promote the ability to float an endotracheal tube introducer (gum elastic bougie) through the lumen and into the trachea, facilitating the exchange of the device with an endotracheal tube. There are a number of studies promoting the ease, reliability, and speed of the I-gel placement.[7-9] The lack of an inflatable cuff may have the advantage of less time required for placement of the device; in addition, some cadaver studies suggest it may actually provide a better seal and protect the airway better than an LMA. This may also be an advantage in air medical transports at higher altitudes where cuff pressure may become an issue.

The **LMA** was originally designed for use in the operating room. It includes a tube blindly inserted into the oropharynx with a distal inflatable cuff shaped to fit around the laryngeal structures. There are limited studies evaluating its use by EMS providers, and it has not been widely adopted, likely due to concerns regarding inadequate airway protection or risk of becoming dislodged.

ENDOTRACHEAL INTUBATION

Paramedics have maintained skills in endotracheal intubation (ETI) for greater than 25 years, and it continues to be included in their training curriculum. Generally, higher level providers such as paramedics have performed intubation; however, select basic-level EMTs are now being trained in the technique, including both the use of alternate airways as well as multiple intubation methods. ETI has long been considered a vital skill for paramedics to maintain, but recently there has been a large body of evidence linking prehospital intubation with worse outcomes or adverse events. A number of these studies have demonstrated patients arriving to emergency departments with tube misplacements, or they are being hyper- or hypoventilated. Other adverse events that have been noted include prolonged hypoxic times and bradycardia during intubation attempts.[3,4] Additionally, there is wide variability in access to adjuncts for intubation including medications to assist the procedure or advanced equipment such as video laryngoscopes.

In general, there are three main approaches to oral ETI by prehospital providers: direct oral intubation (nonmedicated), sedation-assisted intubation, and full drug-assisted intubation (rapid sequence induction [RSI]). There are still a number of programs that perform nasal tracheal intubation; however, this seems to be rapidly falling out of favor with the development of new techniques and airway devices.

Direct, nonmedicated oral ETI is typically reserved for extremely obtunded or cardiac arrest patients and is associated with a high failure rate due to poor visualization and often lack of confirmatory data such as end-tidal capnography. Sedation-assisted intubation has been promoted to be potentially safer than RSI since the patient theoretically maintains some respiratory drive and native airway reflexes. The concern with this approach is that it still does not provide ideal intubating conditions due to lack of muscle relaxation, and many of the same adverse events occur as in RSI. Success rates are considered borderline, although there is some anecdotal evidence suggesting this approach may ultimately require more attempts with the potential for prolonged hypoxia. There are a number of programs that continue to support drug-assisted intubation using the RSI method in which an IV sedative is given in combination with a neuromuscular blocker. Although the literature suggests that ETI in general may result in worse outcomes, there are select groups to which this may not apply. For example, a study of air medical providers actually demonstrated improved outcomes with this technique. It is postulated that this is likely due to the highly trained nature of the crews, both in the procedure and in postintubation management, and access to a larger relative proportion of high-acuity patients. Outcomes of patients are not based on establishing the airway alone, but rather on overall patient management including access to appropriate medications and airway tools, confirmation of airway placement, and postintubation management. This is evident when comparing performance of groups with varying experience and resources. Ultimately, it is clear that prehospital programs that feel there is a regional need to perform drug-assisted intubation must develop and maintain resources for adequate training and maintaining competency in the skill and postintubation management, must provide access to appropriate tools and medications, and must provide a rigorous quality control program to evaluate and continually improve performance.[4]

One final approach that is gaining popularity in EMS is the idea of a "rapid sequence airway" in which the patient is given IV sedation with or without a paralytic in order to facilitate placement of a device. An alternative airway (BIAD) then is placed as the primary device or if one to two intubation attempts are unsuccessful.

SURGICAL AIRWAYS

Most advanced-level EMS providers will receive training in the procedure of establishing a surgical airway when the situation of "can't intubate, can't ventilate" arises. This typically will be in the setting of severe maxillofacial trauma or facial/neck burns that preclude the ability to place an airway device or perform even BLS airway maneuvers. These procedures are potentially lifesaving, but clearly providers need explicit instruction in the appropriate use of the technique. Similar to ETI, there are a number of different methods that are used. Although a standard surgical approach is still used by some, many groups have adopted prepackaged cricothyrotomy kits that use a Seldinger-type approach with a needle and wire. Due to the infrequency of the procedure, there are few data on success rates or associated complications.

Management of Prehospital-Placed Airways

Upon arrival to the emergency department, it is vital to determine the efficacy and placement of any prehospital-placed airway device. For patients who have undergone ETI, confirmation of appropriate placement can be accomplished with the use of end-tidal capnography and/or direct visualization. Patients presenting with an alternative airway in place present

different challenges to the trauma team, including evaluation of its effectiveness and the need for longer-term assisted ventilation. Questions that need to be addressed upon arrival of the patient with these devices include the following:

- Is the patient being adequately oxygenated and ventilated?
- If so, what is the status of patient, and what other trauma priorities need to be addressed?
- What logistical factors determined the use of the alternative airway? For example, does the patient have a difficult airway, and was it placed after multiple ETI attempts?

General considerations for management include immediately exchanging the device in favor of ETI if the alternative airway is not adequately oxygenating and/or ventilating the patient. If the device seems to be functioning adequately, it is likely prudent to delay any exchange until the primary survey is completed at a minimum. Attempting to exchange the device immediately is often unnecessary and can be associated with complications or delays in getting the patient completely assessed. These devices can often provide adequate airway protection and ventilation long enough for not only the primary and secondary surveys to be completed, but also completion of further ancillary studies determining the need for other surgical interventions or the likelihood for longer-term ventilation support. In the event the alternative device is to be exchanged, preparation is vital and anticipation should be made for a difficult airway. Use of the device may have been secondary to multiple intubation attempts with secondary iatrogenic trauma, or the device itself can create significant oropharyngeal edema or bleeding. Both I-gel and King LT airways promote the use of an endotracheal tube introducer to be floated directly through the lumen of the device into the trachea, facilitating the exchange with an endotracheal tube and potentially reducing interruptions in assisted ventilations and hypoxic time.

EMERGENCY DEPARTMENT AIRWAY MANAGEMENT

Preparation, Monitoring, and Equipment

Successful airway management starts with planning and preparation. Planning begins by assembling an airway kit or cart containing the necessary equipment for intubation and rescue devices. The practitioner should take the time to inventory the equipment prior to the intubation, ensuring function and availability. The implementation of checklists has been demonstrated to be very effective in minimizing medical errors in both the operating room and intensive care settings. An airway checklist can be used to ensure all the appropriate personnel, equipment, and medications are in place before proceeding with any interventions (Table 14-2).

EQUIPMENT

The airway cart should consist of drugs, endotracheal tubes, airways, laryngoscopes, airway adjuncts, a variety of syringes and needles, and equipment to establish a surgical airway.

The primary components of the airway kit are the endotracheal tube and laryngoscope. The airway cart should have a variety of tubes in both cuffed and uncuffed types, including tubes down to a 2.0 internal diameter size for pediatrics, and a variety of stylet sizes. Both Miller and Macintosh laryngoscope blades should be included. In addition, the airway cart should be stocked with both the OPA and NPA in all sizes. In the event of failed intubation, several airway adjuncts should be included in the standard airway cart. An array of devices is now available to assist with difficult intubation and failed airway, including alternative airways, lighted wand stylets, retrograde intubation kits, a variety of video laryngoscopic devices, and the endotracheal tube introducer (gum elastic bougie).

The goal of airway management in the trauma admitting area is to closely simulate the control of the operating room. Key personnel should work as a team to assure a successful intubation. The optimal intubating team should consist of a minimum of three to four members including the intubator, a respiratory therapist, and assistants to assist with the procedure including maintaining cervical spine alignment.

MONITORING AND TROUBLESHOOTING

The intubating team should have the patient attached to a cardiac monitor, blood pressure cuff, and pulse oximeter. IV access should be established. Intraosseous devices can be used as well in the event of delayed or difficult IV access. The patient should receive supplemental oxygen via a nonrebreather mask or a BVM depending on the patient's inherent respiratory drive. The correct size of endotracheal tube should be brought to the bedside, and a correctly sized stylet should be inserted. The endotracheal balloon should be checked for leaks. Once the balloon has been checked, a 10-cm^3 syringe is left attached to the pilot balloon. A suction device with a large catheter tip should be readily available and be placed near the right side of the patient's head. The laryngoscope handle/blade connection should be checked for a functional light source. Video laryngoscopes should also be checked for functionality and appropriate power source.

A means to secure the endotracheal tube should be available. Dentures should be removed just before intubation, particularly if the patient is being bagged and his or her dentures allow for a tight mask seal. If cervical spine injury has been excluded, the patient should be positioned with the neck slightly flexed and the head slightly extended on an imaginary axis through the patient's ears. Placing a pillow or towel under the patient's occipital region and elevating the head approximately 10 cm may facilitate this position. Due diligence with respect to preparation of both personnel and equipment makes for a less stressful intubation and improves the practitioner's chances of successfully intubating the patient.

Pulse Oximetry. The pulse oximeter is a portable, noninvasive, and reliable device that measures Spo_2. Although very accurate in analysis of peripheral oxygen delivery, the pulse oximeter may display inaccurate readings in the case of carbon monoxide poisoning, high-intensity lighting, hemoglobin abnormalities, poor perfusion or pulseless extremity, or severe anemia.

Capnography. End-tidal carbon dioxide ($Etco_2$) detectors measure the partial pressure of carbon dioxide in a sample

TABLE 14-2: An Airway Checklist

Date:_____
Time:_____

Emergency Department
Intubation Checklist

Applies to ALL emergent intubations in the ED outside of the cardiac arrest patient

Equipment Necessary:

☐ Intubation cart – includes DL equipment, multiple ET tubes, endotracheal tube introducers (bougie – standard and malleable), stylets, syringes, Magill forceps, nasal trumpet, oral airway, and rescue airways (LMA, BIAD)
☐ Video laryngoscope (GlideScope, McGrath) including rigid stylet and replaceable blade
☐ Difficult airway cart (in room, or immediately accessible outside room)
☐ Monitor – minimum noninvasive BP, HR, Spo_2
☐ $Etco_2$ monitor
☐ Presence of RSI medications and immediate post-intubation medications
☐ Suction
☐ Supplemental oxygen

☐ Lidocaine	☐ Succinylcholine
☐ Fentanyl	☐ Rocuronium
☐ Etomidate	☐ Versed
☐ Ketamine	☐ Propofol

Personnel Necessary to Be Present:

☐ ED attending physician *(all resident intubations need to have an attending ED physician present)*
☐ Respiratory therapist
☐ (2) RNs
☐ Radiology technicians notified and on standby

Procedure:

☐ Patient on monitor, suction on, and accessible
☐ Preoxygenation per RT protocol
☐ Administration of premedications as indicated by condition (lidocaine, fentanyl, etc.)
☐ Administration of rapid sequence induction medications
☐ Application of continuous passive oxygenation per RT protocol
☐ Intubation procedure
☐ Immediate confirmation of tube placement via visualization and capnometry
☐ Tube secured by RT
☐ Patient placed on vent per RT
☐ Patient placed on continuous $Etco_2$ capnography
☐ Chest x-ray obtained and ETT adjusted as indicated
☐ Initiation of postintubation sedation *and* pain management

Signatures:
Recording RN:_____
Attending Physician:_____

BIAD, blind-insertion airway device; BP, blood pressure; DL, direct laryngoscopy; ED, emergency department; ET, endotracheal; ETT, endotracheal tube; HR, heart rate; LMA, laryngeal mask airway; RN, registered nurse; RSI, rapid sequence intubation; RT, respiratory therapy.

gas. The patient's $Paco_2$ is typically 2 to 5 mm Hg higher than the $Etco_2$, and a normal reading in a trauma patient is approximately 30 to 40 mm Hg. $Etco_2$ reading may be used to confirm placement of an endotracheal tube. The presence of carbon dioxide in the exhaled air strongly suggests correct placement of the endotracheal tube in the trachea in a perfusing patient. The disposable capnometer indicates the presence of carbon dioxide with a color change. The electronic capnometer provides the health care provider with a numerical $Etco_2$ and plots the carbon dioxide concentration against time. Although the use of capnometry as an adjunct to monitor the patient's exhaled carbon dioxide has met some success, conditions such as hypotension, increased intrathoracic pressure, and pulmonary embolus resulting in an increased dead space ventilation may decrease the accuracy of the capnometer.

NONINVASIVE AIRWAY MANAGEMENT

Before any airway maneuver is undertaken, a quick visual inspection of the oropharyngeal cavity should be done. Any foreign or loose material should be swept clear with a gloved finger or removed with suction. Blood may be present in the mouth of a trauma patient, and adequate suctioning is essential to maintaining an open airway. Administration of oxygen prior to suctioning may help prevent secondary hypoxia during the procedure. The tongue can cause airway obstruction in the unresponsive patient as it often lacks tone and falls into the oropharynx. Manual airway maneuvers serve to elevate the tongue out of the hypopharynx.

Jaw Thrust. The cervical spine should be kept in normal alignment. The provider should grasp the sides of the patient's face with fingers 3 to 5 along the ramus portion of the mandible. The provider's thumb is on the patient's cheek and the index finger on the chin and lower lip. These two fingers can open the patient's lips or serve to seal the mask on a BVM. The provider's fingers should form an "E" with the three lower fingers and a "C" with the thumb and index finger. Force is applied to the angle of the mandible forcing the mandible forward and anteriorly, while simultaneously opening the mouth with the index finger on the chin.

Chin Lift. With either a free, gloved hand or another provider's gloved hand, the provider's thumb is placed into the patient's mouth, the patient's lower incisors and chin are grasped, and the patient's mandible is lifted anteriorly. This maneuver supplements the jaw thrust and works to lift the mandible anteriorly, elevating the tongue out of the oropharynx.

Basic Mechanical Airway Devices

OROPHARYNGEAL AIRWAY

Oropharyngeal and nasopharyngeal devices can be inserted into either the mouth or nose of the patient, serving to elevate the tongue out of the oropharynx. The OPA is a curved, plastic or hard rubber device that comes in various sizes and has channeling for suction catheters. The device is sized by placing the OPA in the space between the patient's ear and corner of the mouth. A correctly sized OPA will extend from the patient's mouth to the angle of the jaw.

Indications for the use of the OPA include a patient who is unable to maintain his or her airway or to prevent an intubated patient from biting the endotracheal tube. Advantages for use of the OPA include the following:

1. Prevention of obstruction by the patient's teeth and lips
2. Maintenance of the airway in a spontaneously breathing unconscious patient
3. Ease of suctioning
4. Use as a bite block in a patient who is having a seizure

The OPA is contraindicated in a conscious patient as it may stimulate a gag reflex. In addition, it does not isolate the trachea, nor can it be inserted through clenched teeth. It may obstruct the airway if it is improperly placed and can be dislodged easily. To place the OPA, the mouth is opened and the OPA is inserted with the curve reversed and the tip pointing toward the roof of the patient's mouth. Using a twisting motion, the OPA is rotated into position behind the base of the patient's tongue. Alternatively, a tongue blade can be used to depress the tongue with the OPA placed directly into the oropharynx.

NASOPHARYNGEAL AIRWAY

The NPA is a soft rubber or latex uncuffed tube that is designed to conform to the patient's natural nasopharyngeal curvature. It is designed to lift the posterior tongue out of the oropharynx. Like the OPA, it is indicated for patients who cannot maintain their airway. The advantages of the NPA include ease and speed of insertion, patient tolerance and comfort, and effectiveness when the patient's teeth are clenched. Disadvantages of the NPA include its smaller size, the risk of nasal bleeding during insertion, and lack of utility when a basilar skull fracture is suspected.[2]

The provider should first size the NPA by selecting an NPA that is slightly smaller than the patient's nostril. The distance from the patient's nose to earlobe determines the length. The NPA should be liberally lubricated with lidocaine gel prior to insertion. The right nare is preferentially chosen, as it is typically larger. Gentle pressure should be applied until the flange rests against the patient's nostril. After a basic mechanical airway has been inserted, the patient should be oxygenated with supplemental oxygen or a BVM.

BAG-VALVE-MASK

The BVM assists the provider with oxygenation and ventilation in the apneic or hypoventilating patient. With an effective mask seal and an open airway, the BVM can deliver tidal volumes approaching 1.5 L and nearly 100% inspired oxygen with an attached oxygen reservoir. The BVM consists of a bag with a volume of 1.6 L and a standard facemask attached via a one-way, nonrebreathing valve. A reservoir bag and oxygen source are attached to the opposite end of the bag. Multiple sizes are available to treat neonatal, infant, children, and adult patients. To effectively use the BVM, a first provider should establish a properly fitted mask seal while a second

provider squeezes the bag. Using a basic mechanical airway and proper jaw thrust and chin lift techniques while "bagging" the patient can improve maintenance of oxygenation and ventilation.

ENDOTRACHEAL INTUBATION

The majority of injured patients are able to undergo successful orotracheal intubation. In compliance with the Advanced Trauma Life Support (ATLS) course, the preferred definitive airway is tracheal intubation through the mouth using direct laryngoscopy.

Guidelines for Emergency Tracheal Intubation

INDICATIONS

Indications for intubation relate to the following three simple questions:

- First, is the patient able to oxygenate and ventilate?
- Second, is the patient able to maintain an airway?
- Third, will the underlying injury and physiology of the patient lead to a failure to maintain the airway, oxygenate, or ventilate?

The practice management guidelines of the Eastern Association for the Surgery of Trauma (EAST) published in 2012 calls for emergency tracheal intubation in trauma patients exhibiting the following characteristics[10]:

Trauma patients with any of the following traits:

- Acute airway obstruction
- Hypoventilation
- Severe persistent hypoxemia (Spo_2 ≤90%) despite supplemental oxygen
- Severe cognitive impairment (Glasgow Coma Scale [GCS] score ≤8)
- Cardiac arrest
- Severe hemorrhagic shock

Smoke inhalation patients with any of the following traits:

- Airway obstruction
- Severe cognitive impairment (GCS score ≤8)
- Major cutaneous burn (>40% total body surface area)
- Major burns and/or smoke inhalation with an anticipated prolonged transport time to definitive care
- Impending airway obstruction as follows:
  - Moderate to severe facial burn
  - Moderate to severe oropharyngeal burn
  - Moderate to severe burn as seen on endoscopy

Other relative considerations for intubation include:

- Facial or neck injury with the potential for airway obstruction
- Moderate cognitive impairment (GCS score of 9–12)
- Persistent combativeness refractory to pharmacologic agents
- Respiratory distress (without hypoxia or hypoventilation)

In concordance with ATLS, the EAST guidelines promulgate the concept that orotracheal intubation using direct laryngoscopy is the procedure of choice for airway control following trauma.

RAPID SEQUENCE INDUCTION AND INTUBATION

Overview

Intubation by RSI has become the gold standard for management of the airway in trauma and critical illness. The technique of RSI has been demonstrated to increase intubation success rates and reduce complications compared to pre-RSI techniques in a variety of emergent settings.[11] RSI benefits include provision of optimal intubating conditions for injured patients, rapid airway control, high success rates, and reduction of pulmonary aspiration. The adaptability of RSI to individual patient conditions renders the technique optimal for airway control in the injured.

First developed to facilitate operating room intubations in patients with full stomachs, thereby minimizing risk of aspiration, the technique is now widely used by prehospital paramedics, emergency medicine physicians, and trauma surgeons, with a high reported intubation success rate by nonanesthesiologists. Approximately 80% of intubations performed in North American emergency departments use RSI, with a 90% success rate by the first intubator. In the technique of RSI, laryngoscopy and intubation are facilitated by use of sedating induction agents and short-acting neuromuscular blockade (NMB). RSI can be divided into nine components, the nine P's of RSI, as shown in Fig. 14-5.

It is imperative that providers caring for the injured be familiar with all pharmacologic agents used for RSI, including sedative induction agents, NMB agents, benzodiazepines, dissociative agents, and opiates. A "one method fits all" approach is not always applicable, and each patient should be individualized based on type and mechanism of injury,

The Nine P's of Rapid Sequence Induction and Intubation

FIGURE 14-5 The nine P's of rapid sequence induction and intubation.

comorbidities, and potential for adverse events. However, the majority of trauma patients can be effectively intubated using a generalized pharmacologic regimen.

Preparation

Although significant injury with physiologic instability may preclude prolonged preparation for RSI, all efforts should be made to allow for individualized assessment of comorbid conditions, airway status, predictors of difficult intubation, and anticipated pharmacologic regimen. The selection and sequence of pharmacologic agents should be determined, with all agents ready and available in clearly labeled syringes. A *horizontal approach* to the preparatory phase of RSI is optimal, during which multiple personnel with predetermined responsibilities and positions work simultaneously. It should be anticipated that *every* trauma patient requiring ETI will be a difficult airway. There is generally no time or limited ability to perform extensive anatomic evaluations such as Mallampati class or LEMON scores; in addition, these patients often have full stomachs and may have experienced significant maxillofacial or neck trauma. Subsequently it is vital to be prepared with the appropriate personnel and equipment, including the presence of advanced airway backup equipment, devices, and surgical airways. Medications should be chosen based on the physiologic presentation, with thought given to the need for additional sedation, chemical paralysis, analgesia, and blood pressure support in the immediate postintubation phase. All equipment should be prepared and checked as outlined earlier, and the provider should ensure that oxygen access has been established and suction is readily available.

Preoxygenation

Although not originally considered an essential component of RSI, preoxygenation is now considered optimal if the oxygenation, ventilation, and hemodynamic status of the patient permit. The purpose of preoxygenation is to replace the nitrogen-dominant room air occupying the pulmonary functional residual capacity with a 100% oxygen reservoir, prolonging the duration of time before hemoglobin desaturation. Current recommendations for preoxygenation include using a standard reservoir, well-fitting facemask with the oxygen flow rate set as high as possible. Noninvasive, positive-pressure ventilations can significantly improve preoxygenation by using a continuous positive airway pressure mask in the spontaneously breathing patient or gently assisting the hypoventilating or apneic patient with a BVM device. Care must be taken because gastric insufflation may occur, increasing the risk of complications. Recommendations for the duration of preoxygenation necessary for optimal hemoglobin saturation range from 3 to 5 minutes; however, the effectiveness of preoxygenation is dependent on the physiologic status of the patient as well as age, size, and comorbid conditions.[11] For example, an optimally preoxygenated, healthy, 70-kg adult will maintain Sao_2 over 90% for approximately 8 minutes, an obese adult less than 3 minutes, and a 10-kg child less than 4 minutes. More importantly, the desaturation from 90% Sao_2 to 0% occurs much more rapidly than the fall from 100% to 90%. The approximate Pao_2 at 90% Sao_2 is 60 mm Hg, falling to 27 mm Hg at an Sao_2 of 50%. An injured patient with little compensatory reserve can decline from 90% to 0% literally in seconds. Finally, the optimal patient position for preoxygenation will be dependent on the patient's condition. It is known that supine positioning is not ideal as the posterior lung is prone to more atelectatic collapse and it is often more difficult to take full breaths. The ability to sit the patient up in a head-elevated position has been demonstrated to significantly improve preoxygenation ability and prolong times to desaturation; however, this maneuver is limited in trauma patients who may be immobilized for possible spinal injuries. Reverse Trendelenburg positioning can also be used for these supine patients to help facilitate oxygenation.

The concept of a **delayed sequence intubation** (DSI) has gained favor over recent years. It is not uncommon for trauma patients to be significantly agitated secondary to traumatic pathophysiology, hypoventilation, or other intoxicants, inhibiting the ability to adequately preoxygenate. This technique may also be useful in patients who cannot be preoxygenated by other means. DSI involves administration of a sedative, usually ketamine, at procedural sedation doses. The medication is given slowly enough to minimize effects on respiratory drive. This allows for disassociation of the patient to tolerate preoxygenation efforts, including more aggressive maneuvers such as noninvasive positive-pressure ventilation or temporarily placed blind insertion airways. Observational studies suggest that this technique can be used safely and effectively in the hands of experienced providers; however, there needs to be increased awareness of the potential for loss of airway reflexes and the need for immediate intervention.[12]

Pretreatment

Airway stimulation, including laryngoscopy and endotracheal tube placement, results in a *pressor response*, an intense autonomic sympathetic discharge producing tachycardia, hypertension, and increased intracranial pressure. The degree of airway stimulation is proportional to the magnitude of the pressor response. Correspondingly, increased intragastric, intrathoracic, and intracranial pressures may result from Valsalva, bronchospasm, or coughing. As the foundation of RSI relates to abrogating the untoward effects of airway stimulation, preinduction agents can be considered to blunt the physiologic response to laryngoscopy and endotracheal tube placement.

Preintubation medications have both benefit and risk. In order to be effective, these medications should be given at least 3 minutes prior to the intubation attempt. Consideration needs to be given to the potential benefit of the medication and whether the delay created by its administration offsets the need for emergent intubation. Subsequently, these medications should be considered supplementary and not mandatory, and there is no definitive evidence that any of these medications improves outcomes.

Lidocaine. Despite a great deal of controversy regarding the potential benefits of lidocaine during RSI, it is a preinduction agent common to many RSI protocols[13] and is advocated in many emergency airway courses. Lidocaine has a number of theoretical beneficial preintubation effects, including decreasing airway reactivity, the tachycardic response to intubation, and succinylcholine-induced myalgia and fasciculations. It is also proposed that lidocaine reduces the rise in intracranial pressure caused by laryngoscopy, although there has been no high-quality evidence demonstrating this effect. The only absolute contraindications to lidocaine include known allergy or high-grade heart blocks such as third-degree or Mobitz type II. Considering its relative safety, its use should be considered for preintubation, in particular with head-injured patients. Current recommended dosage is 1.5 mg/kg IV, given 3 minutes prior to intubation.

Opioids. Depth of sedation may correlate with speed of intubation in RSI.[14] The sedative and analgesic effects of opioids may provide benefit to the injured patient prior to induction. A commonly used opioid for RSI in the prehospital and emergency department settings is **fentanyl**, which has been shown attenuate the rise in blood pressure and heart rate during RSI. Fentanyl effectively blunts airway reactivity and confers the significant added benefit of analgesia in the injured patient. Fentanyl and other opioids can be associated with respiratory depression and hypotension, which should be taken into consideration with the critically ill or head-injured patient. Current recommended dosage is 3 mcg/kg IV, given over 30 to 60 seconds and 3 minutes prior to intubation.

Atropine. Children, young infants in particular, may experience a pronounced vagal response to intubation attempts. This may be exacerbated by the use of succinylcholine. Current recommendations include the use of atropine for intubation in all children less than 1 year of age and consideration for its use in children under age 5 if using succinylcholine.[15] Dosage should be calculated at 0.02 mg/kg IV with a minimum dose of 0.1 mg and a maximum dose of 0.5 mg. In addition, adults may experience a secondary bradycardia if a second dose of succinylcholine is required. Although shown not to prevent this bradycardia, atropine should be readily available for treatment should bradycardia occur.

Defasciculating Paralytic Agents. **Succinylcholine**, the standard NMB agent used for RSI, produces significant myoclonal fasciculations, prompting a rise in intracranial pressure in patients at risk for intracranial hypertension and the potential for increased oxygen demand. Subsequently, a *defasciculating* dose of a competitive NMB has been previously considered during RSI. Common defasciculating agents include **vecuronium** and **rocuronium** and, less commonly, **pancuronium**. Defasciculating doses are administered as 10% of the paralyzing dose, given 3 to 5 minutes prior to administration of succinylcholine. There is no current high-quality evidence to support the use of a defasciculating dose for patients with elevated intracranial or intraocular pressures, and it is no longer recommended.

Preservation of Blood Pressure

It is common for trauma patients to be hemodynamically unstable, most often caused by hypovolemia due to hemorrhage. Transitioning to positive-pressure ventilation will increase intrathoracic pressure, further decreasing venous return and preload, which can exacerbate this hypotension. In addition, induction medications can directly cause hypotension and the loss of sympathetic drive. The importance of this cannot be understated as even transient drops in blood pressure are associated with adverse outcomes, particularly with head-injury patients. Patients with a **shock index** (heart rate divided by systolic blood pressure) of greater than 0.8 are at increased risk for developing peri-intubation hypotension.[16,17]

Prevention of intubation-induced hypotension begins with appropriate fluid resuscitation. Blood products should be initiated as soon as possible in the hypotensive patient secondary to presumed hemorrhage. RSI medication doses may need to be adjusted, as current dosing recommendations are based on patients without hemodynamic instability. The hypotensive effect of induction medications may be exaggerated when a full dose is administered to a volume-constricted patient. Evolving data recommend reducing their dose by up to 50% in patients with a shock index greater than 0.8.[18,19]

It is unlikely that paralytics have a direct effect on patient's blood pressure; however, consideration should be given to increasing their dose in hypotensive patients. Too small a dose in low-flow conditions may result in inadequate intubating conditions, and a higher dose may be necessary.

Traditionally, vasopressors have been avoided in trauma patients due to concerns for worsening bleeding or unrecognized patient deterioration. However, their use should be considered in high-risk patients such as the severe head-injured patient as they may be beneficial in preventing peri-intubation–associated hypotension. The concept of small "push-dose" or "bolus-dose" pressors has gained popularity in mitigating this hypotensive response, and these agents have demonstrated to be effective in improving hemodynamics in the peri-intubation period. The two most commonly used pressors include epinephrine and phenylephrine; however, epinephrine seems to have some advantages because it has both α and β effects. Consideration can also be given to peripheral IV vasopressor infusions; however, these commonly require more time to establish and administer.

Current recommendations for epinephrine push dose are as follows:

- In 10-mL syringe, draw up 1 mL of epinephrine 1:10,000 and 9 mL of normal saline (equals 10 mL of epinephrine 10 mcg/mL).
- Administer 0.5 to 2 mL every 2 to 5 minutes (5–20 mcg).

Paralysis and Induction Agents

INDUCTION

The perfect **induction** agent would possess rapid onset and elimination, render the patient unconscious but also amnestic, possess analgesic properties, and have negligible side

effects. In injured and critically ill patients, the ideal agent would produce little cardiovascular effects and maintain cerebral perfusion pressure. Regrettably, such an agent does not yet exist. Because many agents produce side effects, including myocardial depression with the potential for hypoperfusion, careful attention should be dedicated to the selection of individual agents. Understanding that all of these medications may create some hypotensive effects, the provider should consider reducing the recommended dose by up to 50% in preintubation hypotensive patients.

Etomidate. Etomidate is a short-acting carboxylated imidazole hypnotic agent frequently used for RSI. It possesses ideal characteristics for urgent and emergent RSI in trauma patients, including rapid onset and clearance, reduction in cerebral metabolic rate, and negligible effects on hemodynamics.[20] This favorable pharmacokinetic profile has led to the widespread use of etomidate for RSI in head injury and hemodynamically labile patients.[21] Accordingly, the American College of Surgeons Committee on Trauma added etomidate to the ATLS course as an induction agent for hypotensive trauma patients. Etomidate decreases cerebral blow flow and cerebral metabolic demand while preserving cerebral perfusion pressure. The most significant side effect of etomidate relates to adrenal insufficiency, as it produces a reversible blockade of adrenal 11-β-hydroxylase. In patients at risk for adrenal insufficiency, including head-injured, mechanically ventilated, and septic populations, etomidate has been independently correlated with reductions in serum cortisol. The controversial question relates to whether transient adrenal suppression produces lasting effects on outcome.[22-24] The majority of research has focused on its use with septic patients. In a systemic review of 18 studies and over 5500 patients, etomidate was not found to increase mortality in septic patients.[24] Further studies are warranted to determine the long-term safety of etomidate for RSI, especially in the setting of trauma. However, given the multiple favorable characteristics of the drug, etomidate remains the standard induction agent in most RSI protocols. Recommended dosage is 0.3 mg/kg IV, onset in 15 to 45 seconds, and duration of action is 3 to 12 minutes.

Ketamine. Ketamine, a rapid-onset dissociative sedative and anesthetic agent, is frequently used for RSI in the pediatric population and in adults with chronic obstructive pulmonary disease. In addition to its sedative effects, ketamine exhibits the beneficial properties of potent analgesia and a partial amnesia and preserves respiratory drive. As a sympathomimetic agent, ketamine may induce tachycardia and increased blood pressure. Secondarily, it is believed to cause bronchodilation, presumably from the release of catecholamines. Controversy has persisted regarding the use of ketamine in patients with head or eye injuries due to suspected elevations in intracranial or intraocular pressures. In actuality, a number of studies demonstrate that ketamine helps to maintain cerebral perfusion pressure and reduce ICP. A number of other studies demonstrated no elevation in intraocular pressures. Ultimately, the evidence to suggest ketamine creates harm in head-injured patients is extremely weak, and considering its associated beneficial effects, hemodynamic stability, and lack of adrenal suppression, its use in RSI in rapidly increasing in popularity.[23] Current recommended dose is 1 to 2 mg/kg IV, with an onset of action in 45 to 60 seconds and a 10- to 20-minute duration of action.

Propofol. Propofol is a nonbarbiturate hypnotic agent that rapidly induces deep sedation and significant relaxation of laryngeal musculature. When used for induction, propofol produces intubation conditions equal to thiopental and equal to or superior to etomidate and, likewise, does not provide any analgesia. Propofol should be used with caution in head-injured or hemodynamically labile patients due to a consistent hypotensive effect and potential reduction of cerebral blood flow. Induction dose is 1.5 to 3 mg/kg IV, with an onset of 15 to 45 seconds and a duration of action 5 to 10 minutes.

Benzodiazepines. Benzodiazepines cause sedation and amnesia through their effects on GABA receptors. **Midazolam** is the most rapidly acting and most commonly used. It does not provide any analgesia but does have anticonvulsant effects that should be taken into consideration in the seizing patient. It usually is associated with hypotension with an average drop of 10% to 25% in the average healthy patient's mean arterial pressure. Subsequently, midazolam should be avoided in the hypotensive or head-injured patient. The usual dose for induction with midazolam is 0.2 mg/kg IV. Other benzodiazepines such as **diazepam** and **lorazepam** are not recommended for RSI.

Barbiturates. **Thiopental** is the most commonly used barbiturate for RSI. Like other induction agents, thiopental has rapid onset and clearance. Thiopental reduces cerebral oxygen consumption and exhibits anticonvulsant effects, rendering it useful in closed-head injury. However, the significant limitation of thiopental use in trauma relates to inhibition of central nervous system sympathetic response. Consequently, thiopental produces reduced myocardial contractility and systemic vascular resistance, inducing hypotension. Therefore, it is best reserved for patients who are euvolemic and normotensive, limiting its application in critically ill patients. **Methohexital** is an additional barbiturate that has been used for RSI. It exhibits similar effects to thiopental, although it is significantly more potent and has shorter onset and duration than thiopental.

PARALYSIS

Pharmacologic paralysis by NMB agents represents an integral component of RSI, facilitating emergent intubation. Paralysis of the musculature improves visualization during laryngoscopy, confers total control of the patient, and reduces complications during intubation. Prehospital NMB has been demonstrated to be safe and to improve intubation success in injured patients undergoing RSI. Potential adverse effects should be diligently assessed, particularly with use of succinylcholine. In addition, preparations for rescue techniques must be made prior to administration of a paralytic agent, in the event of intubation failure. Because paralytic agents provide

no sedative, analgesic, or amnestic effect, it is imperative to combine paralytic use with an appropriate induction agent.

Succinylcholine. Succinylcholine, a depolarizing acetylcholine dimer, acts noncompetitively at the acetylcholine receptor in a biphasic manner to produce muscular paralysis at the motor end plate. Succinylcholine stimulates all muscarinic and nicotinic cholinergic receptors of both parasympathetic and sympathetic systems. Initial brief depolarization results in clinically notable muscular fasciculations, followed by sustained myocyte depolarization. Succinylcholine degradation is dependent on hydrolysis by pseudocholinesterase and is resistant to acetylcholinesterase. Due to rapid onset of action and short half-life, succinylcholine remains the gold standard for RSI in patients not at risk for adverse events. The standard dose of succinylcholine for RSI is 1.5 mg/kg, although recent data suggest a smaller dose of 0.5 to 0.6 mg/kg is sufficient for RSI, facilitating more rapid resumption of spontaneous respiration. Intramuscular injection of succinylcholine has been described, although the required dose, 4 mg/kg, is higher, and onset is slower, than IV injection.

A clear understanding of the potential adverse effects of succinylcholine is critical to its appropriate use in RSI. Contraindications are primarily related to conditions that accentuate the hyperkalemic effects of succinylcholine, as it normally produces a 0.5- to 1.0-mEq/L elevation of serum potassium. Contraindications related to hyperkalemia include thermal injury of age exceeding 24 hours, although receptor upregulation likely does not become clinically relevant until postburn day 5. Therefore, it is safe to use succinylcholine for RSI in most acute burns. Contraindications include crush injury or rhabdomyolysis with hyperkalemia, congenital or acquired myopathies, and conditions of subacute and chronic upper and motor neuron denervation including paralysis and polyneuropathy of critical illness. Contraindications related to known comorbid conditions include history of malignant hyperthermia and pseudocholinesterase deficiency. In addition, succinylcholine is reported to raise intragastric and intracranial pressure due to muscle fasciculations and may contribute to increased intraocular pressure. It should be used with caution in head injury and penetrating globe injury, although the evidence that succinylcholine raises intraocular pressure is anecdotal at best.

Nondepolarizing Agents. Nondepolarizing NMB agents, through competitive blockade of acetylcholine transmission at postjunctional, cholinergic nicotinic receptors, provide an alternative for patients not appropriate for succinylcholine. The aminosteroid compounds, including rocuronium, pancuronium, and vecuronium, represent the commonly used NMB agents for RSI. Nondepolarizing agents for RSI are selected based on the ability to best approximate the rapid onset and elimination of succinylcholine. The most intensively studied nondepolarizing agent used for RSI is **rocuronium**, which exhibits short onset and intermediate duration of action. When contraindications to succinylcholine exist, rocuronium produces acceptable intubating conditions and should remain in the RSI armamentarium as an alternative to succinylcholine. A number of studies have demonstrated no significant differences in intubating conditions with either medication. Proponents against nondepolarizing agents point to their long duration of action in the event the patient cannot be successfully intubated. However, with the addition of newer rescue airway devices and the lack of potential hyperkalemic effect, it has become the preferred paralytic to many providers. As mentioned, consideration should be given to increasing the recommended dose from 1.0 mg/kg up to 1.2 to 1.6 mg/kg in the hypotensive patient to improve intubating conditions.

Sugammadex is an agent developed to rapidly reverse the effects of nondepolarizing agents by binding and encapsulating them, including both rocuronium and vecuronium. Demonstrated to be very effective in reversing the paralytic effect of these drugs, it is approved for use in Europe; however, it has not been approved for use in the United States. In the eventuality that it does become available, nondepolarizing agents likely will become the paralytic medication of choice (Table 14-3).

Passive Oxygenation

Passive, or apneic, oxygenation refers to continuously exposing the oropharynx to high-flow oxygen despite no intrinsic respiratory effort. Oxygenation is a passive process; alveoli will continue to diffuse oxygen into the pulmonary capillary vasculature regardless of diaphragmatic movement. Respiratory movement simply helps expose the alveoli to the oxygen in the environment and force out the accumulated carbon dioxide. By maintaining a high enough partial pressure of oxygen, it will continue to diffuse into the bloodstream. The technique is performed by a number of other specialties, including during bronchoscopies and otolaryngeal procedures.[25] A large number of studies have demonstrated the Pao_2 can be maintained for markedly prolonged periods of time using this method. Eventually patients will become acidotic secondary to carbon dioxide accumulation; however, this technique can significantly help maintain oxygenation during the intubation process and is vital to those patients with poor reserve or at risk for the secondary insult of hypoxemia, such as traumatic brain injuries.[11] Current recommendations are to apply oxygen via nasal cannula to the patient at 15 L/min after preoxygenating the patient and during the intubation procedure. A patent passage to the lungs is vital and can be augmented by use of a nasal pharyngeal airway.

Protection and Positioning

Protection refers to maneuvers used to minimize the risk of aspiration as well as steps to decrease the risk of exacerbating any unstable cervical spine injuries. The Sellick maneuver is the process of an intubation assistant applying direct, downward pressure on the cricoid cartilage using his or her thumb and index or middle finger during BVM ventilations and during the intubation attempt. It was felt that this pressure would compress the esophagus between the cricoid cartilage

TABLE 14-3: Pharmacology of Rapid Sequence Induction and Intubation

Agent	Dose	Onset	Duration	Precautions
Premedication agents				
Fentanyl	1.0–5.0 mcg/kg	30–45 s	0.5–1.0 h	Chest wall rigidity
Midazolam	0.1–0.3 mg/kg	2–3 min	2–3 h	Slow onset
Lidocaine	1.0–1.5 mg/kg	30–90 s	10–20 min	Hypotension
Esmolol	2.0 mg/kg	2–5 min	9–30 min	Hypotension
Vecuronium	0.01 mg/kg	90–120 s	60–75 min	Extended duration
Induction agents				
Etomidate	0.05–0.15 mg/kg	10–60 s	2–5 min	Adrenal suppression
Propofol	0.5–2.0 mg/kg	10–50 s	2–10 min	Hypotension
Thiopental	1.0–3.0 mg/kg	10–60 s	5–30 min	Hypotension
Methohexital	1.0–3.0 mg/kg	30 s	5–10 min	Hypotension
Ketamine	0.5–2.0 mg/kg	30–120 s	5–15 min	ICP[a]
Neuromuscular blockade				
Succinylcholine	0.6–1.0 mg/kg	30–60 s	5–15 min	Hyperkalemia
Rocuronium	1.0 mg/kg	45–60 s	30–60 min	Long duration

[a]Concerns for elevated ICP with ketamine have been refuted in multiple studies.

and the vertebral bodies. There are some studies suggesting this maneuver may help reduce gastric insufflation during BVM ventilations; however, there is minimal evidence demonstrating a reduced incidence of aspiration. In addition, some studies indicate it may contribute to airway obstruction and difficult intubations.[26] Currently, most expert opinions consider the use of the Sellick maneuver to be optional. However, if it is used, the provider performing the intubation needs to control the direction and amount of force applied.

Unless the patient's cervical spine is considered clear of potential injury, immobilization must be maintained. Direct laryngoscopy in particular can impart a significant degree of force to the patient's oropharynx with the potential for lifting, rotating, or flexing or extending the neck. To minimize this and the potential impact on an unstable cervical spine injury, in-line immobilization should be maintained by an assistant, with the provider maintaining pressure on both of the patient's mastoid processes. This allows for a well-controlled head with minimal movement at the cervical spine and the ability to remove or open the cervical collar to minimize its limitations of accessing the airway and neck.[27]

Positioning refers to the position of the patient. The patient's bed should be at an appropriate height for the intubator. In addition, in the rare instance the cervical spine can be cleared prior to intubation attempts, placing a towel, blanket, or sheets directly under the patient's occiput will lift and slightly extend the head in order to optimize viewing the glottis by direct laryngoscopy by optimizing the alignment of the oral, pharyngeal, and laryngeal axes. A functioning large-bore suction catheter should be within arm's reach of the intubator at all times.

Placement with Proof

Success in intubating the injured patient is dependent on thorough knowledge of the anatomy of the upper airway and a meticulous adherence to proper technique. The vocal cords lie posterior and inferior to the pliable epiglottis, which should be visualized as a constant reference point during laryngoscopy. The posterior-most esophagus may be lifted into view with sufficient elevation of the epiglottis. Following preparation of equipment and personnel, the laryngoscope is grasped firmly with the left hand. It should be emphasized that the right hand should be kept free, for suctioning, manipulation of oral structures, and placement of the endotracheal tube. Selection of a straight versus curved blade has less to do with proven efficacy in a particular scenario than the comfort and proficiency of the intubator with a particular blade. In general, the straight blade is used to pass beneath, and directly elevate, the epiglottis. The straight blade is inserted into the esophagus, with the blade withdrawn slowly under direct visualization to expose the glottic opening. The same technique can be applied with a curved blade of sufficient size, although the curved blade technique typically uses insertion of the tip of the blade into the vallecula, with anterior traction of the epiglottis, exposing the glottic opening. The tongue should be displaced by the blade to the patient's left for best visualization of the epiglottis. The motion and direction of the laryngoscope in the left hand during laryngoscopy are of critical importance to safe and successful intubation of the trachea. The proper technique of laryngoscopy employs upward motion of the laryngoscope in the parallel plane of the handle. A "rocking" motion, during which the handle is rotated counterclockwise and posterior, should never be used. This posterior circular motion can impart dangerous extension on the cervical spine or fracture or dislodge teeth. In addition, the left elbow should not be placed on the bed or spine board for stabilization. As the blade is positioned to visualize the glottic opening, the right hand can be used to employ the "BURP" maneuver if the glottic opening is not readily visible. This technique includes **b**ackward-**u**pward-**r**ightward **p**ressure on the thyroid cartilage and is distinct from the Sellick maneuver.

Once the glottic opening is visualized, the tube and stylet should be maneuvered through the cords. If the view is limited, an endotracheal tube introducer (gum elastic bougie) can be placed through the cords first, with confirmation of its placement noted by the distinctive "clicks" felt as the distal portion of the introducer rubs against the tracheal rings. The endotracheal tube without a stylet can then be placed over the top of the introducer directly into the trachea. Once the tube is placed, the cuff should be inflated and the stylet or introducer withdrawn.

Using the centimeter markings on the external surface of the tube can make an estimation of appropriate tube depth. General guidelines for appropriate depth are **21 cm for adult women** and **23 cm for adult men** when measured at the corner of the mouth. The most accurate equation for estimating endotracheal tube depth in children is **depth = age/2 + 13**.[28] Tube placement should always be confirmed by x-ray and adjusted as necessary.

Confirmation of proper endotracheal tube placement is crucial as unrecognized esophageal intubations can lead to devastating complications. The most accurate method of determining this is via end-tidal carbon dioxide detection.[28] This can be done initially with a colorimetric device that reacts with the acidic component of the exhaled carbon dioxide. It is reliable with minimal false positives; however, it is only useful for the first few breaths of the patient. It is now recommended that intubated patients be continuously monitored on a quantitative device (capnometry) or with capnography, in which the exhaled carbon dioxide air is both graphically and quantitatively displaced. These devices are extremely useful not only for recognizing missed or dislodged intubations, but also to significantly improve noninvasive management of the ventilated patient.

Clinical indicators of intubation including tube misting, lung auscultation, and tube visualization through cords cannot be relied on to confirm appropriate tube placement. A chest x-ray should be obtained immediately after intubation; however, it is most useful for endotracheal tube depth and not necessarily endotracheal placement confirmation. Regardless, esophageal intubations need to be recognized as soon as possible and cannot wait on the time necessary to acquire an x-ray.

Postintubation Management

Once endotracheal tube placement is confirmed, the tube needs to be properly secured to the patient to minimize risk of displacement. Tape can be used, although it is not as well tolerated as some of the newer proprietary tube holders. The chosen method needs to be readily available and secure.

As mentioned, a chest x-ray should be obtained to determine appropriate endotracheal tube depth. Close attention should be paid toward any radiographic signs of pneumothorax as this can quickly convert to a tension pneumothorax now that the patient is under positive-pressure ventilation.

Hypotension is a common event immediately after intubation, occurring in approximately 25% of emergent intubations, despite appropriate medication selection. Roughly 2% of critically ill patients will experience cardiac arrest after intubation.[29-31] Proposed causes include decreased venous return due to positive-pressure ventilation, loss of autonomic vascular tone, and lingering effects of the induction medications. Treatment consists of maintaining adequate preload with appropriate fluid and blood resuscitation. Close attention should be paid to airway pressures and the potential development of a pneumothorax. Consideration can also be given to a titratable vasoconstrictor, such as phenylephrine or epinephrine, to be readily available and administered to maintain vascular tone and augment venous return in those patients hypotensive either prior to the procedure or immediately after intubation. Finally, providers need to be cognizant of the potential acid-base status of the patient. Many hypotensive trauma patients will be experiencing a metabolic acidosis secondary to poor perfusion. An increased ventilatory rate will be needed to help compensate for this and can be easily overlooked.

Analgesia and additional sedation also need to be addressed. Despite the induction medications, intubation is an uncomfortable procedure, and many patients will begin to start "fighting" the tube. Fentanyl is an easily titratable medication and more hemodynamically stable than the other opiates. The induction medications are metabolized fairly quickly, and the patient will likely require additional sedation and occasionally paralytics. The choice of sedation is determined by the need for neurologic reassessments and the hemodynamic status of the patient. Propofol is an effective medication and easy to titrate, and its quick "on/off" action allows the patient to be easily reassessed. Benzodiazepines such as lorazepam and midazolam are also used and have a more prolonged effect. All of these can be associated with induced hypotension, particularly with higher doses, and benzodiazepines have also been correlated with intensive care unit delirium. Dexmedetomidine (Precedex) is a newer medication gaining popularity that offers a variety of advantages, including analgesic effects, anxiolysis, hypnosis, and no respiratory depression. The two major downsides of dexmedetomidine are bradycardia, which is dose dependent and can be avoided, and cost. Finally, ketamine has anecdotally been shown to be effective in bolus dosing or as an infusion, in particular with the hypotensive trauma patient; however, prospective studies on its safety and efficacy for this purpose are still lacking.

VIDEO LARYNGOSCOPY

The morbidity and mortality associated with the difficult airway, compounded by potential litigation and the burgeoning epidemic of obesity, have fostered rapid growth in video laryngoscopy (Fig. 14-6). Many devices are now available, including the Verathon GlideScope, Truphatek Truview EVO2, Pentax Airway Scope, McGrath MAC Enhanced Digital Laryngoscope, Storz C-MAC Video Laryngoscope, and AirTraq Laryngoscope, among others. All devices have a rigid blade for laryngoscopy combined with videoscopic visualization of the anatomy in proximity to the end of the blade. The visual field is located through an eyepiece in proximity to the blade handle or on a separate portable monitor. The technology provides direct visualization of the glottic opening,

FIGURE 14-6 Video laryngoscope.

facilitating intubation. The specific features and characteristics of the video laryngoscopes vary, but they each provide an indirect view of the upper airway and a theoretical advantage in minimizing cervical spine motion during intubation.[32-35] Video laryngoscopes are being used in essentially any scenario in which a difficult airway may be encountered, including the emergency department, operating room, and intensive care unit. Application in the prehospital environment has been limited by financial constraints, lack of comparative data, and need for provider training. In comparisons of the effectiveness of video and conventional laryngoscopy, visualization of the glottis has been shown to be superior using video devices, but data regarding speed and efficacy of intubation are conflicting. As noted in the most recent EAST trauma guidelines, video laryngoscopy may offer significant advantages over direct laryngoscopy, including the following[10]:

- Superior views of the glottis (Cormack-Lehane I/II)
- Higher intubation success rates in patients with anatomically difficult airways, in obese patients, and in those with the cervical spine held in line
- Higher intubation success rates by inexperienced airway providers

Direct laryngoscopy (DL) by trained physicians, with the use of in-line stabilization for cervical spine protection, has been shown to be a safe and effective means of intubation in trauma patients. Despite the good success rates with DL, the use of video laryngoscopy (VL) and the studies evaluating its use have been increasing. In a review of current literature, the EAST Trauma guidelines summarize that VL provides an improved Cormack-Lehane view grade, cervical spine motion is lessened, force and pressures exerted on the airway are decreased, hemodynamic responses are minimized, and time to intubation is similar with VL as compared with DL.[10,36,37] One study specifically looking at patients intubated with cervical spine immobilization by a semirigid collar showed improved views with the GlideScope compared with a Macintosh blade. A large retrospective study of 822 emergency department intubations (of which >60% were trauma patients) showed that overall success rates for VL were similar to DL, but first-attempt success rates were higher using the GlideScope.[36] There are a number of challenges in studying the effectiveness of VL versus DL due to the variety of devices available, familiarity with these devices, and experience level of the providers with the use of either direct or video laryngoscopes. A Cochrane review published in 2017 concluded that video laryngoscopes reduced the incidence of intubation failure, particularly in the context of a difficult airway.[38] The importance of first-pass success rates cannot be understated considering the morbidity associated with multiple attempts and missed intubations.[39] Video-assisted devices may have a greater role for patients with potentially difficult airways in whom DL may not provide good visualization, especially in the setting of trauma and the limitations imposed by patient positioning and maintenance of cervical spine precautions.

Additional studies will undoubtedly be forthcoming. It is clear that VL demonstrates some advantages over DL, especially in the trauma patient or the patient with a difficult airway. In consideration of these advantages, gradually decreasing costs, and increased provider training in its use, VL will likely become the preferred primary airway modality.

ADJUNCTS TO ENDOTRACHEAL INTUBATION

The inability to establish a definitive airway or provide effective oxygenation and ventilation to a trauma patient in a timely manner can have devastating effects on their outcome. A number of devices have already been mentioned to help facilitate intubation including the use of video laryngoscopes and endotracheal tube introducers. If using DL, it is imperative to have an endotracheal tube introducer (bougie) immediately available, and some popular airway courses recommend it to be used routinely. Visualization of the patient's vocal cords can often be limited. The endotracheal introducer can often be placed significantly more easily than the endotracheal tube itself and can even be placed blindly using the "feel" of the device as it passes along the tracheal rings. The endotracheal tube can then be advanced directly over the introducer. They are inexpensive and come in multiple types, including malleable introducers that can be formed to maintain the same shape and curve of a video laryngoscope. This can prove quite valuable in the event it is difficult to pass the tube past the placed VL handle and blade.

Although previously mentioned, a stylet is very useful to "shape" the endotracheal tube to provide stability, improved control of the tube, and assist placement. Most video laryngoscope manufacturers recommend the use of proprietary rigid stylets that duplicate the same severe angle of the VL blade. Since the cords are indirectly visualized, the tube is forced to travel around the bend of the oral pharynx into the laryngeal and tracheal space, which the rigid stylets facilitate.

Two other types of stylets include the lighted and optical versions. Lighted stylets have a bright light source at the distal tip, allowing visualization of the glottis through the soft tissues of the anterior neck to confirm placement. Studies demonstrate it does take some time to acquire the skill in using the device with secondary longer times to intubation; however, it has been demonstrated to be useful in anteriorly located airways.[40,41] Optical stylets maintain a video viewing component at the distal end of the stylet and come in different forms including rigid and directable options. The endotracheal tube is loaded onto the stylet prior to the procedure, and then the stylet is advanced until visualized passing through the cords, usually through an attached eyepiece. Few data exist evaluating their comparative effectiveness, and it is generally believed their utility would be limited in airways with significant contamination, such as blood or emesis.[42]

It is vital to remember the importance of maintaining adequate ventilation and oxygenation. Allowing head-injured patients to become hypoxic or hypotensive has been well established to lead to secondary insult and significantly worse outcomes. In the event that an endotracheal tube cannot be easily introduced, alternative devices should be readily available and placed before a patient is allowed to become hypoxic. These devices are well described in the prehospital portion of this chapter but can also be very effective in the emergency department or operating room. Considered to be "extraglottic" because they do not enter the trachea, these airways are typically placed blindly. Examples include the LMA and the I-gel. The LMA is designed to form a seal with an inflatable cuff over the glottic opening and comes in multiple models. These include an intubating LMA, which allows passage of an endotracheal tube directly through the device into the trachea. The I-gel looks very similar to the LMA but has a noninflatable cuff made of a gel-like flexible polymer. There are several studies demonstrating the effectiveness of all these devices, including ease of reliable placement, effective temporary ventilation and oxygenation, and use in managing difficult airways.[7,8,43]

Flexible endoscopes are expensive, long, fiberoptic stylets that can be directed into the patient's trachea. They can be used both for orotracheal and nasotracheal intubation and typically take significant time to place an endotracheal tube. Subsequently, they are not well suited for emergent management of airways in the critically injured trauma patient.

UNIQUE CHALLENGES IN TRAUMA AIRWAY MANAGEMENT

Physiologic Challenges

There a number of nonanatomic patient factors that can influence the outcome of air management. These factors can dramatically worsen patient outcomes and thus should be considered in all patients, in addition to anatomic components, when preparing and planning for intubation. Whenever possible, these physiologic factors need to be prepared for and corrected prior to the procedure.

Considering that the majority of trauma patients requiring intubation are head injured, it is imperative to minimize the risk of a secondary brain injury. It is well documented that allowing these patients to become hypoxic and/or hypotensive leads to significantly worse clinical outcomes, with increases in both morbidity and mortality. The procedure of pharmacologically assisted intubation can create either of these conditions, and diligence must be maintained to minimize the extent. The process requires patients to become apneic, occasionally for several minutes, during the procedure. Combined with a patient who may have decreased pulmonary reserve, this may lead to rapid oxygen desaturation. Appropriate preoxygenation and continuous passive oxygenation are vital to minimize this risk. As previously described, the concept of DSI can be used to facilitate the preoxygenation process. An IV sedative is given at a dose to provide procedural sedation levels. Ketamine is often selected due to its hemodynamic stability and minimal effect on respiratory drive. This delayed approach can assist in improving preoxygenation levels in the combative or obtunded patient. Once sedated, supplemental oxygen can be provided by non-rebreather, BVM with or without a positive end-expiratory pressure valve, or even noninvasive positive-pressure ventilation to maximize alveolar nitrogen washout and oxygen saturation. The goal is maintaining an oxygen saturation greater than 94% for at least 3 minutes prior to making the intubation attempt.

Trauma patients are also at greater risk for developing hypotension during intubation. In addition to the direct effects of traumatic injuries with potential hypovolemia or neurogenic shock, patients may become hypotensive secondary to direct effect of the induction medications or loss of autonomic tone, in addition to converting to positive-pressure ventilation, which can further decrease venous return. In additional to worse outcomes in head-injured patients, preintubation hypotension has been identified as an independent risk factor for peri-intubation cardiac arrest.[30,31,44]

There are several proposed procedures intended to minimize the extent of this hypotensive response. The first is adequate volume resuscitation; in trauma patients with suspected significant hypovolemia secondary to blood loss, this implies early and aggressive resuscitation with blood products. As mentioned, there is also a proposed benefit to decreasing the dose of induction sedation medications and increasing the paralytic dosing. Finally, "push-dose" or "bolus-dose" vasopressors can be used to help sustain blood pressure and mitigate the effects of the induction medications and positive-pressure ventilation. Both phenylephrine and epinephrine have been proposed as agents for this procedure; however, most experts in resuscitation seem to prefer epinephrine due to its effects as an α- and β-agonist, which can increase vascular resistance and blood pressure and also augment cardiac output.

Contaminated Airway

Airways in trauma patients are frequently contaminated by blood, secretions, injuries from maxillofacial trauma, or emesis, leading to increased difficulty in successful intubation.[45] The operator must be prepared for dealing with these circumstances and anticipate this difficulty. James Decanto, MD, an anesthesiologist specializing in airway management training,

has promoted the use of the "SALAD" technique, referring to **s**uction-**a**ssisted **l**aryngoscopy **a**nd **d**econtamination. He promotes using a significantly larger bore suction catheter to minimize obstruction of the device by any debris in the oropharynx. He then promotes aggressive suctioning of the mouth and oropharynx prior to introducing the laryngoscope blade and then using the suction device as a type of tongue depressor to facilitate ideal placement of the blade. Once the blade is in the mouth, the suction catheter can be advanced into the proximal esophagus to provide continuous drainage. The catheter is then pushed to the left side of the patient's mouth and held in place by the laryngoscope blade during the intubation procedure. He further recommends suctioning of the endotracheal tube prior to any ventilations to minimize spread of any aspirated material. One option of this technique is to use the larger bore suction catheter in a similar fashion to the endotracheal tube, using it to intubate the trachea, and then disconnecting it from suction. It can then be used as a conduit for an endotracheal tube introducer (bougie). The catheter is then removed over the introducer and replaced with an endotracheal tube.

Suspected Cervical Spine Injuries

Trauma care providers typically proceed under the assumption that the patient has an unstable cervical spine injury, and patients are traditionally placed in cervical collars and often transported on a rigid backboard, despite little evidence to support that these measures prevent secondary spinal cord injury. These patients are typically supine, limiting the ability to optimally position the patient, and cervical collars or manual in-line stabilization can limit visualization. It is vital that providers tasked with maintaining in-line stabilization immobilize the head and neck without limiting mouth opening or mandibular movement. Evidence suggests these limitations are more pronounced with DL, resulting in higher occurrence of poor views, longer intubation times, and more frequent failed intubation attempts.[46,47] Video laryngoscopes have demonstrated improved glottic views in immobilized patients; however, this does not always translate to improved success rates because there are still challenges in delivering the tube via the hyperangulated approach.

Providers need to be prepared for difficult visualization of the cords or challenges in passing the endotracheal tube and should choose the device in which they have the most experience. Rigid cervical collars should be opened and replaced by manual in-line stabilization. Finally, endotracheal tube introducers may be beneficial is assisting tube placement.

An algorithm for airway management in trauma patients is presented in Fig. 14-7.

MANAGEMENT OF PATIENTS WITH DIRECT AIRWAY TRAUMA

Trauma patients often can present with blunt or penetrating injuries to the head, neck, or chest, which ultimately may result in airway compromise. This compromise can be immediate or delayed. It is imperative to manage any airway that cannot by protected by the patient or in any patient who cannot be adequately oxygenated or ventilated. Additionally, the provider needs to anticipate the potential for delayed obstruction and intervene prior to respiratory failure.[48-50]

Management of patients with direct airway trauma will depend on the severity of the injury and criticality of the patients at that particular time. A subset of patients may be candidates for close observation if they maintain normal mental status and normal vital signs, including pulse oximetry, and do not demonstrate any evidence of impending airway compromise. The majority of patients needing intervention with direct airway trauma can be managed with the described RSI technique; however, it is imperative to recognize that these patients are at significantly higher risk of becoming a difficult intubation. Preparation is vital including immediate access to airway adjuncts and a surgical airway kit. This is especially true in in injuries resulting in severe oropharyngeal trauma or a hematoma within the anterior neck. In patients with direct penetrating trauma or clothesline-type mechanism resulting in an exposed trachea, direct insertion of either an endotracheal tube or tracheostomy tube through a tracheal defect is an alternative option (Fig. 14-8).

In certain patients, there will be a high level of concern for a difficult intubation due to factors such as the extent of injury, excessive bleeding or swelling, facial deformities, or body habitus. In these patients, it is best to prepared with a "double setup" in which the neck is simultaneously prepped and equipment accessed for a surgical airway placement during the intubation preparation phase. Thus, in the event of unsuccessful intubation or failed airway, there is minimal time delay to secure access to a definitive airway. In the event of an associated upper airway obstruction that cannot be immediately cleared, providers should move directly to a surgical airway.

Another approach gaining popularity is the concept of an "awake" intubation, or utilization of the delayed sequence technique in patients with a high suspicion for difficulty placing the endotracheal tube successfully. Ketamine is often selected due to its hemodynamic stability and minimal effect on respiratory drive and can be supplemented with a topical anesthetic, such as atomized or nebulized lidocaine. Once sedated, supplemental oxygen can be provided by nonrebreather, BVM, or even noninvasive positive-pressure ventilation to maximize alveolar nitrogen washout and oxygen saturation. This is especially helpful for preoxygenation of the delirious or combative patient. The provider can then attempt to "look" at the airway using DL or VL techniques. If the cords are adequately visualized, the provider can then either attempt the intubation or subsequently have a chemical paralytic administered to facilitate placement of the tube. Current literature surrounding DSI is limited. One study including mostly nontrauma patients noted improvements in oxygen saturation with preoxygenation interventions and did not observe any complications.[12] It is important to note that this concept has not been extensively studied in the trauma population, and its application should be used with caution.

SURGICAL AIRWAY

A surgical airway is the definitive rescue maneuver to manage patients with a difficult airway that cannot be secured by conventional techniques and results in a failed airway. Three options exist for a surgical airway: open cricothyroidotomy, Seldinger cricothyroidotomy, and needle cricothyroidotomy. The open and Seldinger cricothyroidotomy can be performed in an adult with a failed airway. Needle cricothyroidotomy is the rescue airway of choice in children because surgical cricothyroidotomy is contraindicated in children younger than 12 years old. In addition, a needle cricothyroidotomy may be performed in an adult if no equipment or expertise is available to perform an open or Seldinger cricothyroidotomy.

The key to any surgical airway is preprocedure preparation and a complete understanding of the relevant anatomy and surgical technique, as this uncommon procedure is typically performed in an emergent, time-sensitive manner. Anyone charged with managing a surgical airway for trauma patients should have thorough knowledge of the laryngeal anatomy and become familiar with the instruments available in their practice environment. Regardless of technique or instrumentation, the critical first step of performing a surgical airway is identification of the anatomic landmarks in the anterior neck. The cricothyroid membrane is located between the thyroid cartilage superiorly and the cricoid cartilage inferiorly (Fig. 14-9). It is more easily palpated in men due to a more prominent thyroid cartilage. Although fairly easy to identify in nonobese patients, the cricothyroid membrane can be obscured in trauma patients due to subcutaneous emphysema, hematoma, or direct laryngeal trauma.

Open cricothyroidotomy is performed with standard surgical instruments. Basic instruments required for an open cricothyroidotomy include a scalpel, hemostat, and either a smaller (size 6) tracheostomy or endotracheal tube. A trach hook can also be critically important, as this will provide stability to the tracheal cartilage during tube insertion. Although most surgical procedures require sterile technique, the lifesaving and emergent nature of a surgical airway does not allow time to perform a sterile procedure. Splashing iodine onto the neck prior to incision provides no anti-infective efficacy and merely makes the instruments wet and slippery, making an already challenging and stressful procedure even more difficult. The nondominant hand is used to grasp the laryngeal complex and the same index finger is used to identify the cricothyroid membrane. For this reason, a right-handed surgeon should stand on the patient's right side and a left-handed surgeon should stand on the patient's left side while performing an open cricothyroidotomy. Once the laryngeal complex has been stabilized and cricothyroid membrane identified, the nondominant hand should not be released until the airway is in place. With the dominant hand, the surgeon should make a vertical incision directly over the cricothyroid membrane. Although a horizontal skin incision may be used as well, a vertical incision avoids lacerating an anterior jugular vein and allows superior or inferior extension of the incision if necessary. The first incision should open all subcutaneous tissue between the skin and the cricothyroid membrane. This usually leads to bleeding, and the remainder of the procedure is typically performed with little or no visibility of anatomy. Instead, the next steps are guided by tactile identification of the cricothyroid membrane with the index finger of the nondominant hand. Next, a transverse incision is made in the cricothyroid membrane. If the cricothyroidotomy is not large enough to accept an airway, it may be dilated with the index finger, hemostat, or the end of a scalpel handle opposite the blade. Next, if available, a trach hook can be placed on the midline of the thyroid cartilage, and anterior-superior traction is applied to help prevent the anterior portion of the trachea from collapsing during tube insertion. If a

trach hook is not available, the nondominant hand is used to grasp the laryngeal complex to apply counterpressure. Finally, the tracheostomy or endotracheal tube is placed into the airway, the balloon on the tube is inflated, and confirmation of appropriate tube placement is performed, as discussed previously, and the tube is then sutured in place. If difficulty is encountered while placing the tracheal tube, a gum elastic bougie can be placed into the trachea and used in a Seldinger fashion to guide the tube into the appropriate location.

Seldinger cricothyroidotomy is performed with a prepackaged commercially available kit. As each kit is slightly different, clinicians should familiarize themselves with the kit used at their facility. Regardless of which commercial Seldinger kit is used, there are several basics steps common to all Seldinger cricothyroidotomies. Place the needle with overlying catheter onto a syringe with saline. While aspirating, puncture the cricothyroid membrane pointing the tip of the needle at a 45-degree angle toward the feet. Once bubbles are aspirated, advance the catheter over the needle and into the airway and remove the needle and syringe. Pass the guidewire through the catheter in the usual Seldinger manner and remove the catheter. Next, make a vertical skin incision around the wire, and advance the airway/dilator over the guidewire though the cricothyroid membrane and into the airway. Remove wire and dilator, inflate the cuff, and suture the airway in place.

The technique of needle cricothyroidotomy is the same as the first few steps of Seldinger cricothyroidotomy until the catheter is in the airway. For a needle cricothyroidotomy, once the catheter is in the airway, it is attached to a jet ventilation system using a Luer lock. Alternatively, a 5-mL syringe can be cut and attached directly to oxygen tubing, or the tubing can be wedged into the open end of the syringe and connected to high-flow 100% oxygen. An alternative method is to attach a 3-mL syringe to a 14-gauge catheter with an endotracheal tube adapter inserted into the open end of the syringe (Fig. 14-10). This technique allows direct attachment of the BVM to the syringe. Whatever system is used, an aperture should be created such that when occluded, jet insufflation occurs, and when open, flow may escape. Jet insufflation should proceed at approximately 1 second of flow (inspiration) for every 3 seconds of release (expiration). Because ventilation is not actually occurring, alveolar carbon dioxide rises. A point of emphasis is the temporizing nature of the procedure; life may be sustained for approximately 30 minutes while a definitive airway is established.

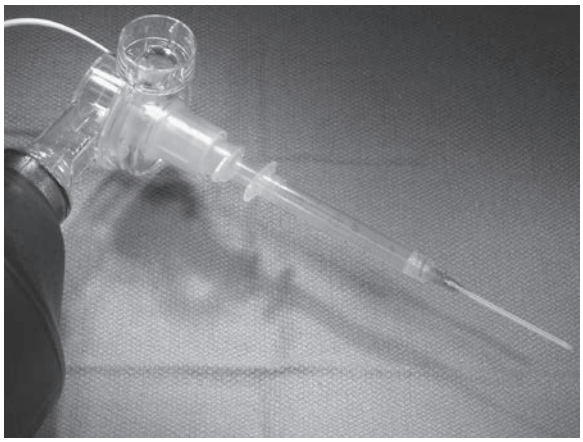

FIGURE 14-10 A photograph of a useful setup for needle cricothyroidotomy, consisting of a standard 8-mm diameter endotracheal tube adapter, a 3-cm^3 syringe, and a 14-gauge angiocatheter. The endotracheal tube adapter is removed and inserted into the open end of the 3-cm^3 syringe (plunger removed). The angiocatheter is affixed to the syringe. A bag valve mask is then able to be attached to the adapter, allowing easy ventilation of the patient.

PEDIATRIC AIRWAY MANAGEMENT

Children and infants have unique anatomic and physiologic features that may impact airway management and intubation. These need to be taken into consideration in the planning and management of pediatric intubations.[51-53]

Anatomy

PROMINENT OCCIPUT

The occiput in infants and younger children is proportionally larger, causing varying degrees of neck flexion in the supine position. This can result in anatomic airway obstruction or potentially interfere with attempts to visualize the glottic opening, particularly during DL. Placing a towel roll under the shoulders can improve airway alignment. This approach is in contrast to placing a pad under the occiput in adults.

LARGE TONGUE

Infants and young children also have larger tongues relative to the size of the oral cavity. Appropriate control and displacement of the tongue are vital to maintain adequate visualization of the larynx and trachea. In addition, the tongue becomes a common source of upper airway obstruction, particularly in patients with depressed level of consciousness and secondary loss of intrinsic airway tone.

LARGER TONSILS AND ADENOIDS

Children more commonly have larger tonsils and adenoids than adults. This may result in more difficulty in ventilating children by standard basic noninvasive measures. The tonsils are also more susceptible to injury and bleeding during intubation attempts.

SUPERIOR LARYNGEAL POSITION

The position of the larynx in infants and children is more superior, or cephalad, compared to adults. It is located opposite the C3 to C4 vertebrae, whereas an adult larynx is typically in line with C4 to C5. This creates a more acute angle between the glottic opening and the base of the tongue. This can make direct visualization more challenging and may favor the use of VL.

LARGER EPIGLOTTIS

The epiglottis is relatively large and floppy in children, particularly those younger than 3 years of age, and is angled more acutely with respect to the axis of the trachea. Subsequently,

more of the glottic opening can be obstructed. During DL, the use of a straight blade to directly lift the epiglottis can improve visualization.

SHORTER TRACHEA

The trachea length is approximately 5 cm in neonates and grows to about 12 cm in adults. Given the shorter segment within which an endotracheal tube can be correctly placed, there is a predisposition to right mainstem bronchus intubation and also inadvertent extubation.

NARROW TRACHEA

In addition to being shorter, the trachea in younger children is also narrower. Airway resistance is inversely proportional to the lumen radius to the fourth power, so even small decreases in the airway size from secretions or edema will have disproportionate effects on airflow. In addition, the space between tracheal rings is very narrow and the cricothyroid membrane is very small, making needle or surgical cricothyroidotomy technically challenging.

ANATOMIC SUBGLOTTIC NARROWING

The cricoid ring has been identified as the narrowest portion of the pediatric airway. Historically it was felt that this narrowing can create an effective anatomic seal without the need for a cuffed endotracheal tube and that the pressure associated with cuffed tubes may result in further subglottic stenosis. However, use of newer cuffed endotracheal tubes in children is associated with a reduced need for endotracheal tube exchanges and no increase in postextubation morbidity when compared to uncuffed tubes. Newer endotracheal tubes maintain a smaller profile and lower pressure cuffs, and the American Heart Association now has approved these for all pediatric patients outside the newborn period, provided the cuff pressure can be maintained at less than 20 cm H_2O.

COMPLIANT CHEST WALL

The thorax is more compliant in children due to the primarily cartilaginous nature of skeletal structure compared to the more rigid bony structures in adults. However, greater intrinsic muscle tone is required to maintain lung volumes and prevent chest wall distortion. Subsequently, infants and young children are more likely to experience respiratory muscle fatigue, atelectasis, and respiratory failure.

Physiology

Airway management can be affected by pediatric-specific physiologic factors as well.

AGE-RELATED RESPIRATORY RATE

Ranges for vital signs will vary by age, including heart rate, blood pressure, and respiratory rate. Variation in respiratory patterns may also occur, such as newborn periodic breathing. It is important to recognize significant variance from normal vital sign values in assessing disease and injury severity as well as response to therapy.

PREFERENTIAL NASAL BREATHING

A larger portion of infants are believed to be obligate nasal breathers. For this portion of children, the nares account for nearly half the total airway resistance. Therefore, obstruction by secretions, edema, or external compression can lead to significant increase in the work of breathing.

SMALLER TIDAL VOLUMES

Infants and young children have small, relatively fixed tidal volumes relative to body size (6–8 mL/kg). Subsequently, they are susceptible to iatrogenic barotrauma from aggressive positive-pressure ventilation. In addition, there is limited ability to increase minute ventilation with deeper breathing. Any compensatory response to physiologic demands for increased minute volume is dependent primarily on an increased respiratory rate. Children have limited ability to maintain a significant tachypnea, predisposing young infants in particular to respiratory failure.

LOWER FUNCTIONAL RESIDUAL CAPACITY

Due to a smaller functional residual capacity, young children have little intrapulmonary oxygen stores to use during hypoventilatory or apneic periods. In particular, apneic infants will have a precipitous decline in oxygen saturation. For this reason, children have a heightened need for preoxygenation and likely require bag-mask ventilation during RSI for intubation.

HIGHER OXYGEN METABOLISM

Infants have a higher metabolic rate and consume oxygen at a rate twice that of adults (6 vs 3 mL/kg/min). A higher oxygen consumption combined with a lower functional residual capacity in children results in a shorter safe apnea time. In a study of preoxygenated children with an American Society of Anesthesiologists physical status of class I (ie, healthy, no medical problems), the mean time to oxygen desaturation to 90% ranged from 1.5 minutes in children less than 6 months old to more than 6 minutes in children greater than 11 years of age.

HIGHER VAGAL TONE

Infants and young children may have a pronounced vagal response to laryngoscopy or airway suctioning. Because hypoxia potentiates the risk for bradycardia, efforts to maintain oxygenation before and during ETI should be maximized. The role of atropine has been discussed to mitigate this risk.

Equipment

It is imperative that providers have immediate access to a variety of sizes of airway interventional devices and equipment.

Both invasive and supportive airway equipment needs to be selected according to the size of the child, and selection criteria can be based on age, height, weight, or length. Access to rapid reference materials such as pediatric resuscitation cards, mobile phone applications, or length-based resuscitation systems (Broselow-Luten) is extremely valuable in determining appropriate-size equipment and reducing reliance on mathematical formulas.

It was a commonly held belief that children should be intubated with an uncuffed tube due to concerns for mucosal injury and secondary subglottic stenosis. However, recent studies have demonstrated safety with the newer high-volume, lower pressure cuffs. These are now recommended, particularly with patients at high risk for aspiration, burn injuries, or requiring higher airway pressures. Endotracheal tubes are measured according to their internal diameter in millimeters and vary in size from 2.5 mm to greater than 8 mm. Tube selection should be based on maximizing tube diameter to minimize air flow resistance, yet the tube should be small enough to fit through the patient's vocal cords comfortably. A commonly used formula to select the appropriate-size endotracheal tube (uncuffed) is **endotracheal tube size (mm) = 4 + (age in years)/4**. For cuffed tubes, the size should be decreased by 0.5 to 1.0 mm. If a cuffed endotracheal tube is used, current recommendations include the use of a manometer to measure cuff pressures, considering pressures in excess of 20 cm H_2O may be associated with mucosal ischemia.

A stylet should be used to facilitate passage of the endotracheal tube by providing additional rigidity. The largest size stylet the tube can accommodate should be used. Tubes greater than 5.5 mm will generally accept an adult-size stylet.

There is also some variety in laryngoscope blade sizing. Direct laryngoscope handles come in adult and pediatric sizes, and there are a variety of different shapes and sizes of laryngoscope blades. For DL, a straight (Miller) blade is usually recommended in order to directly lift the proportionally larger epiglottis out of the way. Blade sizes include size 0 for preterm and newborns, size 1 for infants, and size 2 for children greater than 2 years of age. Adult-size blades range from 3 to 5.

As in adults, alternative airways should be readily accessible and available in multiple sizes, including devices such as LMAs or I-gel airways. Sizing is dependent on the device and manufacturer and is typically based on patient's age, weight, or length.

Pediatric airway interventions will require the same monitoring equipment as adults including cardiac telemetry, noninvasive blood pressure monitoring, pulse oximetry, and capnography. Suction needs to be readily accessible, including access to both rigid and flexible suction catheters in multiple sizes. Oxygen supplementation should be provided and multiple size facemasks available. The appropriate-size mask should fit comfortably over the patient's mouth and nose. OPAs are sized by holding the device along the side of the patient's face with the external flanged end at the edge of the patient's mouth. The tip of the inserted portion should reach the angle of the mandible. NPAs should be selected based on a device that reaches from the nostril to the tragus of the ear.

Multiple video laryngoscope manufacturers also provide pediatric-sized equipment. The providers should prepare this equipment with the manufacturer-recommended size device based on patient age or size.

Technique

The intubation procedural steps are followed in the same format as those described for the adult procedure with some minor differences.[15,51,53] Preoxygenation is extremely important due to children's limited reserve. Their higher oxygen consumption rate and lower functional residual capacity will result in oxygen desaturation much more quickly than in adults. Pretreatment atropine is recommended for all children under age 1 year undergoing intubation and under 5 years of age receiving succinylcholine. Dosing is 0.02 mg/kg IV, with a minimum dose of 0.1 mg and maximum dose of 0.5 mg. Both etomidate and ketamine are considered acceptable agents for induction in pediatric trauma patients. Etomidate dosing is 0.3 mg/kg and ketamine 1.5 mg/kg. Rocuronium (1 mg/kg) and succinylcholine have been used extensively for chemical paralysis and are considered equally efficacious. Current recommended dosing for succinylcholine is 2 mg/kg for infants and 1 to 1.5 mg/kg for older children. In addition, providers should also be aware of the propensity for children to become bradycardic with succinylcholine. Tube placement can be significantly more challenging due to the anatomic variants mentioned. DL should employ the use of a straight (Miller) blade, particularly in infants, in order to lift the epiglottis and provide better cord visualization, whereas older children can be intubated with either a curved or straight blade. VL in children is promising due to some of the anatomical variants encountered; however, early evidence suggests thorough training with the device is necessary to achieve clinically significant success rates.

Management of Shock

Barclay T. Stewart • Ronald V. Maier

KEY POINTS

- In shock, there is an imbalance between substrate delivery (supply) and substrate requirements (demand).
- In the neuroendocrine response to shock, the hypothalamus releases corticotrophin-releasing hormone, causing pituitary release of adrenocorticotropin hormone followed by adrenal cortex release of cortisol.
- Shock-activated neutrophils and their products may produce bystander cell injury and organ dysfunction.
- Because it is difficult to measure oxygen debt during resuscitation of trauma patients, surrogate parameters such as base deficit and serum lactate are measured.
- Crystalloid solutions pass relatively freely across the vascular endothelium and damaged endothelial glycocalyx layer in shock, and this can result in pronounced expansion of the extracellular fluid compartment.
- Lyophilized plasma is compatible with all blood types and can be stored at room temperature for up to 2 years, and its reconstitution requires less than 6 minutes.
- The principles of damage control resuscitation are permissive hypotension, restriction of crystalloid resuscitation, earlier blood and component resuscitation in appropriate ratios, and goal-directed correction of any coagulopathy.
- Exceptions to damage control resuscitation include elderly patients and those with traumatic brain injuries.
- Viscoelastic assays of coagulation such as thromboelastography and rotational thromboelastometry are now commonly used to correct any coagulopathies during resuscitation.
- Forms of shock include hypovolemic, neurogenic, cardiogenic, septic, obstructive, and traumatic.

A MODERN HISTORY OF SHOCK

In 1872, Dr. Samuel Gross, the American trauma surgeon immortalized in the Thomas Eakins painting, *The Gross Clinic*, described shock as a "rude unhinging of the machinery of life."[1] Although imprecise, this rendering of the shock state elegantly characterizes the manifestation of the physiologic derangements of decompensated shock. More precisely, shock is the inadequate delivery of oxygen to and removal of potentially toxic metabolites from tissues, which leads to cellular dysfunction and injury. Significant tissue hypoperfusion and cellular injury may occur despite normal systemic blood pressure; equating shock with hypotension and cardiovascular collapse is a vast oversimplification and results in delayed recognition of early shock, when intervention is most effective at preventing end-organ dysfunction. Therefore, understanding oxygen kinetics, the principle physiologic derangements that occur during shock, host responses to malperfusion, and ways to diagnose and reverse shock states can improve the outcome of injured and critically ill patients.

The initial cellular injury that occurs as a result of tissue malperfusion and dysoxia is reversible. However, cellular injury will become irreversible if tissue hypoperfusion is prolonged or severe enough such that compensation is no longer possible. Rapid recognition of the patient in shock and the prompt institution of steps to correct shock are critical skills for the trauma surgeon and team.

The management of the patient in shock has been integral to the surgeon's expertise for centuries. In 1854, the French physiologist Claude Bernard suggested that an organism attempts to maintain constancy in the internal environment despite external forces that attempt to disrupt the *milieu intérieur*[2]; this idea was later refined into the concept of homeostasis by Dr. Walter Bradford Cannon.[3] In the intact animal, the failure of physiologic systems to buffer the organism against these external forces and maintain homeostasis results in the *shock state*. Proof in point, serial analyses of the genomic response to severe injury identified that the patients able to most rapidly restore homeostasis have the best outcomes.[4]

In addition to the concept of homeostasis, Cannon described the "fight or flight response" generated by elevated levels of catecholamines in the bloodstream. After providing battlefield care for soldiers injured during World War I in the European theater, he published his classic monograph, *Traumatic Shock*, in 1923.[3] He proposed that shock was due to a disturbance of the nervous system that resulted in vasodilatation and hypotension and that secondary shock with its attendant capillary permeability was caused by a "toxic factor" released by injured tissues. His observations led to the early proposition of deliberate or permissive hypotension in patients with penetrating wounds of the torso to minimize intracavitary bleeding: "if the pressure is raised before the surgeon is ready to check the bleeding that may take place, blood that is sorely needed may be lost."[5]

Dr. Alfred Blalock described an association between shock after hemorrhage and reduced cardiac output and declared that hemorrhagic shock was the result of volume loss, not "toxic factors" alone.[6] The concept that hemorrhagic shock was due, in part, to "toxic factors" was abandoned and not considered again for several decades. In 1934, Blalock described four categories of shock: hypovolemic, vasogenic, neurogenic, and cardiogenic (Table 15-1).

- Hypovolemic shock, the most common type, results from loss of circulating blood or its components.
- Distributive or vasogenic shock, as seen in sepsis or anaphylaxis, results from decreased resistance to blood flow within capacitance vessels of the circulatory system, causing an effective functional decrease in circulating volume.
- Neurogenic shock is a form of vasogenic shock in which spinal cord injury (or spinal anesthesia) causes vasodilatation.
- Cardiogenic shock results from failure of the heart's pump function, as might occur with dysrhythmias or heart failure.

Two additional categories of shock have been added to those originally proposed by Blalock:

- Obstructive shock occurs when circulatory flow is mechanically impeded (eg, pericardial tamponade, tension pneumothorax, pulmonary embolism).

TABLE 15-1: Forms of Shock

Forms of shock	Examples
Hypovolemic	Hemorrhage, profound dehydration, pancreatitis
Neurogenic	Spinal cord injury, anesthesia
Cardiogenic	Dysrhythmia, myocardial infarction, heart failure, valve rupture
Distributive	Septic shock, anaphylaxis
Obstructive	Tension pneumothorax, pericardial tamponade, pulmonary embolism
Traumatic	Hemorrhage, tissue damage and activation of proinflammatory cascades

- Traumatic shock is often seen in multisystem trauma with significant soft tissue and bony injuries with or without significant hemorrhage and occurs secondary to the release of "toxins" from injured tissues that are normally excluded molecules, termed damage-associated molecular patterns (DAMPs) or "danger signals," and secondary upregulation of proinflammatory mediators that can create a state of shock that is much more complex than simple hemorrhagic shock.[7] The discovery and role of DAMPs and proinflammatory mediators in traumatic shock confirmed Cannon's early observations.

In addition to seminal observations on the clinical syndrome of shock on the battlefield, the early and mid-20th century witnessed important basic scientific contributions to the understanding of shock. In 1947, Dr. Carl Wiggers developed a model of graded hemorrhagic shock based on the uptake of shed blood into a reservoir to maintain a prescribed level of hypotension.[8] Dr. G. Tom Shires and coworkers performed a series of classical laboratory studies in the 1960s and 1970s that demonstrated that a large extracellular fluid (ECF) deficit occurred in severe hemorrhagic shock that was greater than could be attributed to vascular refilling alone.[9] A triple isotope technique in dogs revealed that this ECF deficit persisted when shed blood or shed blood plus plasma was used in resuscitation. Only the infusion of both shed blood and lactated Ringer's solution (an ECF mimic) repleted the red blood cell mass, plasma volume, and ECF.[10] Differences in mortality after hemorrhage and resuscitation dramatically illustrated the importance of this observation: The mortality rate after resuscitation with blood alone is 80%; with blood plus plasma, 70%; and with blood plus lactated Ringer's solution, 30%. The existence of this ECF deficit was subsequently confirmed in human patients.

Additional studies by Shires' group demonstrated significant dysfunction of the cellular membrane in prolonged hemorrhagic shock.[11] Depolarization of the cell membrane resulted in an uncontrolled uptake of water and sodium by the cell and loss of potassium in association with the loss of membrane integrity. The depolarization of the cell membrane was proportional to the degree and duration of hypotension. Ultimately, the study of red blood cells, hepatocytes, and skeletal muscle during hemorrhagic shock suggested that an abnormality in membrane active transport (Na^+/K^+-ATPase pump) was the basis of the cellular membrane dysfunction. In addition, the uptake of fluid by the intracellular compartment was a major site of fluid sequestration following prolonged hemorrhagic shock. These changes were reversible with appropriate resuscitation, further supporting the importance of prompt fluid resuscitation of severe hemorrhagic shock with balanced salt solution in addition to red blood cells.

With advances in our understanding of the pathophysiology and treatment of shock, new clinical problems soon became apparent. The Vietnam War provided a lurid clinical laboratory for shock research. Aggressive fluid resuscitation with red blood cells, plasma, and crystalloid solutions provided a survival advantage for the war-wounded who previously would have

succumbed to the effects of hemorrhagic shock, including a high rate of acute renal failure (ARF). More aggressive resuscitation made ARF a less frequent problem but, in its place, fulminant pulmonary failure appeared as an early cause of death after severe hemorrhage. Initially labeled "shock lung" or "Đà Nẵng lung," the clinical problem soon became characterized as acute respiratory distress syndrome (ARDS).[12] Resuscitation with excessive volumes of crystalloid solution was initially proposed as the primary mechanism of ARDS. However, ARDS was eventually recognized to be a component of the multiple organ dysfunction syndrome (MODS) or multiple organ failure syndrome (MOF), a result of complex upregulation of proinflammatory mediators greatly compounded by excessive volume resuscitation. The concepts of ARDS and MODS/MOF will be discussed in subsequent chapters (see Chapters 59 and 63, respectively).

Stemming from additional research during the Vietnam War, the role of the endothelium in shock has been clarified. For the better part of the 20th century, it had been assumed that fluid physiology, volume resuscitation, and clinical edema formation were governed solely by Starling's principle of microvascular fluid exchange.[13] Starling's principle states that capillary hydrostatic pressure and interstitial protein oncotic pressure drives transendothelial filtration, and a counteracting absorptive force is exerted by plasma protein oncotic pressure and interstitial hydrostatic pressure. However, fluid resuscitation does not result in the ECF expansion expected based on Starling's model's assumptions and is affected by the endothelial glycocalyx layer (EGL).[14] The EGL is a web of membrane-bound glycoproteins and proteoglycans on the luminal side of endothelial cells that regulate the passage of fluid, electrolytes, and proteins (eg, albumin, immunoglobulins).[15] When the EGL is damaged, fluid, electrolytes, and proteins are able to pass into the interstitial fluid space more easily, resulting in interstitial edema and fluid sequestration.[14] Disruption of the EGL, termed *compaction* or *shedding*, results in an increase in the plasma concentrations of the glycosaminoglycans that compose EGL. Thus, high plasma concentrations of these molecules are thought to represent EGL injury, which occurs during rapid fluid infusion, sepsis, shock, and surgery, and after injury.[16]

Several decades of research using the principles of the Wiggers models of hemorrhagic shock emphasized the importance of early control of hemorrhage in conjunction with restoration of intravascular volume with red blood cells and crystalloid solutions. Studies have extended the observations initially made by Cannon in 1918 on the futility of vigorously resuscitating patients with ongoing bleeding and have challenged traditional thinking on the appropriate end points of resuscitation from uncontrolled hemorrhage. The concepts of delayed fluid resuscitation and limited or controlled resuscitation are now advocated.[17]

Several essential concepts in the management of shock in the trauma patient have withstood the tests of time: (1) early definitive control of the airway should be achieved prior to circulatory collapse; (2) delay in hemorrhage control increases mortality; (3) inadequate resuscitation results in avoidable deaths and disabilities; and (4) excessive or uncontrolled fluid resuscitation is harmful.[18]

PATHOPHYSIOLOGY

Pathophysiology of Shock

Shock exists when the delivery of oxygen and metabolic substrates to tissues and cells and removal of metabolites are insufficient to maintain normal aerobic metabolism. This concept of mal- or hypoperfusion highlights the imbalance between substrate delivery (supply) and substrate requirements (demand) that occurs at the cellular level in shock states. Tissue hypoperfusion activates a cascade of cardiovascular and neuroendocrine responses designed to compensate for inadequate oxygen delivery and metabolite removal. The pathophysiologic sequelae of shock may be due to the direct effects of inadequate tissue perfusion on cellular and tissue function and/or the host's overzealous responses to the shock state.

The magnitude of both the shock insult and response varies depending on the degree and duration of shock. The consequences of shock may also vary from minimal physiologic disturbance with complete recovery to profound circulatory disturbance, end-organ dysfunction, and death. Accumulating evidence suggests that, although the quantitative nature of the host response to shock may differ between the various etiologies of shock, the qualitative nature of the host response to shock is similar regardless of the cause of the insult. This response consists of profound changes in cardiovascular, neuroendocrine, and immunologic functions. Furthermore, these responses vary with host genetics, time, and response to resuscitation. For example, in hemorrhagic shock, the initial compensation for blood loss occurs primarily through neuroendocrine responses to maintain tissue perfusion. This represents the compensated phase of shock (Fig. 15-1). With ongoing hypoperfusion, cellular injury worsens and the decompensated phase

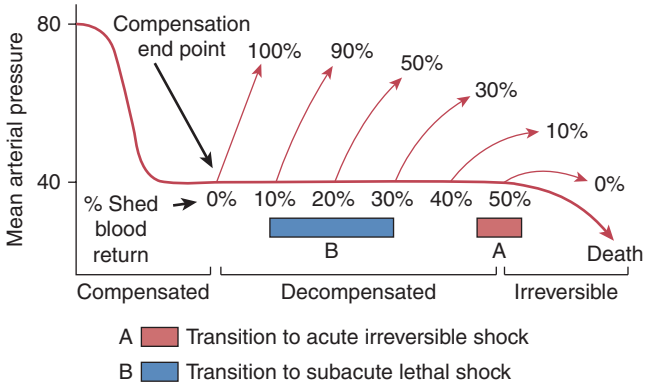

FIGURE 15-1 A rodent model of hemorrhagic shock depicting the relation between volume loss, duration of shock (represented by length of time in compensated, decompensated, and irreversible shock), and transition from reversible to irreversible shock. The percentages shown above the curve represent survival rates. (Reproduced with permission from Peitzman AB, Harbrecht BG, Udekwu AO, et al. Hemorrhagic shock. *Curr Probl Surg*. 1995;32:974, Copyright © Elsevier.)

of shock ensues. Microcirculatory dysfunction, cellular injury and death, and inflammatory cells activation perpetuate the hypoperfusion and may exacerbate tissue injury. If resuscitation is achieved, ischemia/reperfusion injury may further exacerbate the initial insult. Persistent hypoperfusion results in further physiologic and hemodynamic derangements and cardiovascular collapse, which has been termed the irreversible phase of shock. At this phase, extensive parenchymal and microvascular injury has occurred such that further volume resuscitation fails to reverse the process, leading to death of the patient.

Afferent Signals

Afferent impulses transmitted from tissue beds are processed within the central nervous system (CNS) and activate reflexive effector responses or efferent impulses designed to expand plasma volume, maintain peripheral perfusion and tissue oxygen delivery, and reestablish homeostasis (Fig. 15-2). The afferent impulses that initiate the body's intrinsic adaptive responses converge in the CNS and originate from a variety of sources.

The initial inciting event is often loss of actual or relative circulating blood volume. Other stimuli that can produce afferent impulses include tissue trauma, pain, hypoxemia, hypercarbia, acidosis, infection, change in temperature, emotional arousal, or hypoglycemia. As an example, the sensation of pain from injured tissue is transmitted via spinothalamic tracts and activates the hypothalamic–pituitary–adrenal axis. The sensation of pain can also activate the autonomic nervous system (ANS) and increase direct sympathetic stimulation of the adrenal medulla to release catecholamines.

Baroreceptors represent an important afferent pathway in initiating adaptive or corrective responses to shock.[19] Volume receptors within the atria of the heart are sensitive to changes in both chamber pressure and wall stretch. These receptors become activated with low-volume hemorrhage or mild reductions in right atrial pressure. Receptors in the aortic arch and carotid bodies respond to alterations in pressure or stretch of the arterial wall and respond to greater reductions in intravascular volume or changes in pressure. These receptors normally inhibit activation of the ANS. When these baroreceptors are activated, their output is diminished, resulting in greater ANS output principally via sympathetic activation at the vasomotor centers of the brainstem; this produces centrally mediated constriction of peripheral vessels that attempts to maintain blood pressure and tissue perfusion.

Chemoreceptors in the aorta and carotid bodies are sensitive to changes in oxygen tension, H^+ ion concentration, and carbon dioxide level.[20] These receptors also provide afferent

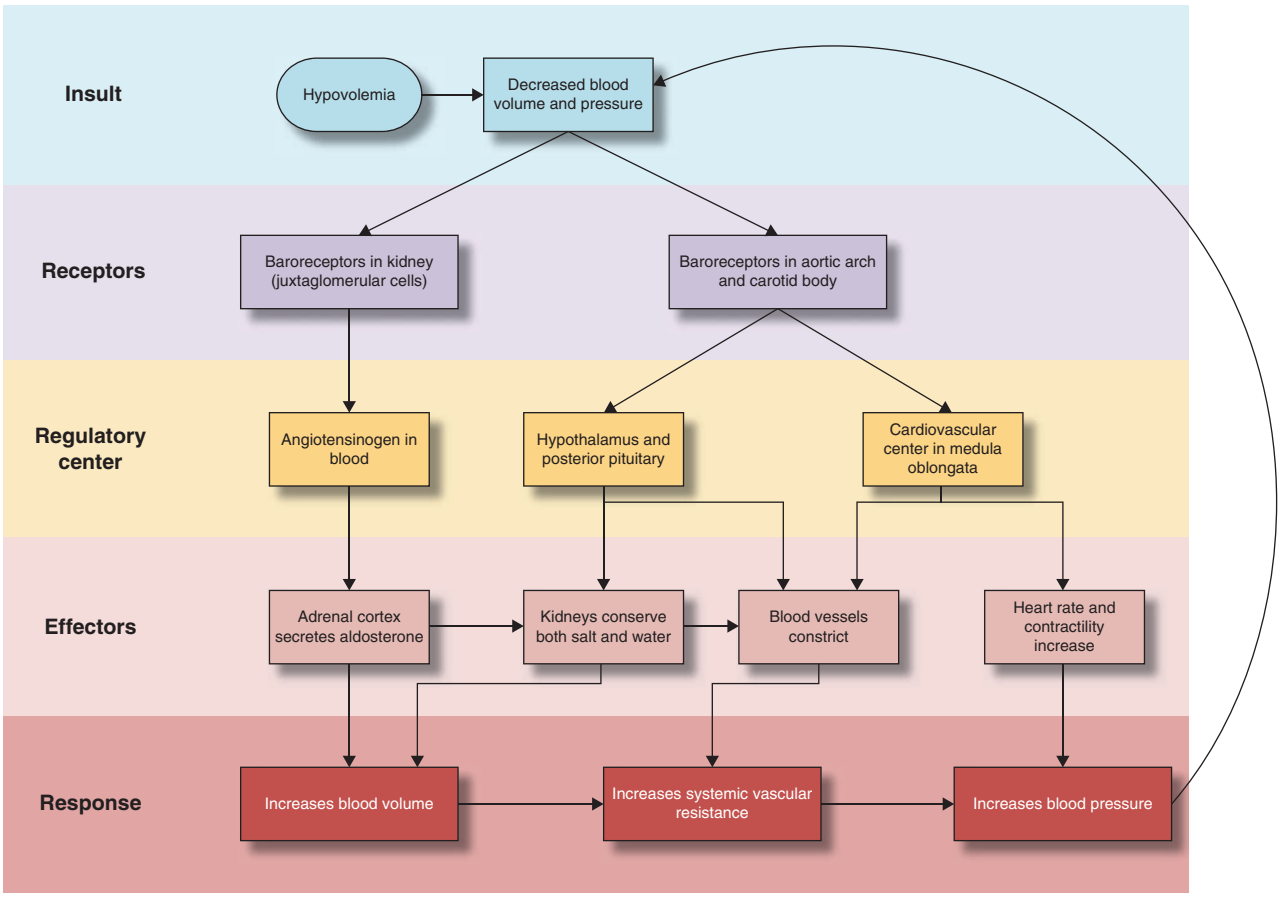

FIGURE 15-2 Afferent signals and efferent responses in hypovolemia and hemorrhagic shock.

stimulation when the circulatory system is disturbed and activate effector response mechanisms. In addition, a variety of protein and nonprotein mediators produced at the site of injury and inflammation act as afferent impulses and induce both central and peripheral responses to trauma and shock. Some of these compounds are components of the host immunologic response to shock and include histamine, cytokines, eicosanoids, endothelins, and others that will be discussed in greater detail in this and subsequent chapters.

Efferent Signals

CARDIOVASCULAR RESPONSE

The neuroendocrine and ANS responses to shock result in changes in cardiovascular physiology, which constitute a prominent feature in the host's adaptive reactions and clinical presentation of the patient in shock (see Fig. 15-2). Stimulation of sympathetic fibers innervating the heart activates β_1-adrenergic receptors that increase both heart rate (chronotropy) and contractility (inotropy) in an attempt to increase cardiac output. However, this response carries a cost: increased myocardial oxygen consumption occurs as a result of the increased workload. Adequate myocardial oxygen supply must be achieved and maintained or myocardial ischemia and dysfunction will develop and exacerbate the shock state.

Direct sympathetic stimulation of the peripheral circulation via activation of α_1-adrenergic receptors on arterioles increases vasoconstriction and causes a compensatory increase in systemic vascular resistance and blood pressure. Selective perfusion of tissues due to regional variations in arteriolar resistance from these compensatory mechanisms occurs in shock. The majority of afterload increase to maintain mean arterial pressure (MAP) is provided by splanchnic vasoconstriction. Blood is shunted away from organs such as the intestine, kidney, liver, and skin that are less essential to the host's immediate needs during shock.[21] Organs such as the brain and heart have autoregulatory mechanisms that attempt to preserve their blood flow despite a global decrease in cardiac output. Direct sympathetic stimulation also induces constriction of veins, akin to Trendelenburg positioning, which decreases the capacitance of the circulatory system and augments blood return to the central circulation.

Increased sympathetic output stimulates catecholamine release from the adrenal medulla. Catecholamine levels increase and peak within 24 to 48 hours of injury before returning to baseline; persistence of elevation in catecholamine levels is consistent with ongoing hypoperfusion and poorer prognosis after injury.[22] Most of the epinephrine that circulates systemically is produced by the adrenal medulla, while norepinephrine is also derived from synapses of the sympathetic nervous system. Catecholamines also have profound effects on peripheral tissues in ways that support the host's ability to respond to shock and hypovolemia. For example, catecholamines stimulate hepatic glycogenolysis and gluconeogenesis to increase the availability of circulating glucose to peripheral tissues, increase glycogenolysis in skeletal muscle, suppress the release of insulin, and trigger the release of glucagon. The genomic response is one of decreased intracellular signaling in response to insulin and decreased expression of cellular membrane proteins required for cellular uptake of glucose.[23] Together, these responses increase the availability of glucose to tissues that require it for maintenance of essential metabolic activity. In addition, hyperglycemia functions as an endogenous osmotic load to further retain and increase intravascular volume.

NEUROENDOCRINE RESPONSE

As earlier described, a variety of afferent stimuli lead to activation of the hypothalamic–pituitary–adrenal axis, an integral component of the adaptive response of the host following shock (see Fig. 15-2). Shock stimulates the hypothalamus to release corticotrophin-releasing hormone, which results in the release of adrenocorticotropin hormone (ACTH) by the pituitary. ACTH subsequently stimulates the adrenal cortex to release cortisol. Cortisol acts synergistically with epinephrine and glucagon to induce a catabolic state.[24] Cortisol stimulates gluconeogenesis and insulin resistance, resulting in hyperglycemia; it also induces protein breakdown in muscle cells and lipolysis, which provide substrates for hepatic gluconeogenesis. Cortisol causes retention of sodium and water by the kidney that aids in restoration of circulating volume. In the setting of severe hypovolemia, ACTH secretion occurs independently of negative feedback inhibition by cortisol. Absence of appropriate cortisol secretion during critical illness or after injury has been postulated as a contributor of ongoing circulatory instability in critically ill patients.[25] In addition, absence of immune cell glucocorticoid receptors prevents the normal downregulation of the immunoinflammatory response to stress and greatly increases mortality, particularly after septic shock.[26]

The pituitary also releases vasopressin or antidiuretic hormone (ADH) in response to hypovolemia, changes in circulating blood volume sensed by baroreceptors and stretch receptors in the left atrium, and increased plasma osmolality detected by hypothalamic osmoreceptors. Epinephrine, angiotensin II, pain, and hyperglycemia further stimulate the production and release of ADH. ADH levels remain elevated for about 1 week after the initial insult, depending on the severity and persistence of the hemodynamic perturbation. ADH acts on the distal tubule and collecting duct of the nephron to increase water permeability and sodium reabsorption, thereby decreasing loss of water and preserving intravascular volume. Vasopressin acts as a potent mesenteric vasoconstrictor, shunting circulating blood away from the splanchnic organs during hypovolemia. The intense mesenteric vasoconstriction produced by vasopressin may contribute to intestinal ischemia and predispose to dysfunction of the intestinal mucosal barrier in shock states.[27] Vasopressin also regulates hepatocellular function in concert with epinephrine and cortisol by increasing hepatic gluconeogenesis and hepatic glycolysis.

The renin–angiotensin system is likewise activated in shock states. Decreased perfusion of the renal artery, β-adrenergic stimulation, and increased sodium concentration in the renal

tubules cause the release of renin from the juxtaglomerular cells. Renin catalyzes the conversion of angiotensinogen (produced by the liver) to angiotensin I, which is then converted to angiotensin II by angiotensin-converting enzyme (ACE; produced in the lung). Although angiotensin I has no significant functional activity, angiotensin II is a potent vasoconstrictor of both splanchnic and peripheral vascular beds and stimulates the secretion of aldosterone, ACTH, and ADH. Aldosterone, a mineralocorticoid, acts on the nephron to promote sodium and water resorption in exchange for potassium and hydrogen ions that are lost in the urine. In the short run, oliguria in the patient with hypovolemic shock is acute renal success, not ARF. However, prolonged renal hypoperfusion results in depletion of renal ATP stores with subsequent acute renal injury, renal failure, and at times, paradoxical urine production despite systemic hypovolemia.

IMMUNOLOGIC AND INFLAMMATORY RESPONSE

Inflammatory and innate immune responses are a complex set of interactions between circulating soluble factors and cells that respond to injury, infection, ischemia, and toxic or autoimmune stimuli.[28] The function of the host's immune system after shock is intimately related to alterations in the production of mediators generally considered part of the body's innate response to localized inflammation, tissue injury, and infection (Fig. 15-3). However, when these mediators gain access to the systemic circulation, they induce changes in a number of tissues and organs. Although proinflammatory activation is a central feature of septic shock, proinflammatory cytokine production and mediator release also occur in other forms of shock, particularly traumatic shock, during which DAMPs and other endogenous stimulatory molecules are released from damaged tissue.[29] Severe trauma and shock have been shown

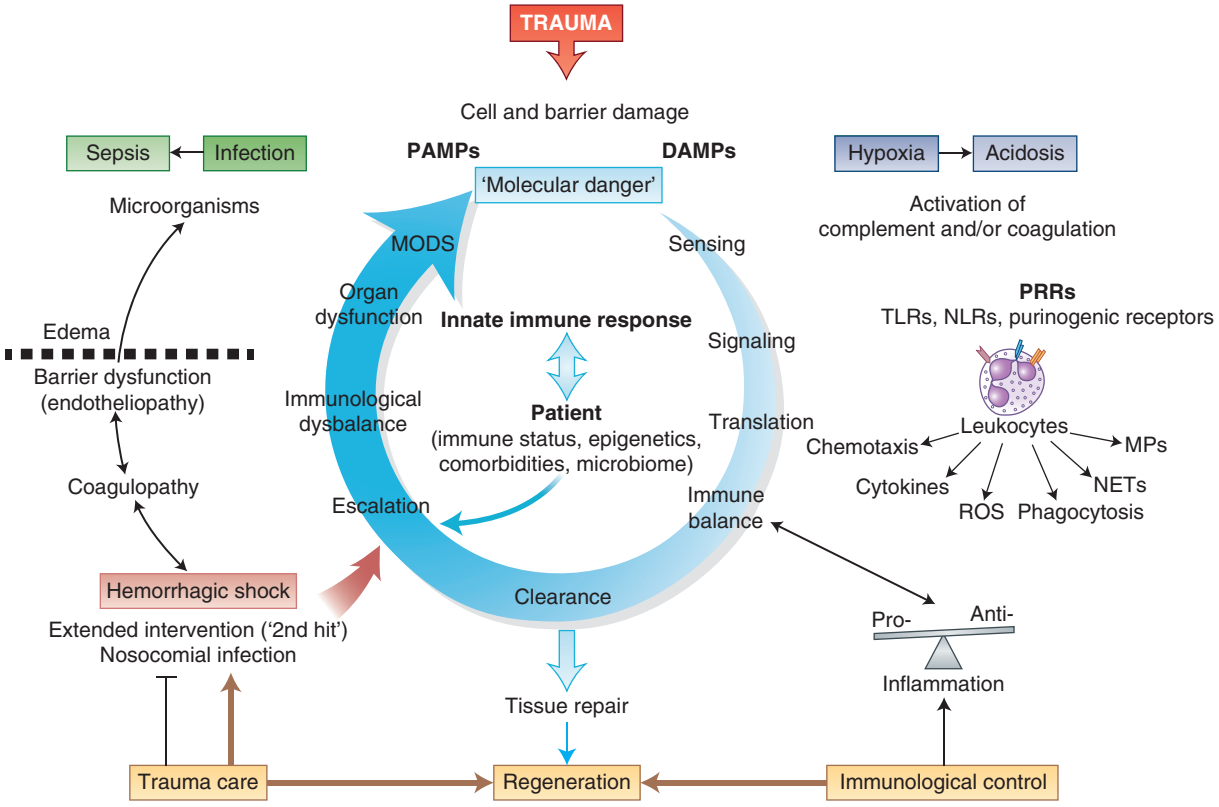

FIGURE 15-3 Innate immune responses to trauma. Trauma leads to the damage of external and internal barriers and thus exposes the immune system to damage-associated molecular patterns (DAMPs) and pathogen-associated molecular patterns (PAMPs). Molecular danger signals and the destruction of local barriers are sensed by the complement and the coagulation systems and induce intracellular signaling in leukocytes via pattern recognition receptors (PRRs), which leads to translation into an instantaneous cellular immune response. Ideally, a balanced proinflammatory and anti-inflammatory reaction leads to rapid clearance of debris and the induction of effective tissue repair and regeneration; adverse events can be caused by individual factors of the patient or aggravated tissue damage after hemorrhage, nosocomial infection, or extended surgical intervention. Escalation of the innate immune response in the form of coagulopathy and excessive inflammation leads to barrier disturbance, edema formation, and compromised innate defense against invading microorganisms. Such changes can aggravate hypoxic conditions, the accumulation of metabolites, and bacterial invasion, all of which can "feed in" more DAMPs and PAMPs and thus generate a vicious cycle of the innate immune response. This eventually results in organ dysfunction and systemic infection, which emphasizes the importance of damage-adjusted trauma care principles as well as control of the balance of the immune system, particularly in the acute phase after injury. MODS, multiorgan dysfunction syndrome; MPs, microparticles; NETs, neutrophil extracellular traps; NLRs, NOD-like receptors; ROS, reactive oxygen species; TLR, toll-like receptor. (Reproduced with permission from Huber-Lang M, Lambris JD, Ward PA. Innate immune responses to trauma. *Nat Immunol*. 2018;19:327-341. Copyright © Springer.)

to alter the gene response in up to 80% of the entire human genome, leading to a total body "genomic storm."[4] Thus, as initially proposed by Cannon in the early part of the 20th century, inflammatory "toxic" mediators can be a cause of shock as well as a by-product of the host response to shock.

Most mediators have a variety of effects due to the redundant and overlapping nature of the host response to injury. Therefore, in addition to regulating immune function in the host, many of these mediators have effects on the cardiovascular system, coagulation system, cellular metabolism, and cellular gene expression. Many compounds already discussed have substantial effects on the cardiovascular and/or neuroendocrine responses to shock. As an example, catecholamines have effects on immune function and activate proinflammatory cytokines.[30] Cytokines are small polypeptides and glycoproteins that exert most of their actions in a paracrine fashion and are responsible for fever, leukocytosis, tachycardia, tachypnea, and the upregulation of other cytokines. Their levels are elevated in hemorrhagic, septic, and traumatic shock.[28] The overexpression of certain cytokines is associated with the metabolic and hemodynamic derangements often seen in septic shock or decompensated hypovolemic shock, and certain patterns of cytokine production after shock correlate with the development of MODS.[29] The immune response to injury and infection is discussed in greater detail in Chapters 21 and 63. A brief review of several of the key components of the immune response is provided in the following paragraphs.

Tumor necrosis factor-α (TNF-α) is one of the earliest proinflammatory cytokines released by monocytes, macrophages, and T cells in response to injurious stimuli.[31] The classic model of TNF-α production is the injection of bacterial endotoxin in an animal subject. Under these controlled conditions, TNF-α levels peak within 90 minutes of the insult and return to baseline within 4 hours. Endotoxin stimulates TNF-α release and may be a primary inducer of cytokines, as in the case of septic shock. TNF-α release may also be a secondary event following the release of DAMPs and other mediators from injured tissue.[32] TNF-α levels are increased after hemorrhagic shock, and TNF-α levels correlate with mortality in animal models of hemorrhage.[33,34] In humans, TNF-α, interleukin-6 (IL-6), and IL-8 levels increase during hemorrhagic shock, although the magnitude of the increase is less than that seen in septic patients.[35] Once released, TNF-α can cause peripheral vasodilation, activate the release of other cytokines such as IL-1β and IL-6, induce procoagulant activity and increased consumption of coagulation factors, and stimulate a wide array of cellular metabolic changes. TNF-α enhances mechanisms of host defense against infection by promoting activation of macrophages and neutrophil intracellular killing of pathogens. During the stress response, TNF-α contributes to the breakdown of muscle protein and cachexia. Despite being linked to tissue injury and dysfunction, TNF-α appears to be essential in combating bacterial infection since neutralizing TNF-α in live bacterial peritonitis and pneumonia models increases mortality.[36,37]

IL-1β has actions that are similar to TNF-α and can cause hemodynamic instability and vasodilation.[31] It has a very short half-life (6 minutes) and primarily acts in a paracrine fashion. IL-1β produces a febrile response by activating prostaglandins in the posterior hypothalamus and causes anorexia by activating the satiety center. This cytokine also augments the secretion of ACTH, glucocorticoids, and β-endorphins. In conjunction with TNF-α, IL-1β can induce the release of other cytokines such as IL-2, IL-4, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor (GM-CSF), and interferon-γ (IFN-γ). IL-2 expression is important for the cell-mediated immune response, and its attenuated expression has been associated with transient immunosuppression in injured patients. IL-6 has consistently been shown to be elevated in animals subjected to hemorrhagic shock or trauma and in patients after major surgery. Elevated IL-6 levels correlate with mortality in some forms of shock.[38] IL-6 contributes to neutrophil-mediated injury to the lung after hemorrhagic shock and may play a role in the development of diffuse alveolar damage and ARDS.[39] IL-6 and IL-1β are mediators of the hepatic acute phase response to injury and enhance the expression and/or activity of complement, C-reactive protein, fibrinogen, haptoglobin, amyloid A, and α_1-antitrypsin. Activation of neutrophils is promoted by IL-6, IL-8, and GM-CSF, and IL-8 also serves as a potent chemoattractant to neutrophils.

The complement cascade is activated by injury and shock and contributes to proinflammatory activation in both animal models and human patients. The degree of complement activation is proportional to the magnitude of the traumatic injury and may serve as a marker for severity of injury in trauma patients. Patients in septic shock also demonstrate activation of the complement pathway with elevation of the activated complement proteins C3a and C5a.[40] Complement activation can occur after hemorrhagic shock and may contribute to the hypotension, coagulopathy, metabolic acidosis, and MODS observed following shock and resuscitation.[41] The development of coagulopathy, ARDS, and MODS in trauma patients correlates with the intensity of complement activation.[29,42]

Activation of neutrophils is one of the early changes induced by the inflammatory response, and neutrophils are the first cells to be recruited to sites of injury and inflammation. These cells are important in the clearance of infectious agents, foreign substances that have penetrated host barrier defenses, and toxin-generating nonviable tissue. However, activated neutrophils and their products may also produce bystander cell injury and organ dysfunction. Activated neutrophils generate and release a number of substances such as reactive oxygen species, lipid peroxidation compounds, proteolytic enzymes (eg, elastase, cathepsin G), vasoactive mediators (eg, leukotrienes, eicosanoids), and platelet-activating factor (PAF); the latter leads to diffuse and nondiscriminatory activation, adherence, and clearance of platelets from the circulation that results in microcirculatory thrombosis and regional hypoxia. Oxygen radicals such as superoxide anion, hydrogen peroxide, and the hydroxyl radical are potent inflammatory molecules that activate peroxidation of lipids, inactivate cellular enzymes, and consume cellular

antioxidants (eg, glutathione and tocopherol). Intestinal ischemia and reperfusion cause activation of neutrophils and induce neutrophil-mediated organ injury in experimental animal models.[43] In both animal models of hemorrhagic shock and human patients with septic shock, activation of neutrophils correlates with irreversibility of shock and mortality, and neutrophil depletion prevents many of the pathophysiologic sequelae of hemorrhagic and septic shock.[44,45] In humans, activation of neutrophils in trauma and shock also plays a role in the development of MODS after injury.[46] Plasma markers of neutrophil activation such as elastase and other enzymes correspond to phagocytic activity and correlate with severity of injury.[29]

Interactions between endothelial cells, leukocytes, and platelets are important in host defense and the initiation and perpetuation of the inflammatory response in the host. The vascular endothelium regulates blood flow, adherence of leukocytes, and activation of the coagulation cascade. Adhesion molecules such as intercellular adhesion molecules (ICAMs), vascular cell adhesion molecules (VCAMs), and the selectins (E-selectin, P-selectin) are expressed on the surface of endothelial cells and are responsible for the adhesion of leukocytes and platelets to the endothelium. The interaction of surface proteins on leukocytes, platelets, and vascular endothelial cells allows activated neutrophils to marginate into the tissues in order to engulf invading organisms. However, the migration of activated neutrophils into tissues and adherence of platelets also lead to neutrophil-mediated cytotoxicity, microvascular damage, and tissue injury; this tissue damage contributes to microvascular thrombosis, coagulopathy, and organ dysfunction after shock.[47] It is important to note that the activation of platelets can lead to opposing hypo- and hypercoagulopathic states, further compounding the care of patients in shock.

Cellular Effects

Depending on the magnitude of the insult and the intrinsic compensatory mechanisms present in different cells, the response at the cellular level may be one of adaptation, dysfunction and injury, or death. The aerobic respiration of the cell (ie, oxidative phosphorylation by mitochondria) is the pathway most susceptible to inadequate oxygen delivery and toxic oxygen radicals. As oxygen tension within cells decreases, oxidative phosphorylation decreases and the generation of adenosine triphosphate (ATP) slows or stops. The loss of ATP, the cellular "energy currency," has widespread effects on cellular function, physiology, and morphology. As oxidative phosphorylation slows, the cells shift to anaerobic glycolysis that generates ATP from the rapid breakdown of cellular glycogen. However, anaerobic glycolysis is much less efficient than oxygen-dependent mitochondrial pathways. Under aerobic conditions, pyruvate, the end product of glycolysis, is fed into the Krebs cycle for further oxidative metabolism. Under hypoxic conditions, the mitochondrial pathways of oxidative catabolism are impaired and pyruvate is instead converted to lactate. The accumulation of lactic acid and inorganic phosphates is accompanied by a reduction in pH, resulting in intracellular metabolic acidosis. As cells become hypoxic and ATP depleted, other ATP-dependent cell processes are affected: synthesis of enzymes and structural proteins, repair of deoxyribonucleic acid (DNA) damage, and intracellular signal transduction. Tissue hypoperfusion also results in decreased availability of metabolic substrates and the accumulation of metabolic by-products such as oxygen radicals and organic ions that may be toxic to cells.

The consequences of intracellular acidosis on cell function can be quite profound. Decreased intracellular pH can alter the activity of cellular enzymes, lead to changes in cellular gene expression, impair cellular metabolic pathways, and interfere with ion exchange in the cell membrane.[48] Acidosis can also lead to changes in cellular calcium metabolism and calcium-mediated cellular signaling that can interfere with the activity of specific enzymes and alter cell function. These changes in normal cell function can produce cellular injury or cell death.[49] Changes in both cardiovascular and immune function in the host can be induced by intracellular acidosis.[50,51]

As cellular ATP is depleted under hypoxic conditions, the activity of the membrane Na^+/K^+-ATPase slows and thus the regulation of cellular membrane potential and volume is impaired. Na^+ accumulates intracellularly, whereas K^+ leaks into the extracellular space. The net gain of intracellular sodium is accompanied by an increase in intracellular water and the development of cellular swelling and tissue edema. This cellular influx of water is associated with a corresponding reduction in ECF volume.[52] Swelling of the endoplasmic reticulum is the first ultrastructural change seen in hypoxic cell injury. Eventually, swelling of the mitochondria and cells is observed. The changes in cellular membrane potential impair a number of cellular physiologic processes such as myocyte contractility, cell signaling, and the regulation of intracellular Ca^{2+} concentrations. Once intracellular organelles such as mitochondria, lysosomes, or cell membranes rupture, the cell will undergo death by either apoptosis or necrosis.[53]

Hypoperfusion and hypoxia cause widespread cell death by apoptosis. Apoptosis has also been detected in trauma patients with ischemia and reperfusion injury. Apoptosis of lymphocytes and intestinal epithelial cells occurs within the first 3 hours of injury.[53] Apoptosis in intestinal mucosal cells may compromise barrier function of the intestine and lead to proinflammatory activation of submucosal immune cells with release of mediators into the portal circulation during shock. Also, lymphocyte and neutrophil apoptosis has been hypothesized to contribute to the immune suppression that is observed in trauma, as well as increased risk of nosocomial infections and MODS.[54]

Tissue hypoperfusion and cellular hypoxia may also result in systemic metabolic acidosis as metabolic by-products of anaerobic glycolysis exit the cells and gain access to the circulation. In the setting of acidosis, oxygen delivery to the tissues is improved as the oxyhemoglobin dissociation curve is shifted toward the right. The decreased affinity of hemoglobin for oxygen in erythrocytes results in increased tissue oxygen release and increased tissue extraction of oxygen. In addition, hypoxia stimulates the production of erythrocyte 2,3-diphosphoglycerate (2,3-DPG), which also contributes to

the shift to the right of the oxyhemoglobin dissociation curve and increases oxygen availability to the tissues during shock.

Epinephrine and norepinephrine released during shock have a profound impact on cellular metabolism beyond their effects on vascular tone. Hepatic glycogenolysis, gluconeogenesis, ketogenesis, breakdown of skeletal muscle protein, and lipolysis of adipose tissue are all increased by these catecholamines. Cortisol, glucagon, and ADH also participate in the regulation of catabolism during shock. Epinephrine induces the release of glucagon while inhibiting the release of insulin by pancreatic β-cells. In addition, shock blocks genomic and cellular responses necessary for insulin recognition and uptake and utilization of glucose. The result is a catabolic state with glucose mobilization, hyperglycemia, protein breakdown, negative nitrogen balance, lipolysis, and insulin resistance during shock and injury.[55] The relative underutilization of glucose by peripheral tissues preserves it for the glucose-dependent organs such as the heart and brain.

In addition to inducing changes in cellular metabolic pathways, shock also induces changes in cellular gene expression. The DNA-binding activity of a number of nuclear transcription factors is altered by the production of oxygen radicals, nitrogen radicals, and hypoxia that occurs at the cellular level in shock. The expression of other gene products including heat shock proteins, vascular endothelial growth factor (VEGF), inducible nitric oxide synthase (iNOS), and cytokines is also increased in shock.[56,57] Many of these shock-induced gene products, such as cytokines, have the ability to subsequently alter gene expression in specific target cells and tissues.

Shock induces profound changes in tissue microcirculation that may contribute to organ dysfunction and the systemic sequelae of severe hypoperfusion. These changes have been studied most extensively in the microcirculation of skeletal muscle in models of sepsis and hemorrhage. Whether microcirculatory changes are primarily a result of the development of shock or a pathophysiologic response that promotes tissue injury and organ dysfunction has been difficult to determine. After hemorrhage, larger arterioles vasoconstrict, most likely due to sympathetic stimulation, whereas smaller distal arterioles dilate, presumably due to local metabolic mechanisms.[58] Flow at the capillary level is heterogeneous with swelling of endothelial cells and aggregation and activation of leukocytes and platelets, which produces microvascular thrombosis and diminished capillary perfusion in some vessels both during shock and following resuscitation.[59]

Platelets play a pivotal role in traumatic shock, hemostasis, and coagulopathy.[60] Recent evidence suggests that there is an inverse relationship between platelet count on admission and early mortality and transfusion in critically injured patients. In addition to platelet loss and consumption, platelet adhesion, degranulation, and dysfunction all occur and cause both microcirculatory thrombosis and generalized coagulopathy. After injury, platelets demonstrate significantly decreased adenosine diphosphate (ADP)–mediated and thrombin receptor agonist peptide (TRAP)–mediated platelet aggregation and ADP-mediated P-selectin expression.[60] Such dysfunction is particularly encountered after severe traumatic brain injury. Platelet dysfunction measured by light transmission aggregometry has been associated with a more than 10-fold higher early mortality.[60,61] In the massively bleeding patient, early platelet transfusion along with transfusion of a ratio of 1:1 packed red blood cells (PRBCs) and fresh frozen plasma (FFP) is associated with higher rates of hemostasis, fewer hemorrhagic deaths, and shorter duration of mechanical ventilation (see Chapter 16).

Damaged EGL and endothelial cells express procoagulant mediators and cause consumption of coagulation factors (Fig. 15-4). Hemorrhage-induced microcirculatory dysfunction also occurs in vascular beds besides skeletal muscle (eg, lungs, kidneys, liver) and contributes to tissue injury and organ dysfunction.[62,63] In sepsis, similar changes in microcirculatory function occur. Aggregation and sludging of neutrophils and platelets in the microcirculation with thrombosis can aggravate shock-induced hypoperfusion, induce direct cellular injury via toxic neutrophil-dependent processes such as production of oxygen radicals or release of proteolytic enzymes, and impair cellular metabolism.[64] Further, microcirculatory changes in patients with traumatic shock have been shown to portend MODS.[65]

The decreases in microcirculatory blood flow and capillary perfusion result in decreased capillary hydrostatic pressure. The changes in hydrostatic pressure promote an influx of fluid from the extravascular space into capillaries in an attempt to increase circulating volume. These changes are associated with additional decrements in the volume of ECF due to simultaneous increased cellular swelling. These basic cellular and microcirculatory changes have significant physiologic importance in the ability of the organism to recover from circulatory shock. Resuscitation with volumes of fluid sufficient to restore the ECF deficit is associated with improved outcome after shock.

Quantifying Cellular Hypoperfusion

Hypoperfused tissues and cells experience what has been called oxygen debt, a concept first proposed by Drs. Jack Crowell and Elvin Smith in 1964.[66] Oxygen debt is the deficit in tissue oxygenation over time that occurs during shock. When oxygen delivery (DO_2) is limited, oxygen consumption (VO_2) may be inadequate to meet the metabolic needs of cellular respiration due to a deficiency in oxygen at the cellular level. The measurement of oxygen deficit is calculated by taking the difference between the estimated oxygen demand and oxygen consumption (VO_2). Under normal circumstances, cells can "repay" the oxygen debt during reperfusion. The magnitude of oxygen debt correlates with the severity and duration of hypoperfusion. In a canine model of hemorrhagic shock, Crowell and Smith demonstrated a direct relation between survival and degree of shock.[66] They determined that a marker of mortality was the inability to recover from the oxygen debt. The median lethal dose (LD_{50}) occurred at 120 mL/kg of oxygen debt. In a canine model of hemorrhagic shock, mortality was directly correlated to the calculated oxygen debt and similar to the LD_{50} reported by Crowell and Smith (113.5 mL/kg).[67] A relation between oxygen debt and survival in human patients has also been shown. In over 250 high-risk surgical patients, the calculated

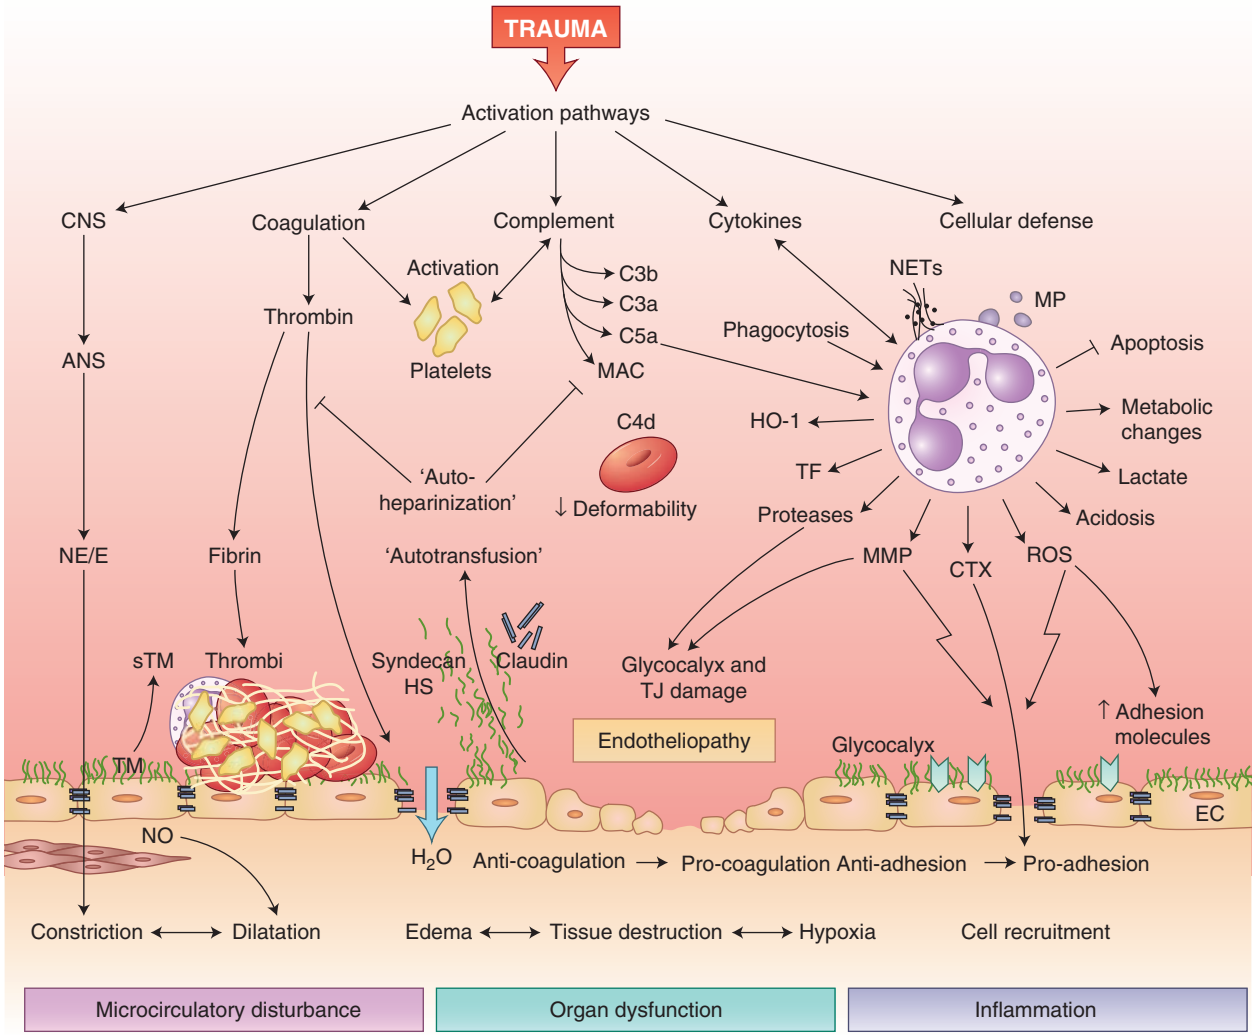

FIGURE 15-4 Activation of innate immune responses and endothelial dysfunction after trauma. After trauma, various pathways of innate immunity can induce posttraumatic endotheliopathy and further tissue damage. Activation of the autonomic nervous system (ANS) and its systemic release of norepinephrine and/or epinephrine (NE/E) leads to instant vasoconstriction (centralization), activates the endothelium, and induces the release of thrombomodulin (TM), which thereby diminishes the anticoagulant features of the endothelium. The dilation of subendothelial smooth muscle cells through stimulation with nitric oxide (NO) potentiates microcirculatory disturbances and hypoxia. Cleavage of thrombin during activation of the clotting cascade leads to the formation of a microthrombus on the endothelial surface and loosening of intercellular barriers, with efflux of water (H_2O) into the interstitial tissues. Activated platelets, in concert with products of the activation of coagulation and/or complement and leukocytes, form the thromboinflammatory response. The activation of complement on red blood cells compromises their deformability. The activation of innate leukocytes, particularly neutrophil granulocytes, by complement and proinflammatory cytokines creates an overall proinflammatory microenvironment with released neutrophil extracellular traps (NETs) and microparticles (MPs), reduced apoptosis, and metabolic changes that lead to local generation of lactate. The generation of reactive oxygen species (ROS) and matrix metalloproteinase (MMP) increases endothelial expression of adhesion molecules and widens cell–cell junctions, which facilitate the migration of leukocytes into inflamed tissue. Proteases secreted from leukocytes can damage the glycocalyx layer and tight junctions (TJs), which leads to the intravascular release of glycosaminoglycans that exhibit colloidal–osmotic and heparin-like effects. CNS, central nervous system; CTX, chemotaxis; EC, endothelial cell; HO-1, heme oxygenase-1; HS, heparan sulfate; MAC, membrane attack complex; NLR, NOD-like receptor; sTM, soluble thrombomodulin. oxygen debt correlated directly with organ failure and mortality.[68] The maximum oxygen debt in nonsurvivors (33.2 L/m^2) was greater than that of survivors with organ failure (21.6 L/m^2) and survivors without organ failure (9.2 L/m^2). In addition, the total duration of oxygen debt and the time required to restore perfusion correlated with outcome. Survivors were able to reverse the oxygen debt–induced injury, whereas nonsurvivors were unable to recover from the oxygen debt. Thus, the magnitude of the oxygen debt, its rate of accumulation, and the time required to correct it all correlate with survival.

It is difficult to directly measure the oxygen debt during resuscitation of trauma patients. Easily obtainable clinical parameters such as arterial blood pressure, heart rate, urine output, central venous pressure (CVP), and pulmonary artery occlusion pressure are poor proxies of tissue perfusion. Therefore, surrogate parameters have been sought to estimate the

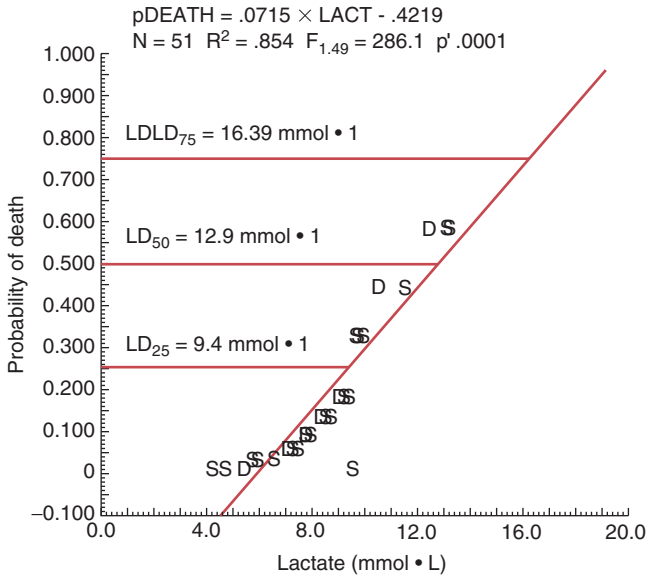

FIGURE 15-5 The relation between mortality and serum lactate levels is described by data generated in a canine hemorrhagic shock model. LD, lethal dose. Oxygen debt and metabolic acidemia or quantitative predictors of mortality and the severity of the ischemic insult in hemorrhagic shock. *Crit Care Med*. 1991;19:231.)

oxygen debt. Experimental studies have shown that serum lactate and base deficit (BD) correlate with oxygen debt.[67,69] Cardiac output, blood pressure, and shed blood volume were all inferior to the BD and lactate in estimating the oxygen debt and in predicting mortality in hemorrhaged animals. Dunham et al[67] demonstrated a direct correlation between arterial lactate and probability of survival in a model of canine hemorrhage (Fig. 15-5). The LD_{50} for lactate was 12.9 mmol/L in hemorrhaged dogs.

BD is the amount of base in millimoles that is required to titrate 1 L of whole blood to a pH of 7.40 with the blood fully saturated with oxygen at 37°C (98.6°F) and a $Paco_2$ of 40 mm Hg. It is usually measured by arterial blood gas analysis using automated devices and has a rapid turnaround time. Good correlation between the BD and survival has been shown in patients with shock[70]; in blunt trauma patients with a BD of 0 mmol/L at presentation, mortality was 8% compared with 95% mortality among patients with a BD of 26 mmol/L. In the canine hemorrhage model previously mentioned, the LD_{50} occurred at a BD of 11.8 mmol/L (Fig. 15-6).

Other clinical parameters such as blood pressure, heart rate, hemoglobin, plasma lactate, and oxygen transport variables were not as accurate as the BD in determining the probability of death in trauma patients. However, neither BD nor serum lactate is precise for measuring physiologic stress as the oxygen debt. In Crowell's model of hemorrhage and resuscitation, lactate level decreased too slowly and tended to estimate higher residual oxygen debt, whereas the BD decreased more rapidly and tended to estimate lower values of oxygen debt. However, in the absence of better proxies, both lactate and BD are useful in the assessment of trauma patients and in the evaluation of the patient's response to resuscitation.

EVALUATION OF THE TRAUMA PATIENT IN SHOCK

General Overview

The manifestations of shock may be dramatic, as in the patient with profound hypotension. However, the signs of shock can be subtle and require careful assessment and interpretation by the trauma team. The evaluation, diagnosis, and treatment of the trauma patient in shock begin with the ABCs (airway, breathing, circulation) of the primary survey.[71]

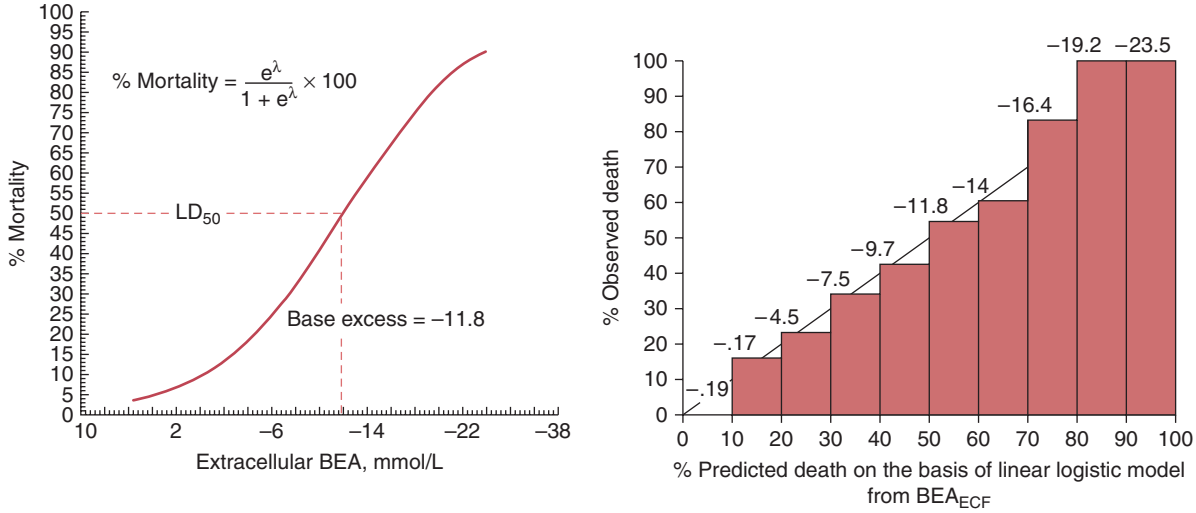

FIGURE 15-6 The relation between base deficit (negative base excess) and mortality is depicted for patients who suffered blunt hepatic injury. BEA, arterial base excess; ECF, extracellular fluid; LD_{50}, medial lethal dose. (Reproduced with permission from Siegel JH, Rivkind AI, Dalal S, et al. Early physiologic predictors of injury severity and death in blunt multiple trauma. *Arch Surg*. 1990;125:498, Copyright © 1990 American Medical Association. All rights reserved.)

Advanced shock may produce coma with loss of the ability to maintain and protect the airway, so that endotracheal intubation is necessary. Marked tachypnea may be present as a symptom of a primarily respiratory homeostatic response as the respiratory system attempts to compensate for metabolic acidosis or in response to generalized anxiety from hypoperfusion of the CNS.

During the primary survey, the circulation can be rapidly assessed by evaluation of the presence and location of the pulse (central vs peripheral), its rate, and its character. A rough estimation of systolic blood pressure (SBP) is possible by palpation of the radial pulse (SBP ≥80 mm Hg), both carotid and femoral pulses (SBP ≥70 mm Hg), or only carotid pulse (SBP ≥60 mm Hg). Absent peripheral pulses (ie, radial, pedal) associated with weak, rapid central pulses (ie, femoral, carotid) denote a profound circulatory disturbance that requires prompt intervention. Pulse pressure (systolic pressure minus diastolic pressure) is determined by stroke volume and vascular capacitance. Stroke volume is reduced in hypovolemic shock, which leads to a narrowed pulse pressure (normal range is 40–60 mm Hg). A narrowed pulse pressure is a sensitive indicator of impending severe shock for patients with less than 30% of blood volume lost; however, pulse pressure may be unreliable in older patients with less aortic and peripheral vascular compliance. Further, a normal SBP is markedly different in the extremes of age, which should be considered when attempting to evaluate a patient in shock or impending shock. For example, an SBP of 120 mm Hg in a baseline hypertensive adult may be less than adequate to maintain CNS perfusion. Associated findings that may be manifestations of abnormal tissue perfusion include cool clammy skin, altered sensorium (eg, confusion, lethargy, coma), and tachycardia. Low urine output, often considered an indicator of hypovolemia, is unlikely to be a useful adjunct in the initial assessment of the patient in the trauma resuscitation area. Further, measurement of blood pressure may be misleading because SBP may not be diminished in the early stages of shock. Compensatory mechanisms to maintain cerebral and coronary perfusion may maintain relatively normal systemic arterial pressure despite hypovolemia and significant hypoperfusion of splanchnic and peripheral tissues. Up to 30% of a patient's blood volume may be lost before significant changes in blood pressure occur. When present, hypotension represents an abject circulatory derangement and failure of compensatory mechanisms that portends imminent cardiovascular collapse and requires immediate intervention(s).

The correction of shock should begin immediately once recognized. Treatment generally begins before an etiology for shock is identified. The forms of shock are listed in Table 15-1; the most common etiology for shock in the injured patient is hypovolemia from loss of circulating blood volume (Fig. 15-7). Two large-bore intravenous lines (ie, at least 16-gauge peripheral or 7F central resuscitation catheters) should be inserted, and volume resuscitation ensues. The availability of rapid infusion systems facilitates prompt volume expansion with the delivery rate limited predominantly by the size and length of the intravenous cannulae (ie, catheter resistance). Fluid warmers to heat the infusate are essential to prevent hypothermia and mitigate the effects of concomitant coagulopathy and acidosis. For patients in profound shock, immediate blood replacement is necessary. As soon as possible, PRBCs should be given alongside both FFP and platelets to prevent the start or worsening of coexistent coagulopathy.

Hospitals should have a massive transfusion protocol (MTP) in place to ensure immediate access to blood components when necessary. Massive transfusion has traditionally been defined as administration of 10 or more units of PRBCs within 24 hours. However, this definition does not allow for prospective use or promote balanced blood product transfusion practices. A more recent definition for massive transfusion is the critical administration threshold, which is defined as the transfusion of at least 3 PRBC units within any 1-hour period in the first 24 hours of admission.[72] This new definition accounts for the intensity of ongoing resuscitation and need for early intervention to produce optimal results, avoids survivor bias implicit in the historical definition of massive transfusion, and has been prospectively validated as a sensitive predictor of mortality.[73]

As correction of the shock state is underway, the etiology for shock is systematically sought. Physical examination may indicate potential etiologies (eg, obvious external hemorrhage, flaccid warm extremities from spinal cord injury, penetrating precordial wounds). Rapidly performed adjunct examinations (ie, x-rays of chest and pelvis, focused assessment with sonography for trauma [FAST], diagnostic peritoneal aspiration [DPA]) can provide additional information while the initial resuscitation is being conducted and the response to resuscitation is being evaluated. Diagnostic maneuvers that do not directly contribute to the identification and treatment of shock should be deferred until shock has been corrected. As an example, traumatic brain injury is not considered a cause of shock until all other potential sources of hemorrhage or spinal cord injury are eliminated; therefore, head computed tomography is deferred until the source of shock is identified and managed.

Trauma patients can be categorized into three general groups with respect to their response to resuscitative maneuvers: responders, transient responders, and nonresponders (see Fig. 15-7).

- Responders are patients who rapidly correct their shock state with minimal replacement of intravascular volume. These patients often have had an intravascular volume loss but do not have ongoing bleeding; bleeding has stopped or been tamponaded (eg, multiple extremity fractures), or the patient has an etiology for hypoperfusion other than hypovolemia such as neurogenic shock or obstructive shock. Aggressive resuscitation should cease with return of normal clinical parameters to avoid fluid overload.
- Transient responders are patients who initially improve with resuscitative efforts but subsequently deteriorate. These patients frequently have intracavitary bleeding that will require surgical control or interventional radiology intervention (eg, high-grade liver or spleen laceration).

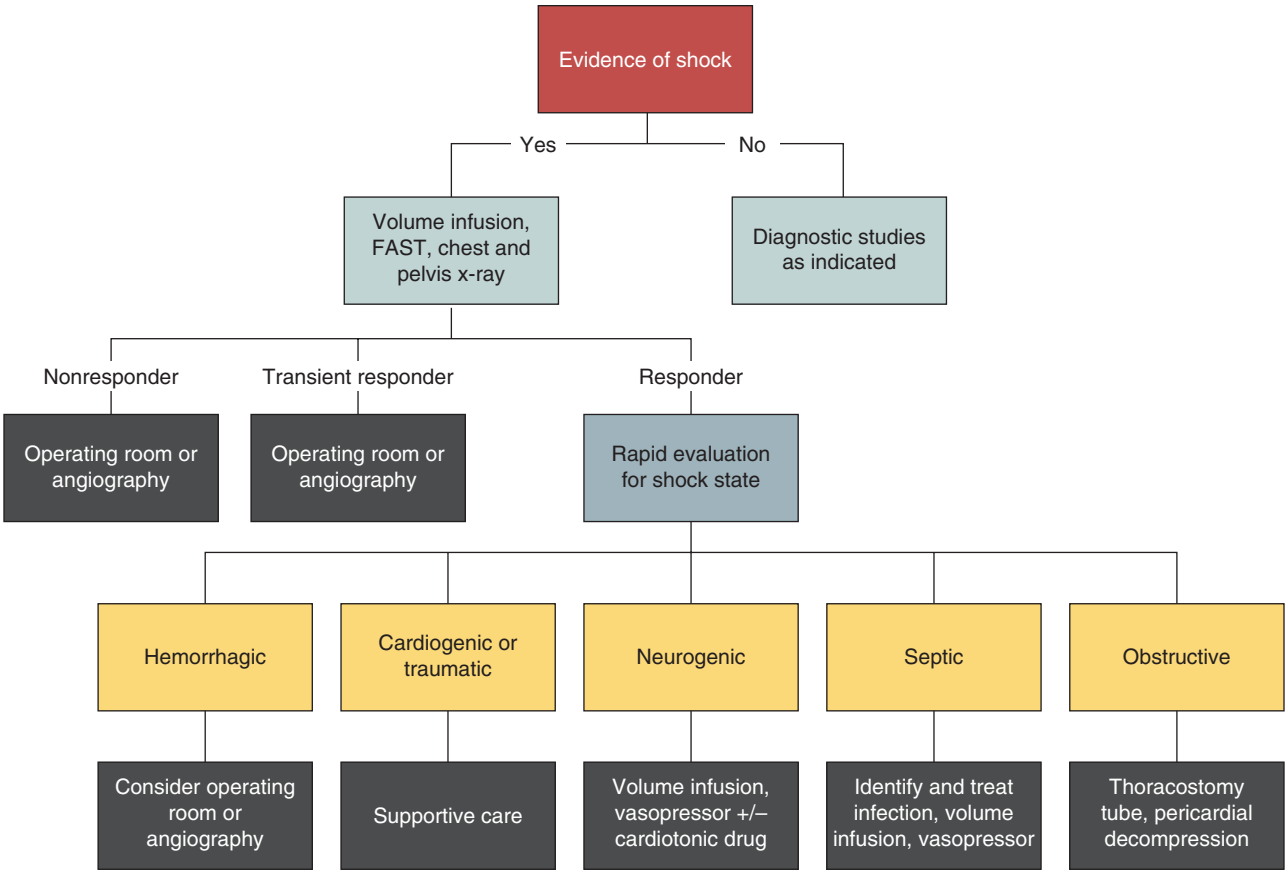

FIGURE 15-7 Tissue hypoperfusion algorithm. Trauma patients can be categorized into three general groups with respect to their response to resuscitative maneuvers. FAST, focused assessment with sonography for trauma.

- Nonresponders are patients who have persistent manifestations of shock despite vigorous resuscitative efforts. These patients are gravely ill and often present in extremis. These patients typically have high-volume bleeding from injuries to major vessels or severe injuries to solid organs that require immediate operative intervention or other invasive control maneuvers (eg, emergency resuscitative thoracotomy or endovascular balloon occlusion of the aorta [REBOA]). They will rapidly die from circulatory collapse or develop the progressive lethal triad of acidosis, hypothermia, and coagulopathy, and irreversible shock unless bleeding is rapidly controlled. Patients who have active, ongoing hemorrhage cannot be successfully resuscitated until hemorrhage has been controlled; survival depends on rapid identification of conditions that require operative or other invasive interventions.

VASCULAR ACCESS AND CONTROL FOR PATIENTS WITH SEVERE HEMORRHAGE

In the trauma patient presenting with multiple serious injuries and/or hemorrhagic shock, vascular access is necessary to restore intravascular volume rapidly. The most important factor in considering the procedure and route for vascular access is the anatomic location and magnitude of hemorrhagic injuries and the trauma team's expertise.

Venous access should never be initiated in an injured limb. In patients with injuries below the diaphragm, at least one intravenous (IV) line should be placed in a tributary of the superior vena cava, as there may be vascular disruption or obstruction of the inferior vena cava. In patients with severe multiple trauma in whom occult thoracoabdominal damage is suspected, it is ideal to have one IV access site above the diaphragm and one below the diaphragm, thus accessing both the superior vena cava and inferior vena cava, respectively. For rapid administration of large amounts of IV fluids, short large-bore catheters should be used. Recalling Poiseuille's law, doubling the internal diameter of the venous cannula increases the flow through the cannula 16-fold. When using 8.5F pulmonary vascular catheter introducers, the side port should be removed, as this increases the resistance roughly fourfold.

Advanced Trauma Life Support (ATLS) guidelines recommend rapid placement of two large-bore (ie, 16-gauge or larger) IV catheters in the patient with serious injuries and/or hemorrhagic shock.[71] The first choice for IV insertion should be a peripheral extremity vein. The most suitable veins are at the wrist, the dorsum of the hand, the antecubital fossa in the arm,

and the saphenous in the leg. The complication rate of properly placed IV catheters is low. Intravascular placement of a large-bore IV should be verified by assessing backflow. An IV site should infuse easily without added pressure. IV fluids can leak into soft tissues when pumped under pressure through an infiltrated IV line and may create a compartment syndrome.

Subclavian, internal jugular, and femoral catheterization should be used with caution in hypovolemic trauma patients as the venous collapse associated with their hypovolemia may increase the risk of inadvertent arterial puncture and cannulation. In part, for this reason, the rate of success is lower and complications are more frequent in these situations. Rapid peripheral percutaneous IV access may be difficult to achieve in patients with hypovolemia and venous collapse, edema, obesity, scar tissue, history of IV drug abuse, or burns. In such cases, subclavian or femoral vein catheterization usually provides rapid and safe venous access in experienced hands. The most frequent complication of subclavian vein catheterization is pneumothorax. Pneumothorax is more likely to occur on the left side because the left pleural dome is anatomically higher.

Subclavian and internal jugular catheters should be inserted on the side of injury in patients with chest wounds, reducing the chances of collapse of the uninjured lung. A simple pneumothorax may result in respiratory compromise in individuals with pulmonary contusions or a pneumothorax in the contralateral hemithorax. Regardless of the site of insertion, it is extremely important not to force the wire, dilator, or introducer if resistance is encountered. Forcing the introducer could result in perforation of large central veins or arteries and bleeding. Venous air embolism is another complication of central line insertion. All central venous access lines should be placed with complete aseptic technique.

Although percutaneous placement of internal jugular catheters is an excellent means of attaining rapid large-bore catheter access, this is a rather unusual site for intravenous insertion in trauma patients because of the possibility of cervical trauma and the need for cervical collar immobilization.

Thrombophlebitis or line infection is more common with femoral catheters; however, this is most common with prolonged use. Any lines placed during resuscitation of a trauma patient without strict aseptic technique should be removed as soon as the patient's condition permits.

In patients with hemodynamic shock and in situations where percutaneous peripheral or central venous access is either contraindicated or impossible to achieve, intraosseous (IO) placement is a feasible alternative for both volume replacement and infusion of therapeutic agents; however, massive transfusions may not be achieved using the IO route. Preferred locations are the proximal or medial tibia or lateral aspect of the greater tubercle of the humerus.

In addition to IV access for volume resuscitation, REBOA is a tool useful in select patients with noncompressible torso hemorrhage.[74] Although there is no high-grade evidence that unequivocally demonstrates improved survival compared to standard care in patients with severe hemorrhage, REBOA is less invasive and, in well-trained hands, may be more rapidly applied than emergency resuscitative thoracotomy. Arterial access can be achieved percutaneously by ultrasound guidance, palpation, or direct cutdown; the latter is often considered after traumatic arrest or when circulating volume is extremely low.[75] Current indications for use of REBOA in trauma include[74]:

1. Life-threatening hemorrhage below the diaphragm in patients who are unresponsive or transiently responsive to resuscitation
2. Life-threatening hemorrhage below the diaphragm and traumatic arrest (no evidence exists for the duration of arrest and use of REBOA, but it should be used within the same time period as resuscitative thoracotomy would be used)
3. Severe intra-abdominal or retroperitoneal hemorrhage, or those with traumatic arrest and inflation of the balloon catheter in the distal thoracic aorta (zone 1)
4. Severe pelvic, junctional, or proximal lower extremity hemorrhage and inflation of the balloon catheter in the distal abdominal aorta (zone 3)

There are a number of potential complications related to REBOA, namely those related to arterial access (eg, arterial disruption, dissection, pseudoaneurysms, hematoma, extremity ischemia), aortic and iliac injuries, balloon rupture and loss of hemorrhage control, spinal cord ischemia, stroke and other thromboembolic events, and complications of visceral malperfusion.[76] REBOA should only be used in situations where a surgeon is immediately available to definitively address the hemorrhage to avert complications related to spinal cord, visceral, and limb ischemia. Specifically, placement of REBOA in zone 1 should only be performed if the anticipated time to the start of the operation is less than 15 minutes. REBOA in zone 3 may be tolerated for a longer period of time and may be use for temporary hemorrhage control prior to angioembolization, preperitoneal packing, or exploration; however, once aortic occlusion is achieved, hemostasis should occur immediately and the balloon deflated as soon as possible. Although not well studied, intermittent deflation and/or partial aortic occlusion may prolong the safe interval for REBOA use; when this is performed, care should be taken to avoid catheter migration and inadvertent balloon inflation in an unintended zone or the iliac vessels. Lastly, removal of the sheath should be done as soon as possible. Vigilant assessment of extremity perfusion should occur before, during, and after REBOA use and sheath removal. Consultation with vascular surgeons when using the REBOA and during sheath removal is recommended.

In addition to intravascular access and hemorrhage control and application of manual pressure, early tourniquet application can be used to arrest life-threatening extremity hemorrhage.[77] Certain tourniquets have proven efficacy in achieving broad and appropriately high arterial occlusion pressure (eg, combat application tourniquet, special operations forces tactical tourniquet, emergency and military tourniquet) and should be used when possible. Tourniquet time should be documented,

and the tourniquet should be removed as soon as possible in a facility with definitive hemorrhage control capacity.[78]

RESUSCITATION FLUIDS

Systemic reviews have consistently shown that there is little evidence that resuscitation with one type of fluid compared with another reduces mortality or that one solution is more effective or safer than another.[79,80] However, there is mounting evidence that the types and dose of resuscitation fluid administered may affect patient outcomes in specific populations. Therefore, the selection and administration of fluid should be based on the patient's degree and type of shock, comorbidities, and potential toxic effects of excessive fluid to capitalize on the benefits of appropriate resuscitation while minimizing adverse effects, namely those related to fluid overload.

Crystalloid Solutions

Crystalloids are solutions of ions, which determine the fluid's tonicity (eg, lactated Ringer's, normal saline, PlasmaLyte, hypertonic saline). These solutions are the mainstay of resuscitation given their relatively physiologic pH and electrolyte compositions. In general, crystalloids are inexpensive, easy to ship and store, and fairly innocuous in small doses. However, crystalloid solutions pass relatively freely across the vascular endothelium and damaged EGL, often resulting in pronounced ECF expansion during resuscitation with negative consequences on organ systems when given indiscriminately.

LACTATED RINGER'S

Ringer's solution was developed in 1885 to aid the development of an extracorporeal beating heart model.[81] As such, the original solution was an isotonic salt solution that contained calcium required for perpetuation of the cardiac cycle. In the 1930s, Hartmann added lactate to the Ringer's solution to act as a buffer, which is metabolized to bicarbonate and carbon dioxide. Lactated Ringer's is a relatively balanced solution that mimics normal human electrolyte composition and has a pH of 6.5. No human study has unequivocally demonstrated superiority of lactated Ringer's versus other crystalloid solutions. However, resuscitation with large volumes of lactated Ringer's was less likely to potentiate acidosis and cause hyperchloremia, hyperkalemia, and/or dilutional coagulopathy in animal models of hemorrhagic shock.[82,83] Data have also shown that the *R*-isomer of lactate is capable of activating the innate proinflammatory response and aggravating tissue and organ injury, reinforcing the use of *L*-lactate isomer in lactated Ringer's solutions.[84]

NORMAL SALINE

Saline solution was developed during the Indian blue cholera epidemic in the 1830s.[85] The solution was designed to be "normal" or isotonic, measured by its tendency to not lyse red blood cells. However, normal saline (0.9% sodium chloride) has supraphysiologic amounts of sodium and chloride (154 mEq of each) and is markedly more acidotic than human plasma (pH 5.0). Thus, resuscitation with significant volumes of normal saline causes hyperchloremic metabolic acidosis that compounds the acidemia characteristic of shock states.[82] Renal dysfunction has been attributed to hyperchloremic metabolic acidosis from normal saline resuscitation.[86,87] Plasma chloride content regulates renal blood flow and may contribute to acute kidney injury.[88] Delivery of chloride to the macula densa drives mesangial contraction and decreases glomerular filtration.[89] A meta-analysis of high- versus low-chloride fluid resuscitation in critically ill patients found an increased incidence of acute kidney injury but no difference in mortality.[90]

PLASMALYTE

PlasmaLyte is a family of balanced crystalloid solutions with formulations developed to mimic the pH, osmolality, and electrolyte compositions of normal human plasma.[91] PlasmaLyte has a significant buffer capacity from the addition of lactate, acetate, and gluconate. Use of PlasmaLyte for resuscitation has been shown to result in a lower base deficit and more physiologic chemistry profile compared to use of normal saline.[91] In general surgical patients, use of PlasmaLyte has been associated with a lower rate of major complications (eg, postoperative infection, renal replacement therapy, blood transfusion, acidosis-related investigations) compared to normal saline.[92,93] Although cost constraints have been reported as barriers to the use of PlasmaLyte, a cost-minimization analysis of PlasmaLyte suggested that use of it is overall more cost effective due to less need for electrolyte repletion and lower incidence of ongoing acidemia compared to normal saline.[94]

HYPERTONIC SALINE

Concerns about the effect of large-volume isotonic crystalloid resuscitation led to experimentation with small-volume resuscitation using hypertonic saline (eg, 3%, 5%, and 7.5% sodium solutions). There is no high-quality evidence that the use of hypertonic saline for resuscitation provides short- or long-term mortality benefits to the critically ill.[95] However, use of low-volume hypertonic saline among patients who underwent damage control surgery resulted in a lower incidence of ARDS, sepsis, MODS, and mortality.[96] Further, there is some evidence that patients who had hypertonic saline used as a maintenance fluid after damage control laparotomy were more likely to achieve primary fascial closure and were closed more quickly than those who did not receive hypertonic saline.[97]

However, Resuscitation Outcomes Consortium (ROC) trials for both shock and traumatic brain injury were halted after preliminary data showed no beneficial effect of hypertonic saline for either one of these groups studied in the clinical trials.[98,99] In addition, use of hypertonic saline appears to increase the coagulopathy seen in severe hemorrhagic shock.[100] Better evidence is needed before recommending the routine use of hypertonic saline in this population.

Colloid Solutions

Colloid solutions (eg, albumin hetastarch, gelatins, dextran) contain macromolecules suspended in salt solutions that were designed to remain within the intravascular fluid compartment under Starling's original assumptions regarding the role of plasma oncotic pressure in fluid physiology. However, as described earlier, the disrupted EGL does not retain large molecules, limiting the theoretical effectiveness of these solutions. Given that there is no significant absorption of interstitial fluid to the plasma in the setting of damaged EGL and increased interstitial oncotic pressure, one can understand why colloid-based resuscitation (eg, albumin, dextran) does not prevent or improve tissue edema or result in a sustained expansion of intravascular volume.

ALBUMIN

Albumin was made available with the advent of blood fractionation in 1941 and was used for the first time in large quantities as a resuscitation fluid for patients burned during the attack on Pearl Harbor.[101] Human recombinant albumin is commonly available in 5% and 25% solutions suspended in an isotonic salt solution. Albumin is produced by the fractionation of blood and is heat treated to reduce the risk of transmission of bloodborne infections; thus, albumin is relatively expensive to produce and distribute compared to other crystalloid and colloid solutions.

A meta-analysis compared albumin with crystalloid solutions in patients with hypovolemic shock, burns, or hypoalbuminemia. Pooled analysis found that use of albumin-based resuscitation was of no benefit and was potentially associated with an increased rate of death compared to crystalloid solutions.[102] Subsequently, a randomized trial examined the safety of 4% albumin for use in critically ill adults.[103] The Saline versus Albumin Fluid Evaluation (SAFE) study of 7000 critically ill patients randomized to 4% albumin or normal saline reported no difference between albumin and saline with regard to 28-day mortality or development of new organ failure. Secondary analyses of results from the SAFE study suggested an association between albumin and death at 2 years among patients with traumatic brain injury.[104] However, albumin resuscitation was associated with a decreased risk of death at 28 days in patients with severe sepsis and septic shock.[105]

In contrast to the SAFE study, the Albumin Italian Outcome Sepsis (ALBIOS) study randomized 1818 patients with severe sepsis to daily administration of 20% albumin targeting a serum albumin level of 3 g/L or crystalloid resuscitation.[105] There were no differences in either 28- or 90-day mortality rates between the two groups. Similarly, the multicenter Colloids Versus Crystalloids for the Resuscitation of the Critically Ill (CRISTAL) trial did not show a mortality difference at 28 days between patients with hypovolemic shock randomized to albumin or saline.[106]

Given the additional cost of albumin and a recent meta-analysis reporting no impact of albumin on sepsis-related mortality, the Surviving Sepsis Campaign (SSC) continues to recommend crystalloids as the initial sepsis resuscitation fluid.[107] However, the SSC has advised consideration of albumin when patients require substantial amounts of crystalloids.[108]

SEMISYNTHETIC COLLOIDS

The donor pool required and relative cost of albumin prompted the development of semisynthetic colloid solutions (eg, hydroxyethyl starch [HES], succinylated gelatin, dextran). Globally, HES solutions are the most commonly used semisynthetic colloids and have gained popularity in the recent past due to use in military medicine.[109] HES solutions are produced by hydroxyethyl substitution of amylopectin from starches (eg, sorghum, maize, potatoes)[110]; this substitution protects against hydrolysis by nonspecific amylases in the blood, which has been proposed to prolong the intravascular expansion associated with the volume and increased oncotic pressure provided by the larger molecules. However, when the vascular endothelium and EGL are damaged and leaky, HES accumulates in tissues, such as skin, lung, liver, and kidney, and has been shown to cause significant adverse effects.[111] Further, large-volume HES resuscitation has been associated with risks of renal injury and coagulopathy.[112] Studies of the use of HES in blunt trauma and burns and among critically ill patients requiring volume resuscitation suggest a potential correlation with increased risk of renal replacement therapy and mortality.[109,113,114] Therefore, the potential harms and cost of HES likely outweigh the benefits of its administration when other solutions are available and suggest that semisynthetic colloids should not be used for volume resuscitation in critically ill patients.

PLASMA

Although plasma is typically considered for patients at risk of or with clinically significant coagulopathy, it has other potential uses in resuscitation. For example, plasma has extreme buffering capacity that can be useful in profound acidemia and may better maintain and potentially restore damaged vascular endothelium and EGL compared with other solutions.[115,116] The use of plasma as a resuscitation fluid is limited by its cost and limited donor pool, as well as risks of transfusion reactions (eg, transfusion-related acute lung injury [TRALI], transfusion-associated circulatory overload, ABO incompatibility), immunosuppression, and transmission of bloodborne infections. Further, the use of plasma for resuscitation in patients without coagulopathy has been associated with development of sepsis, MODS, and ARDS.[117-119]

Given the aforementioned limitations and risks, solvent/detergent-treated plasma has been introduced that minimizes risk of the transmission of enveloped viruses (eg, HIV, hepatitis B and C) and is hypothesized to reduce the risk of TRALI.[120] However, solvent/detergent-treated plasma is prohibitively expensive in most settings. Freeze-dried plasma and lyophilized plasma were developed to lengthen the storage life of plasma and make its transport easy for use in combat settings.[121,122] These products have demonstrated the same hemostatic properties as fresh plasma after reconstitution.

Further, lyophilized plasma is compatible with all blood types and can be stored at room temperature for up to 2 years, and its reconstitution requires less than 6 minutes.[122] Further research is needed to determine specific indications for such products in the management of civilian patients with severe hemorrhage.[123,124]

EXCESSIVE RESUSCITATION

Early landmark work in the physiology of shock states identified several perturbations of normal homeostasis, including abnormal capillary permeability, decreased oncotic pressure, and a loss of intravascular volume into the interstitial fluid compartment.[14] Therefore, pioneers in shock resuscitation advocated for aggressive replacement of the fluid sequestered from the intravascular space in addition to maintenance fluid. This led to the legacy of supraphysiologic resuscitation and excessive resuscitation, which has profound functional consequences on multiple organ systems.[125]

Excessive resuscitation in trauma patients is associated with impaired oxygen delivery, preventable cardiopulmonary morbidity, prolonged intensive care unit and hospital stay, prolonged mechanical ventilation, intestinal anastomotic failure, compartment syndromes, increased intracranial pressure in the setting of traumatic brain injury, MODS, and death.[125-132]

Conversely, excessive fluid restriction and fixed, unmonitored fluid resuscitation are associated with hypovolemia, poor oxygen delivery, secondary brain injury in patients with traumatic brain injury, and overall worsened organ dysfunction.[133] Therefore, it has been inferred that a restrictive but goal-directed fluid resuscitation approach to maintain adequate perfusion while avoiding excessive intravascular pressure that enhances blood and volume loss during shock states may lead to better outcomes.[134]

DAMAGE CONTROL RESUSCITATION

There is significant evidence that the best resuscitative fluid for a person in persistent or severe hemorrhagic shock is not crystalloid or colloid but, in fact, a balanced infusion of blood components to mimic, as possible, replacement of lost whole blood.[135] This includes early administration of PRBCs, which have been shown to improve outcomes when given early in resuscitation of hemorrhagic shock. A balanced transfusion strategy of PRBCs, FFP, and platelets has been shown to enhance hemostasis, reduce the incidence of MODS, and decrease death due to exsanguination.[136,137]

Major advances in the resuscitation of hemorrhagic shock have come from the experiences and research of military medicine. Most recently, damage control resuscitation (DCR) was developed by the Tactical Combat Casualty Care Committee of the US military and used for combat casualties in Iraq and Afghanistan.[138] The principles of DCR include the following:

- Permissive hypotension
- Restriction of crystalloid resuscitation
- Earlier blood transfusion with balanced plasma and platelet to red blood cell transfusion ratios
- Goal-directed correction of coagulopathy

Traditionally, the management of patients in shock has been focused on providing aggressive fluid resuscitation with crystalloid or colloid solutions to rapidly restore circulating blood volume and thus maintain "optimal" vital organ perfusion. This approach can potentially increase bleeding by elevating the blood pressure and dislodging established blood clots. Other unwanted effects of aggressive fluid resuscitation include worsening coagulopathy and increased tissue edema, which play a role in the occurrence of abdominal compartment syndrome and MODS/MOF.

Hypotensive resuscitation is not a new concept. As described earlier, in 1918, Cannon described the deleterious effects of injecting fluids before the surgeon could achieve vascular control of the injury.[5] Cannon suggested an end point of resuscitation prior to definitive hemorrhage control of a systolic pressure of 70 to 80 mm Hg using a crystalloid/colloid mixture as his fluid of choice. In 1994, Bickell et al[139] published a prospective analysis comparing immediate and delayed fluid resuscitation in hypotensive adult trauma patients with penetrating torso injuries. In the delayed group, fluid administration was withheld until the time of operative intervention. Improved survival was seen in this population, with a trend toward fewer complications. These data corroborated the concept that delaying fluid resuscitation until hemorrhage is controlled improves outcome in this select group of penetrating trauma patients.

In subsequent publications, investigators have shown that increased prehospital time associated with attempts to place an intravascular access as well as prehospital use of rapid infusion were correlated with increased mortality.[140] Importantly, outcomes were not significantly different when patients were randomized to either a blood pressure of 70 mm Hg or SBP of 100 mm Hg. Multiple studies have since confirmed these findings.[141] Such findings support a resuscitation approach that mimics the management of patients with another form of shock, those with a ruptured abdominal aortic aneurysm, in whom aggressive volume resuscitation during their preoperative management has been found to increase the perioperative risk of death regardless of their SBP measurements.[142]

Management protocols currently adapted from military experience recommend the use of a palpable radial pulse (ie, SBP of 80–90 mm Hg) and/or the presence of a normal mental status as the most appropriate indicators of adequate perfusion. Combat casualties found at the scene with a palpable radial pulse and normal mentation are given intravenous access, but no intravenous fluids are infused until arriving to a far-forward facility where initial surgical management can be simultaneously instituted.

In civilian trauma, a goal-directed approach in the prehospital setting demonstrated that while a 2-L bolus of crystalloid in the normotensive patient was associated with an increased mortality, the same bolus in the significantly hypotensive (SBP <90 mm Hg) patient led to an improvement in survival, supporting the need for a controlled volume in

the severely hypotensive patient with a goal SBP of 90 mm Hg. Overall, preservation of native hemostatic mechanisms appears best achieved by allowing for a lower than normal blood pressure, thus reducing the rate of bleeding while still ensuring adequate tissue perfusion pressure for optimal survival. The characteristics of the local environment, the type of injury, and whether fast and adequate hemostasis can be promptly achieved are the current determinants for the use of limited resuscitation.

Exceptions to this resuscitative strategy include two main groups: elderly patients and those with traumatic brain injury. For elderly patients, many of whom are on antihypertensive medications at baseline, even an SBP of 110 to 120 mm Hg may be indicative of relative hypotension and cerebral hypoperfusion. Therefore, resuscitation in these individuals must take their expected baseline perfusion pressures into account. Second, in civilian trauma centers, patients with multiple blunt injuries are the most common, and the most critical injury is a traumatic brain injury. In the setting of potential traumatic brain injury, hypotension remains the best-defined risk factor known to produce a secondary insult to the injured brain tissue at risk and a significant worsening of functional outcome. Hypotension in these individuals has been associated with an increased mortality.[143] A controlled but less hypotensive approach (ie, goal SBP of 110 mm Hg) to resuscitation appears most appropriate in these settings.

Restricting crystalloid infusion resuscitation is another contrasting concept to traditional overly aggressive volume resuscitation that aimed to prevent occult hypoperfusion from splanchnic vasoconstriction and subsequent MODS. Studies have demonstrated that large-volume crystalloid-based resuscitation in the absence of physiologic targets is associated with an increased risk of ARDS, abdominal compartment syndrome, and MODS and higher mortality.[125,144-146] In patients with hemorrhagic shock, administration of large volumes of crystalloid solutions promotes dilutional and consumptive coagulopathy, promotes hypothermia, and may worsen metabolic acidosis with high doses of chloride; these three states have been termed *the lethal triad* and, when present, are associated with a marked increase in the risk of death.[147] Therefore, modern strategies for early fluid resuscitation focus on immediate whole blood or balanced blood component transfusions in massively bleeding patients.

Transfusion ratios of plasma to platelet to PRBC of nearly 1:1:1 closely approximate the whole blood that has been lost leading to hemorrhagic shock. The Prospective, Observational, Multicenter, Major Trauma Transfusion (PROMMTT) Study evaluated the association between in-hospital mortality and the timing and amount of blood products.[136] Among patients dying from hemorrhage, there was a protective association of higher blood product ratios (>1:2 plasma or platelet to PRBC) and decreased mortality that was concentrated to the first 24 hours for plasma and the first 6 hours for platelets. The results from the PROMMTT Study prompted the first multicenter randomized trial to compare blood component transfusion ratios, the Pragmatic, Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial.[137] PROPPR was conducted to assess the effectiveness and safety of a 1:1:1 transfusion ratio (plasma to platelets to PRBCs) compared to a 1:1:2 transfusion ratio for patients requiring a massive transfusion. There was no difference in overall mortality at 24 hours or 30 days between the two transfusion ratio groups. However, fewer patients died of exsanguination in the 1:1:1 group. Rates of transfusion-related complications (eg, ARDS, MODS, sepsis, venous thromboembolism) were not different between the two treatment groups. From these studies, the American College of Surgeons Committee on Trauma recommends a plasma to red blood cell (RBC) transfusion ratio of 1:1 to 1:2. Additionally, the recommended ratio of platelets to RBCs is 1:6, with one platelet pack as either a single donor apheresis or random donor platelet pool equal to 6 units of PRBCs.[148]

Recently, military experience has demonstrated that early, far-forward transfusion of fresh whole blood is associated with less total volume transfusion, less coagulopathy, limited inflammatory response, and improved survival compared to standard blood component transfusion.[149-151] Application of whole blood transfusion in civilian trauma centers has been limited by concerns surrounding the theoretical reduction in the hemostatic efficacy of cold-stored platelets, risk of hemolytic transfusion reactions if group O whole blood is used in non–group O recipients, and logistical issues of providing whole blood through a civilian hospital blood bank.[152] In response to these concerns, multiple studies have demonstrated that the hemostatic effects of platelets in cold-stored whole blood are well preserved and bacterial growth is retarded by cold-stored platelets compared to room temperature–stored platelets due to decelerating lactate metabolism.[153,154] Additionally, use of strict donor criteria (eg, group O positive, male to mitigate risk of TRALI, titer of anti-A and anti-B antibodies <50), platelet-sparing leukoreduction, whole blood storage and component salvage protocols, and careful selection of recipients have made transfusion of fresh whole blood possible in the civilian setting.[155] There has been only one randomized controlled trial of whole blood transfusion versus component blood transfusion in the civilian setting.[156] Although this trial did not show a difference in the primary outcome of volume of blood transfused between the two arms, the study had several limitations. The whole blood used in the study was platelet depleted and supplemented with transfusion of apheresis or pooled random-donor platelets once 6 units of whole blood were transfused. Additionally, the study included severe and nonsurvivable traumatic brain injuries that likely confounded analysis of the primary outcome measure. A sensitivity analysis that excluded patients with traumatic brain injuries demonstrated that use of whole blood significantly reduced transfused volume compared to blood component therapy. Trials comparing transfusion of whole blood leukoreduced with a platelet-sparing filter versus balanced transfusion of blood components in the civilian setting are underway.

Conventional coagulation assays (ie, the international normalized ratio, prothrombin time, partial thromboplastin time, platelet count, fibrinogen concentration) and newer

viscoelastic assays of coagulation (ie, thromboelastography and rotational thromboelastometry) should be used to further guide correction of coagulopathy during ongoing resuscitation (see Chapter 16).[157]

FORMS OF SHOCK

Hypovolemic Shock

Hypovolemic shock occurs when rapid loss of fluids results in inadequate intravascular volume and subsequent inadequate perfusion. As previously noted, the most common cause of shock in the trauma patient is loss of circulating volume from hemorrhage. Acute blood loss causes decreased stimulation of baroreceptors (ie, stretch receptors) in the large arteries, resulting in decreased inhibition of vasoconstrictor centers in the brainstem, increased stimulation of chemoreceptors in vasomotor centers, and diminished output from atrial stretch receptors. These changes increase vasoconstriction and peripheral arterial resistance. Hypovolemia also induces sympathetic stimulation, leading to the release of epinephrine and norepinephrine, activation of the renin–angiotensin cascade, and increased release of vasopressin. Peripheral and splanchnic vasoconstriction is prominent in the maintenance of MAP, whereas lack of sympathetic effects on cerebral and coronary vessels and local autoregulation promote maintenance of blood flow to the heart and brain.

DIAGNOSIS

Shock in a trauma patient should be presumed to be due to hemorrhage until proven otherwise. Treatment is instituted as soon as shock is identified, typically before a source of hemorrhage is located.

The clinical and physiologic response to hemorrhage has been classified according to the magnitude of volume loss. Loss of up to 15% of the circulating volume (ie, 700–750 mL for a 70-kg patient) may produce little in terms of obvious symptoms, whereas loss of up to 30% of the circulating volume (ie, 1.5 L) may result in mild tachycardia, tachypnea, and anxiety. Hypotension, marked tachycardia (ie, adult pulse >110 bpm), and confusion may not be evident until more than 30% of the blood volume has been lost, whereas loss of 40% of circulating volume (ie, 2 L) is immediately life threatening. Symptoms of the degrees of hypovolemic shock are summarized in Table 15-2. Thus, there is a fine line between the development of mild symptoms of shock and the presence of life-threatening blood loss. Young, healthy patients with vigorous compensatory mechanisms may tolerate larger volumes of blood loss while manifesting fewer clinical signs. These patients may maintain a near-normal blood pressure until a precipitous cardiovascular collapse occurs. Elderly patients may be taking medications that either promote bleeding (eg, warfarin, aspirin, novel oral anticoagulants) or mask the compensatory response to hypovolemia (eg, β-blockers, calcium channel blockers, ACE inhibitors). In addition, atherosclerotic vascular disease, diminished cardiac compliance with age, inability to elevate heart rate or cardiac contractility in response to hemorrhage, and overall decline in physiologic reserve decrease the ability of the elderly patient to tolerate hemorrhage.[158]

Understanding the mechanism of injury of the patient in shock will help direct the evaluation and management. Identifying the source of blood loss in patients with penetrating wounds is relatively simple since potential bleeding sources will be located along the known or suspected path of the wounding agent. Patients with penetrating injuries who are in shock usually require operative intervention. Occasionally, patients in shock from penetrating injuries may have problems in addition to hemorrhage that are readily treated by simple maneuvers outside the operating room. Treatment of a tension pneumothorax (ie, obstructive shock) with insertion of a thoracostomy tube in the emergency department (ED) is one example. Generally speaking, shock from penetrating wounds is typically due to ongoing hemorrhage that mandates operative control.

Patients who suffer multisystem injuries from blunt trauma often have multiple sources of potential hemorrhage. However, there is a limited number of sites that can harbor sufficient extravascular blood volume to induce hypoperfusion or hypotension. Prehospital medical reports may confirm a significant blood loss at the scene of an accident, history of massive blood loss from wounds, visible brisk bleeding, or presence of an open wound in proximity to a major vessel. Injuries to major vessels should be suspected when there is ongoing hemorrhage from an open pelvic fracture. Although persistent bleeding from uncontrolled small vessels can, over time, precipitate shock if left untreated, attributing profound blood loss to these wounds (eg, scalp lacerations) should be

TABLE 15-2: Symptoms Associated with Blood Loss and Hypovolemic or Hemorrhagic Shock

0%–15% loss	15%–30% loss	30%–40% loss	>40% loss
Normal or increased pulse pressure	Tachycardia	Marked tachycardia	Extreme tachycardia
Mildly anxious	Decreased pulse pressure	Decreased systolic blood pressure	Hypotension
	Tachypnea	Marked tachypnea	Extreme tachypnea or respiratory failure
	Delayed capillary refill	Oliguria	Negligible urine output
	Anxious	Cool, clammy skin	Cold, pale skin
		Confusion or agitation	Lethargic or loss of consciousness

done only after major intracavitary bleeding or other etiologies have been excluded.

When major blood loss is not immediately visible, intracavitary blood loss should be suspected. Intraperitoneal hemorrhage is a common source of blood loss inducing shock. Its presence may be suspected based on physical examination (eg, distended abdomen, abdominal tenderness, visible abdominal wounds), although the sensitivity of the physical examination for detecting substantial abdominal injuries after blunt trauma is notoriously unreliable. A large volume of intraperitoneal blood from abdominal injuries may be present before the physical examination is abnormal. Therefore, FAST or DPA is used frequently in the resuscitation area to rapidly identify potential significant intraperitoneal blood in the unstable patient who may require emergency laparotomy. In selected patients, diagnostic laparotomy may be indicated.

The chest can be a significant source of hemorrhage as each pleural cavity has the capacity to hold 2 to 3 L of blood. Diagnostic and therapeutic tube thoracostomy may be indicated in patients based on clinical findings or evidence of a hemopneumothorax on a chest x-ray or extended FAST (eFAST; includes the FAST scan and sonographic examination of bilateral lungs and thoracic spaces).[159] In addition, with the immediate removal of greater than 1000 mL of blood, a second tube thoracostomy should be placed to ensure patency and accurate monitoring of ongoing blood loss.

Major retroperitoneal hemorrhage occurring in association with a pelvic fracture can be diagnosed by urgent pelvic radiography. The pattern of the pelvic fracture may provide clues as to the risk of massive blood loss, but none is adequately predictive in the individual patient to exclude need for further evaluation.

TREATMENT

Hemorrhage control is a central component of resuscitation of the patient in shock and is part of the primary survey. Treatment of hemorrhagic shock is instituted concurrently with diagnostic evaluation to identify a source. As mentioned earlier, all trauma patients in shock should be presumed to have hemorrhage until proven otherwise. The method of treatment will depend on the patient's response to resuscitation, the specific injury or injuries responsible for the blood loss, and consideration of factors such as mechanism of injury, age of the patient, associated injuries, and institutional resources. Patients who fail to respond to initial resuscitative efforts should be assumed to have ongoing active hemorrhage (eg, external bleeding, pleural cavity, peritoneal cavity, retroperitoneum, femur fracture[s]) and require prompt intervention. Identification of the body cavity harboring active hemorrhage will help focus operative efforts, but since time is of the essence, rapid treatment is essential and diagnostic laparotomy or thoracotomy may be indicated. Alternatively, temporary or definitive endovascular control of distal or central hemorrhage can be attempted using angiographic intervention with embolization, stenting, or REBOA, where appropriate.[160] The actively bleeding patient cannot be resuscitated until control of ongoing hemorrhage is achieved.

Patients who respond to initial resuscitative efforts but then deteriorate hemodynamically frequently have injuries that require operative intervention. The duration of their response will dictate whether and which diagnostic maneuvers can be performed safely to identify the site of bleeding. Hemodynamic deterioration typically denotes ongoing bleeding for which some form of surgical or angiography-based intervention is required. As noted earlier, with cessation of hemorrhage, even patients who have lost significant intravascular volume will often respond to resuscitative efforts if the degree and duration of shock have been limited. In patients with hemorrhagic shock, survival is improved if the time between injury and control of bleeding is reduced. Clarke et al[161] demonstrated that trauma patients with major abdominal injuries requiring emergency laparotomy had an increased probability of death with increasing length of time in the ED. This probability increased approximately 1% for every 3 minutes in the ED up to 90 minutes.

A subset of patients fails to respond to resuscitative efforts despite adequate control of ongoing hemorrhage. These patients may present in one or more ways: have ongoing fluid requirements despite adequate control of hemorrhage; have persistent hypotension despite restoration of intravascular volume; require vasopressor support to maintain their systemic blood pressure; and/or exhibit a futile cycle of uncorrectable hypothermia, hypoperfusion, acidosis, and coagulopathy that cannot be interrupted despite maximum therapy. These patients have classically been described to be in decompensated or irreversible shock, and mortality may be inevitable. The hemodynamic decompensation and paradoxical peripheral vasodilation responsible for irreversible shock and the clinical factors that predict its onset have not been elucidated.

Neurogenic Shock

Neurogenic shock refers to diminished MAP and tissue perfusion as a result of loss of vasomotor tone to peripheral vascular beds. Loss of vasoconstricting impulses results in increased vascular capacitance, decreased venous return, and decreased cardiac output. Neurogenic shock is typically due to injuries to the spinal cord from fractures of the cervical or high thoracic vertebrae that disrupt sympathetic regulation of peripheral vascular tone (see Chapter 26). Occasionally, an injury such as an epidural hematoma impinging on the spinal cord can produce neurogenic shock without an associated vertebral fracture. Penetrating wounds to the spinal cord can also produce neurogenic shock.

Sympathetic input to the heart that normally increases heart rate and cardiac contractility and input to the adrenal medulla that increases the release of catecholamines can be disrupted by a high injury to the spinal cord, preventing the typical reflex tachycardia that occurs with the relative hypovolemia from increased venous capacitance and loss of vasomotor tone.

In addition, acute spinal cord injury results in activation of multiple secondary injury mechanisms: (1) vascular

compromise to the spinal cord with loss of autoregulation, vasospasm, and thrombosis; (2) loss of cellular membrane integrity and impaired energy metabolism; and (3) neurotransmitter accumulation and release of free radicals. Importantly, hypotension contributes to the worsening of acute spinal cord injury as a result of further reduction in blood flow to the injured spinal cord.

DIAGNOSIS

The classic description of neurogenic shock consists of the following: decreased blood pressure associated with bradycardia or normal heart rate (indicating the absence of reflexive tachycardia due to disrupted sympathetic discharge); warm extremities due to loss of peripheral vasoconstriction; motor and sensory deficits indicative of an injury to the spinal cord; and radiographic evidence of a fracture or injury in the vertebral column or spinal cord (see Chapter 26). However, determining the presence of neurogenic shock may be difficult since patients with multisystem trauma may have confounding injuries such as a traumatic brain injury, tension pneumothorax, and/or uncontrolled intracavitary hemorrhage. In a study of patients with injuries to the spinal cord from penetrating wounds, most patients with hypotension had blood loss as the etiology (74%) and not a neurogenic cause, and few (7%) had all the classic findings of neurogenic shock.[162] Hypovolemia from hemorrhage should be sought and excluded before the diagnosis of neurogenic shock is made. To assume that the cause of hypotension in a multiply injured patient is due to neurogenic shock without first evaluating and treating potential hemorrhage is often a costly mistake.

In patients who have neurogenic shock, the severity of the spinal cord injury seems to correlate with the magnitude of the cardiovascular dysfunction. Patients with complete motor deficits from spinal cord injury are over five times more likely to require vasopressors for neurogenic shock compared to those with incomplete lesions.[163] Similarly, patients with high cervical spine injuries (ie, C1–C5) are more likely to require cardiovascular intervention compared to those with lower cervical or high thoracic spine injuries.[164]

TREATMENT

After the airway is secured and ventilation is adequate, fluid resuscitation and restoration of functional intravascular volume will often improve systemic blood pressure and perfusion in neurogenic shock. Most patients with neurogenic shock will respond to volume resuscitation alone, with adequate improvement in perfusion and resolution of hypotension. Administration of vasoconstrictors (eg, norepinephrine, phenylephrine) can improve peripheral vascular tone, decrease vascular capacitance, and increase venous return, but should only be considered once hypovolemia is excluded and the diagnosis of neurogenic shock is established. Some studies suggest that norepinephrine promotes better restoration of blood flow and oxygenation compared to phenylephrine, particularly in cervical and upper thoracic injuries.[165] There are no high-quality data regarding optimal MAP goals and duration in the management of acute spinal cord injury. However, MAP goals of 85 to 90 mm Hg for 5 to 7 days should be considered.[166] The duration of the need for vasopressor support for neurogenic shock may correlate with the overall prognosis for improvement in neurologic function.[163]

Appropriate and rapid restoration of blood pressure may also improve perfusion to the spinal cord, prevent progressive ischemia of the spinal cord, and minimize secondary injury to the spinal cord.[167] Restoration of normal hemodynamics should precede any operative attempts to stabilize the vertebral fracture. Patients who are hypotensive from spinal cord injury are best monitored in an intensive care unit and should be carefully followed for evidence of cardiac or respiratory dysfunction.

Cardiogenic Shock

Cardiogenic shock refers to a failure of the circulatory pump leading to inadequate forward flow and subsequent tissue hypoperfusion and ischemia, in the setting of adequate intravascular volume. Hemodynamic criteria for cardiogenic shock include sustained hypotension (ie, SBP ≤90 mm Hg for at least 30 minutes in a young adult), reduced cardiac index (<2.2 L/min/m^2), and elevated pulmonary artery occlusion pressure (>15 mm Hg) if left heart failure is present, or elevated CVP (>8 mm Hg) if isolated right heart failure is present. Acute myocardial infarction is the most common cause of cardiogenic shock. In this population, mortality for cardiogenic shock ranges between 50% and 80%.

In the trauma patient, inadequate cardiac function after blunt thoracic trauma can be due to blunt myocardial injury, cardiac arrhythmia, myocardial infarction, or direct injury to a cardiac valve. As the average age of the population increases, the prevalence of comorbid medical conditions in trauma patients will also increase. In addition, a large proportion of the elderly population is on β-blockers and calcium channel blockers, which confound expected hemodynamic responses to hemorrhage. Elderly patients with preexisting intrinsic cardiac disease will be more susceptible to suffering an acute myocardial infarction or significant arrhythmia associated with the stress of injury that can also induce cardiac failure and cardiogenic shock (see Chapter 58).

Diminished cardiac output or contractility in the face of adequate intravascular volume (ie, preload) may lead to hypoperfused vascular beds and reflexive sympathetic discharge. Increased sympathetic stimulation of the heart, either through direct neural input or from circulating catecholamines, increases heart rate, myocardial contraction, and myocardial oxygen consumption. Patients with fixed, flow-limiting stenoses of the coronary arteries may not be able to increase coronary perfusion to meet the increased myocardial oxygen demands; thus, these lesions further increase the risk for myocardial damage. Diminished cardiac output decreases coronary artery blood flow, resulting in a scenario of increased myocardial oxygen demand at a time when myocardial oxygen supply may be limited and insufficient.

Acute heart failure can also result in fluid accumulation in the pulmonary microcirculatory bed, impairing the diffusion of oxygen from the alveolar space and decreasing myocardial oxygen delivery even further.

DIAGNOSIS

Rapid identification of the patient with pump failure and initiation of treatment are essential in preventing further decreases in cardiac output. If increased myocardial oxygen needs cannot be met, there will be progressive and unremitting cardiac dysfunction. Blunt injury to the heart is rarely severe enough to induce pump failure, but manifestations of shock in the setting of a patient at risk should raise one's index of suspicion (see Chapter 58). Elderly patients with known preexisting cardiac disease are at increased risk of suffering injury-related cardiac complications including cardiac failure. Furthermore, elderly patients with intrinsic cardiac disease are at risk of suffering a primary cardiac event that induces syncope, a fall, or loss of control of one's vehicle that then leads to presentation to a trauma center.

Making the diagnosis of cardiogenic shock involves the identification of cardiac dysfunction or acute heart failure in a susceptible patient. Since patients with blunt cardiac injury typically have multisystem trauma, hemorrhagic shock from intra-abdominal bleeding, intrathoracic bleeding, and bleeding from fractures must be excluded. In most instances of blunt cardiac injury, the symptoms are self-limited with no long-term cardiac sequelae. Relatively few patients with blunt cardiac injury will develop dysfunction of the cardiac pump, and those who do generally exhibit cardiogenic shock early in their evaluation.[168] Therefore, establishing the diagnosis of blunt cardiac injury is secondary to excluding other etiologies for shock and establishing that significant cardiac dysfunction is present.

Invasive cardiac hemodynamic monitoring, which generally is not necessary, may be useful in the complex patient with the combination of hemorrhagic shock and cardiogenic shock, when it is necessary to exclude right ventricular infarction or mechanical cardiac complications, or in the patient with known preexisting myocardial disease (see Chapter 58). This typically involves continuous monitoring of cardiac output and other hemodynamic variables using the pulmonary artery catheter (PAC). Transesophageal echocardiography (TEE) provides excellent views of the myocardium that are not hindered by subcutaneous air, bandages covering chest wounds, thoracostomy tubes, or unfavorable body habitus that may limit evaluation of cardiac function by transthoracic echocardiography. However, the rapid evaluation of cardiac function by TEE may be problematic in the presence of severe maxillofacial trauma or unstable injuries to the cervical spine that can interfere with probe placement. There is evidence that evaluation of cardiac function using bedside ultrasound by surgeons, emergency medicine practitioners, and intensivists demonstrates adequate accuracy to direct treatment.[169] In addition to these tools, serum troponin assays are both sensitive and specific for myocardial damage and can be used to assess for ischemic, demand-associated, or trauma-related injury. It is important to note that all of these tools are only point-in-time assessments and serial evaluation is routinely needed.

TREATMENT

Patients with blunt cardiac injury will often have associated injuries that produce hypovolemia, and expansion of intravascular volume as an initial maneuver can improve perfusion significantly. However, hypervolemia can magnify the physiologic derangements produced by cardiac dysfunction and should be avoided. In addition, under conditions of limited flow, anemia becomes a potential limiting factor and requires transfusion to higher levels as a buffer to help ensure adequate oxygen delivery. In the face of acute myocardial infarction or acute myocardial ischemia, maintaining a hematocrit of 30% may be indicated.[170] When profound cardiac dysfunction exists, ionotropic support may be indicated to improve cardiac contractility and cardiac performance. Several agents are available, and selection is dependent on the overall cardiovascular pathophysiology (see Chapter 58).

Patients whose cardiac dysfunction is refractory to cardiotonics may require mechanical circulatory support with an intra-aortic balloon pump.[171] This can be inserted at the bedside in the intensive care unit via the femoral artery through either a cutdown or percutaneous approach. In addition, recent data support use of venoarterial extracorporeal membrane oxygenation for acute cardiac failure due to trauma.[172] Aggressive circulatory support of patients with cardiac dysfunction from intrinsic cardiac disease has led to more widespread application of these devices and more familiarity with their operation by both physicians and critical care nurses (see Chapter 58).

Patients who have suffered an acute myocardial infarction around the time of their injury should have preservation of existing myocardium and cardiac function as priorities of therapy. The use of anticoagulation or thrombolytic therapy for the management of acute coronary syndromes will depend on associated injuries and the risk of secondary bleeding. Patients in cardiac failure from an acute myocardial infarction may benefit from pharmacologic or mechanical circulatory support, similar to that of patients with cardiac failure related to blunt cardiac injury. Additional pharmacologic tools include the use of β-blockers to control heart rate and myocardial oxygen consumption, nitrates to promote coronary blood flow through vasodilation, and ACE inhibitors to reduce ACE-mediated vasoconstriction that increases myocardial workload and oxygen consumption.[173] Selected patients who do not have significant associated injuries may be candidates for coronary angiography and subsequent procedures to improve coronary blood flow such as transluminal angioplasty, coronary artery stents, or urgent coronary artery bypass grafting.

Septic Shock

Sepsis is an inflammatory response to severe infection characterized by hypovolemia, vasodilation, and capillary leak treated by early antibiotics and fluid resuscitation. The multidisciplinary consensus consortium, the Surviving Sepsis

Campaign, has established useful standardized definitions for the patient with an inflammatory response with or without sepsis.[174] First, the *systemic inflammatory response syndrome* (SIRS) defines the clinical innate immune clinical manifestation that occurs in response to a wide variety of physiologic insults and is defined as the presence of two or more of the following conditions:

- Temperature greater than 38°C or less than 36°C
- Pulse rate greater than 90 bpm
- Respiratory rate greater than 20 breaths/min or $Paco_2$ less than 32 mm Hg
- White blood cell count greater than 12,000/mm^3 or less than 4000/mm^3 or greater than 10% immature (band) forms

Because of the lack of specificity of SIRS, the third International Sepsis Task Force defined *sepsis* as life-threatening organ dysfunction caused by a dysregulated host response to infection and *septic shock* as a subset of sepsis with circulatory and cellular/metabolic abnormalities associated with higher risk of mortality.[175] The new definition emphasizes the pathologic response to infection, the increased risk of mortality, and the need for urgent recognition of sepsis. In addition to the new definition of sepsis, the task force published recommendations for the use of clinical criteria to identify patients with sepsis and septic shock. The Sequential Organ Failure Assessment (SOFA) score is used to identify organ dysfunction in patients with suspected infection.[176,177] Baseline SOFA score in a patient without preexisting organ dysfunction (prior to infection) is assumed to be 0. Patients with a presumed infection and an increase in SOFA score of 2 or greater have an overall mortality risk of 10%.[178] For patients in the ED or on the hospital wards (outside of the intensive care unit), the Quick SOFA (qSOFA) score is a bedside tool that does not require laboratory tests to screen patients for possible infection. qSOFA uses three criteria, assigning one point each for low SBP (≤100 mm Hg), high respiratory rate (≥22 breaths/min), and altered mental status (Glasgow Coma Scale score <15). Identification of patients with two or more qSOFA criteria should prompt further workup for organ dysfunction and initiation of therapy as indicated. Use of SOFA and qSOFA scores is primarily intended to facilitate earlier recognition and initiation of treatment for patients with sepsis and septic shock. Without such scores and systematic screening tools, sepsis and septic shock are often underdiagnosed, and treatment delays and poor outcomes are common.

These definitions reinforce that septic shock is a clinical syndrome that occurs as a result of the body's immune and inflammatory responses to invasive or severe localized infection, typically from bacterial or fungal pathogens. In its attempt to eradicate the pathogens, the innate immune system elaborates a wide array of proinflammatory mediators (eg, cytokines, chemokines). These mediators enhance effector mechanisms for macrophage and neutrophil killing, increase procoagulant-induced microcirculatory thrombosis and fibroblast activity to localize the invaders, and increase surrounding microvascular blood flow to enhance delivery of bactericidal mediators to the area of invasion. When this response is overly exuberant or becomes systemic rather than localized, manifestations of sepsis become evident. These findings include peripheral vasodilation, fever, leukocytosis, and tachycardia.

Sepsis is an uncommon etiology for shock in the acute presentation of a trauma patient unless there has been a substantial delay between injury and presentation to the ED. Typically, invasive infection occurs days to weeks after injury and is prevalent in the severely injured and immunosuppressed patient who develops a nosocomial infection in the intensive care unit.[179]

DIAGNOSIS

Attempts to standardize terminology have led to the establishment of criteria for the diagnosis of sepsis in the hospitalized adult.[175] These criteria include manifestations of the host response to infection (eg, fever, leukocytosis, mental contusion, tachypnea, tachycardia, hypotension, oliguria), as well as identification of an offending organism. Septic shock requires the presence of these conditions associated with hypotension resistant to volume resuscitation and evidence of organ dysfunction due to tissue hypoperfusion.

Recognizing septic shock in the trauma patient begins with defining high-risk groups: critically ill patients in the intensive care unit with organ dysfunction requiring invasive support and who are immunosuppressed from their injuries; patients who have suffered injuries associated with significant contamination (eg, colorectal wounds with fecal spillage, soft tissue wounds embedded with soil or dirt); patients with injuries that may be associated with persistent devitalized tissue (eg, crush or electrical injury); patients whose wounds put them at risk for complications (eg, anastomotic disruption, pancreatic leak); or patients with missed injuries.

The clinical manifestations of septic shock should prompt the empiric initiation of treatment after obtaining appropriate cultures and before bacteriologic confirmation of an organism or source of active infection is identified. An aggressive search for the source of the infection includes a thorough physical examination, inspection of all wounds, evaluation of intravascular catheters or other foreign bodies (eg, urinary catheter, thoracostomy tube, surgical drain), sampling of appropriate body fluids for culture, and imaging studies as indicated by the patient's condition.

The hemodynamic parameters characteristic of septic shock include peripheral vasodilatation with resultant decrease in systemic vascular resistance. Initially, there is a hyperdynamic cardiac state, and after volume resuscitation, the cardiac output may be significantly elevated. Diagnosis and treatment do not usually require placement of a PAC to guide therapy in patients with septic shock. Most of these patients can be resuscitated using CVP, central venous oxygen saturation ($Scvo_2$), and serum lactate.

TREATMENT

Obtunded patients may require intubation to protect their airway while patients whose work of breathing is excessive may require intubation and mechanical ventilation to prevent

respiratory collapse. Empiric antibiotics that cover the most likely pathogens based on institution-specific antibiogram should be chosen while culture results are pending (see Chapter 21).[108] Antibiotics should be tailored to cover the responsible organisms once culture data are available and, if appropriate, the spectrum of coverage narrowed. Long-term empiric use of broad-spectrum antibiotics should be minimized to reduce the development of resistant organisms and avoid the potential complications of fungal overgrowth and antibiotic-associated colitis from *Clostridium difficile*.

Patients with sepsis are typically hypovolemic from decreased intake, large-volume intravascular volume losses into the interstitium from EGL disruption, and increased insensible losses. In addition, the inflammation related to the immune response to infection alters systematic vascular resistance, venous capacitance, and myocardial function, further exacerbating hypoperfusion. Resultant decreases in stroke volume and cardiac output imbalance oxygen delivery and demand, precipitating tissue hypoxia, shock, anaerobic metabolism, and lactic acidosis. The rationale for fluid resuscitation in sepsis is to restore intravascular volume, cardiac output, and oxygen delivery before irreversible injury occurs. As sepsis progresses, pathogen and host mediators impede mitochondrial and endoplasmic reticular function and cellular uptake and utilization of the oxygen delivered.[180]

The landmark study by Rivers et al[181] on the use of early goal-directed therapy (EGDT) in the treatment of severe sepsis and septic shock highlighted most importantly the early prompt recognition and treatment of sepsis to prevent ongoing organ insults. The study randomized 263 patients with sepsis and hypoperfusion to either standard therapy or EGDT. Standard therapy involved arterial and central venous catheterization and a protocol targeting CVP of 8 to 12 mm Hg, MAP of at least 65 mm Hg, and urine output of at least 0.5 mL/kg/h. EGDT included all elements of standard therapy in addition to a catheter measuring $Scvo_2$; 6 hours of treatment in the ED before admission; and protocolized administration of 500 mL of IV crystalloid every 30 minutes to achieve CVP goals, vasopressors and vasodilators to maintain MAP goals, and blood transfusion or dobutamine to achieve $Scvo_2$ of 70% or greater. During the 6 hours of intervention, EGDT patients received more IV fluids, red cell transfusions, and dobutamine. In-hospital mortality was 16% lower with EGDT compared to standard therapy. The mortality benefit demonstrated by the study by Rivers et al[181] made early, protocol-driven, goal-directed fluid resuscitation the preferred strategy for septic shock globally.

Over the past decade, three large, multicenter trials (ProCESS, ARISE, and ProMISe trials) compared EGDT to usual care in which invasive management was optional (eg, central venous access in ProCESS) or not permitted (eg, $Scvo_2$ measurement in ARISE).[182-184] These trials reported no differences in any clinical outcome between EGDT and usual care among the 4201 patients in these trials, calling into question the need for invasive hemodynamic monitoring in the current era of sepsis awareness, aggressive early treatment, and earlier and better access to critical care services.[88]

After initial resuscitation, the potential benefits of fluid must be balanced against the risks of excessive resuscitation. Observational studies have associated positive fluid balance with additional morbidity and mortality. Multiple trials have reported increased odds of mortality for patients with higher fluid balance after resuscitation compared to those who were maintained more euvolemic.[185,186] Although these studies were inherently limited by indication bias (ie, that patients with higher severity of illness may have been more likely to both have fluid administered and die compared to those with a less severe illness), the association calls into question unchecked resuscitation and the potential role of deresuscitation or diuresis. The Fluid and Catheter Treatment Trial (FACTT) controlled postresuscitation fluid management for 1000 ARDS patients, of whom 70% had underlying sepsis.[128] Once adequate resuscitation was achieved, the fluid strategy that emphasized diuresis and limiting fluid boluses reduced the number of ventilator and intensive care unit days without precipitating cardiovascular or renal dysfunction.

Vasopressor therapy may be required as a supportive measure when hypotension is refractory to volume infusion in patients in septic shock. α-Adrenergic agents promote peripheral vasoconstriction, improve systemic blood pressure, and can be titrated by continuous infusion to target an adequate MAP to maintain core organ perfusion (see Chapter 57).

For patients in septic shock, current recommendations advise immediate initiation of resuscitation with a minimum of 30 mL/kg of IV crystalloid fluid administered within the first 3 hours.[108] During this resuscitation, serial evaluation with diagnostics and reassessment of responsiveness to fluid should take place. Patients with circulatory failure may require an additional fluid bolus to increase stroke volume. However, the risk of repeated fluid challenges is fluid overload, which has potentially deleterious effects on the function of the heart, lungs, and kidneys, leading to increased mortality in patients with septic shock. A study of postresuscitation fluid boluses in severe sepsis and septic shock demonstrated that ongoing and repeated fluid boluses did not have a sustained effect on parameters typically associated with improved outcomes (eg, urine output, $Scvo_2$, lactate). While resuscitation commences, efforts should be made to obtain cultures prior to initiation of antibiotic therapy, promptly perform imaging to identify the source of infection as appropriate, initiate broad-spectrum antibiotic therapy within 1 hour of diagnosis of septic shock, achieve source control, and subsequently narrow antibiotic coverage once microbiologic and susceptibility data allow.

In the trauma patient, IV antibiotics alone will frequently be insufficient to adequately treat a severe surgical infection. Source control (ie, drainage of infected fluid collections, removal of infected foreign bodies, and debridement of devitalized tissue) is essential to eradicate the infection. This process may require multiple operations. For patients who manifest symptoms of septic shock early in their hospitalization, consideration of the possibility of a missed injury to a hollow viscus should be entertained. Missed abdominal injuries represent a significant source of sepsis and the septic response leading to MODS.

Stress-dose glucocorticoid therapy should be given primarily to patients with septic shock based on clinical parameters and only if hypotension is poorly responsive to fluid and vasopressor therapy, so-called "refractory shock." Multiple strategies for immune modulation have been developed and tested for the treatment of sepsis and septic shock. Use of antiendotoxin antibodies, anticytokine antibodies, cytokine receptor antagonists, immune enhancers, anti–nitric oxide compounds, and oxygen radical scavengers has been tried.[187,188] Each of these compounds is designed to alter a specific aspect of the host immune response to shock. To date, each of these strategies has failed to demonstrate clinical efficacy in improving patient outcome despite utility in well-controlled experiments. For example, previous trials demonstrated efficacy of activated protein C in improving mortality from sepsis, but subgroup analysis of patients with sepsis at low risk of death documented an increased risk of bleeding complications associated with therapy without a substantial improvement in survival.[189,190] It is unclear whether the failure of these interventions is due to trial design, inadequate understanding of the interactions of the complex immune response to injury and infection, or use of animal models of shock that poorly represent human disease.[191]

Sepsis and nosocomial infections in critically ill patients continue to represent significant sources of morbidity and consume substantial health care resources. Despite advances in critical care, the mortality rate for severe sepsis and shock remains at 30% to 50%.

Obstructive Shock

Hypoperfusion can be due to mechanical or anatomic obstruction impeding venous return to the heart or preventing cardiac filling. The end result of either of these two events is decreased cardiac output leading to decreased peripheral perfusion. Most commonly, obstruction is due to the presence of a tension pneumothorax, massive pulmonary embolism, or cardiac tamponade (see Chapters 28 and 30). With any of these conditions, there is decreased cardiac output associated with increased CVP.

DIAGNOSIS AND TREATMENT

The manifestations of a tension pneumothorax are the presence of shock in the context of diminished breath sounds over one hemithorax, hyperresonance to percussion, jugular venous distension, and shift of mediastinal structures to the unaffected side. Unfortunately, not all of the clinical manifestations of tension pneumothorax may be evident on physical examination. Hyperresonance may be difficult to appreciate in a noisy resuscitation area. Jugular venous distension or tracheal deviation may be obscured by a cervical collar and not seen unless specifically sought. Furthermore, hypovolemia from concurrent bleeding may diminish CVP and prevent jugular venous distension even when increased pleural, pulmonary artery, or pericardial pressure restricts outflow.

For the multiply injured patient with life-threatening hypotension, the placement of bilateral chest tubes may be both diagnostic and therapeutic. In these circumstances, a chest x-ray is unnecessary and potentially a dangerous waste of time. Due to the immediate threat to life, the diagnosis of tension pneumothorax should be a clinical one. If a chest x-ray is obtained due to missing the diagnosis on clinical examination, the typical findings include deviation of mediastinal structures, depression of the hemidiaphragm (ie, deep sulcus sign), and hypo-opacification with absent lung markings.

Cardiac tamponade results from the accumulation of blood within the pericardial sac and most commonly occurs from penetrating trauma. While precordial wounds are most likely to injure the heart and produce tamponade, any projectile or wounding agent that passes in proximity to the mediastinum can potentially produce tamponade. Blunt rupture of the heart is rare but has been reported. The diagnosis is aided by the FAST examination, which can be performed immediately on all injured patients presenting with signs of shock at risk of cardiac injury. The manifestations of cardiac tamponade may be as catastrophic as total circulatory collapse and cardiac arrest, or they may be more subtle. A high index of suspicion is warranted to make a rapid diagnosis. Patients who present with circulatory arrest due to cardiac tamponade from a precordial penetrating wound require emergency pericardial decompression through a sternotomy or left anterolateral thoracotomy, and the indications for these maneuvers are reviewed in Chapters 27 and 30. Cardiac tamponade may also be associated with hypotension, muffled heart tones, jugular venous distension (Beck triad), and elevated CVP with tachycardia.[192] Absence of these clinical findings may not be sufficient to exclude cardiac injury and cardiac tamponade. As described earlier, muffled heart tones may be difficult to appreciate in a busy trauma center, and jugular venous distension may be diminished by coexistent bleeding and hypovolemia. Therefore, patients at risk for cardiac tamponade whose hemodynamic status permits should undergo diagnostic testing.

Invasive hemodynamic monitoring may support the diagnosis of cardiac tamponade if elevated CVP, pulsus paradoxus (ie, decreased systemic arterial pressure with inspiration), or elevated right atrial and right ventricular pressure by PAC is present. These hemodynamic profiles suffer from lack of specificity, the time required to obtain them, and their inability to exclude cardiac injury in the absence of tamponade. Chest radiographs may provide information on the possible trajectory of a projectile but are rarely diagnostic since the acutely filled pericardium distends poorly. Pericardial ultrasound as part of a FAST examination through either the subxiphoid or transthoracic approach has excellent sensitivity in detecting pericardial fluid.[193] The yield in identifying pericardial fluid obviously depends on the skill and experience of the ultrasonographer, body habitus of the patient, and absence of wounds that preclude visualization of the pericardium. Standard two-dimensional transthoracic echocardiography or TEE to evaluate the pericardium for fluid is typically performed by cardiologists or anesthesiologists skilled at evaluating ventricular function, valvular abnormalities, and integrity

of the proximal thoracic aorta. These skilled examiners may not be immediately available, and waiting for this test may result in inappropriate delays and poor outcomes. In addition, although both ultrasound techniques may demonstrate the presence of fluid or characteristic findings of tamponade (ie, large volume of pericardial fluid, right atrial collapse, poor distensibility of the right ventricle), negative tests do not exclude cardiac injury.

Pericardiocentesis to diagnose pericardial blood and potentially relieve tamponade has a long history in the evaluation of the trauma patient. However, its inability to evacuate clotted blood and potential to produce cardiac injury make it a poor alternative. Diagnostic pericardial window represents the most direct method to determine the presence of blood within the pericardium (see Chapter 30). It can be performed through either the subxiphoid or transdiaphragmatic approach. Some authors report performing this technique using local infiltrative anesthesia. However, the ability to achieve satisfactory safety and visualization in the trauma victim who may be intoxicated, in pain, or anxious from hypoperfusion usually mandates the use of general anesthesia. Once the pericardium is opened and tamponade relieved, hemodynamics will usually improve dramatically, and formal pericardial exploration can be performed. Exposure of the heart can be achieved by extending the incision to a sternotomy, a left anterolateral thoracotomy, or bilateral anterior thoracotomies ("clamshell") depending on the injury, as reviewed in Chapters 27 and 30.

Traumatic Shock

Traumatic shock is defined by a combination of several insults after injury that, alone, may be insufficient to induce shock, but together produce profound hypoperfusion. Hypoperfusion from relatively modest loss of volume can be magnified by the proinflammatory activation that occurs following direct injury and/or shock-induced tissue damage. The systemic response after trauma, combining the effects of soft tissue injury, long bone fractures, and blood loss, is clearly a distinct physiologic response compared to hemorrhagic shock alone. In addition to ischemia or ischemia/reperfusion, hemorrhage alone can induce qualitatively proinflammatory activation and cause many of the cellular changes typically attributed previously only to septic shock.[42] Examples of traumatic shock include small-volume hemorrhage accompanied by significant injury to tissue (eg, femur fracture, crush injury) or combination of hypovolemic with neurogenic, cardiogenic, or obstructive shock that induces rapidly progressive activation of proinflammatory innate immunity and potential diffuse tissue and bystander organ injury. As a consequence, ARDS and MODS develop relatively often in the blunt trauma patient, but rarely after pure hemorrhagic shock alone. The hypoperfusion in traumatic shock is magnified by the proinflammatory activation that occurs following the induction of shock and the release of "danger" stimuli following tissue damage.

At a cellular level, the pathophysiology of traumatic shock may be attributable to the release of cellular products termed *damage-associated molecular patterns* (DAMPs; eg, mitochondrial DNA, ribonucleic acid, uric acid, high mobility group box 1 [HMGB1]) that activate the same set of cell surface receptors as bacterial products, initiating similar cell signaling.[7,32] The receptors are termed *pattern recognition receptors* (PRPs) and include the toll-like receptor (TLR) family of proteins. In models of traumatic shock, the addition of a soft tissue or long bone injury to the hemorrhage produces lethality with significantly less blood loss than when animals are stressed by hemorrhage alone.

Therapy for this form of shock is focused on correction of the individual derangements to diminish the cascade of proinflammatory activation contributing to its progression. Therapeutic maneuvers include prompt control of hemorrhage, adequate volume resuscitation to correct oxygen debt, stabilization of bony injuries, early debridement of nonviable tissue (including amputation as necessary), and appropriate treatment of soft tissue wounds.

END POINTS IN RESUSCITATION OF THE TRAUMA PATIENT

Most clinicians would agree that heart rate, systemic arterial blood pressure, skin temperature, and urine flow provide relatively little information about the adequacy of oxygen delivery to tissues. Physiologically, shock begins when DO_2 falls below the tissue VO_2 requirements. A persistent mismatch between the DO_2 and VO_2 has been associated with progressive MODS. Unfortunately, there are major limitations in our ability to quantify this mismatch and assess perfusion status. Due to these limitations, it is necessary to use surrogates of tissue hypoxia. During anaerobic metabolism, large quantities of pyruvate are converted to lactate rather than being recycled by entering the tricarboxylic acid cycle, and substrate-level phosphorylation of ADP to ATP causes a net accumulation of protons. Increases in blood lactate concentration are often evidence of an increase in the rate of anaerobic metabolism. Numerous studies have documented that high blood lactate levels (≥2 mmol/L) portend an unfavorable outcome in patients with shock, but it has not been proven that survival is improved when therapy is titrated using blood lactate concentration as an end point. Serum lactate levels are also affected by hepatic and renal clearance, both of which can be depressed due to preexisting comorbidities or prolonged tissue dysoxia. BD has been shown to have prognostic value in patients with shock.[194] However, it remains to be proven that titrating therapy to a BD end point improves survival.

There are numerous parameters that have been used as surrogates to measure intravascular volume as a surrogate for adequate resuscitation, including CVP. Similarly, the inferior vena cava diameter measured by ultrasound has been shown to correlate with the CVP and to predict fluid responsiveness in critically ill patients.[195] One study found that patients with an inferior vena cava diameter of less than 2 cm were almost uniformly volume responsive compared to those with inferior vena cava diameters of 2 cm or greater.[196] However, titration

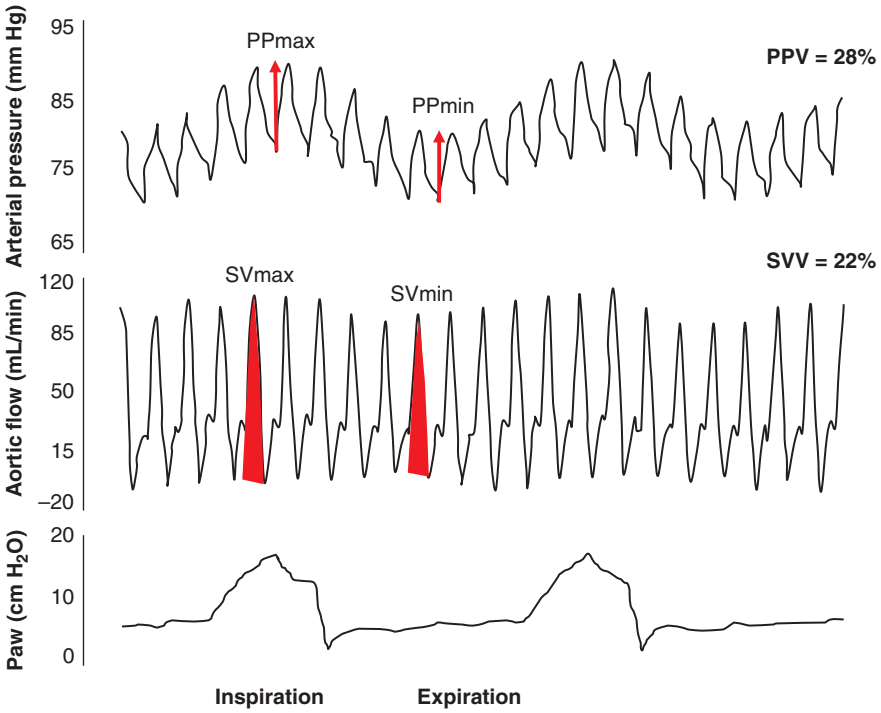

FIGURE 15-8 Pulse contour analysis. Paw, airway pressure; PPmax, maximum pulse pressure; PPmin, minimum pulse pressure; PPV, pulse pressure variation; SVmax, maximum stroke volume; SVmin, minimum stroke volume; SVV, stroke volume variation.

of resuscitation to CVP or inferior vena cava diameter has not been shown to improve survival.

Cardiopulmonary interactions are responsible for pulse pressure variation (PPV), which is a surrogate for stroke volume variation (SVV) (Fig. 15-8). Pulse pressure is the difference between the systolic and diastolic blood pressures at any given point in time as measured in mm Hg. PPV is the difference in pulse pressure that occurs over a respiratory cycle and can be monitored by examining the alterations of the arterial waveform in patients who are mechanically ventilated, not spontaneous breathing, and in sinus rhythm. In mechanically ventilated patients with controlled respiratory effort (ie, not overbreathing the ventilator, synchronous respirations), the positive pressure delivered with each breath forces blood from the lungs to the left heart, effectively increasing preload and stroke volume. Simultaneously, the positive intrathoracic pressure decreases venous return to the right heart, lowering right heart preload and stroke volume. The pulmonary transit time of the smaller right heart stroke volume accounts for the short delay in decreased left heart stroke volume that is manifest during exhalation. PPV increases in states of hypovolemia where decreased intrathoracic blood volume and ventricular filling pressures are more sensitive to changes in intrathoracic pressure that occur during a respiratory cycle with positive-pressure ventilation.[197] A PPV of 13% has been shown to discriminate between patients in whom additional volume will increase their cardiac index (responders) and those that will not (nonresponders) with a sensitivity and specificity of 94% and 96%, respectively.[198] A recent meta-analysis of PPV in septic shock reported a pooled sensitivity of 0.72 (95% confidence interval [CI], 0.61–0.81) and a specificity of 0.91 (95% CI, 0.83–0.95) in predicting fluid responsiveness.[199] However, resuscitation using an end point of a PPV of less than 13% has not been shown to improve meaningful outcomes in critical illness.

Arterial waveform analysis is a noninvasive way to measure cardiac output (CO) and further characterize PPV and SVV in critically ill patients. CO, PPV, SVV, and other hemodynamic parameters can be measured continuously with a minimally invasive lithium dilution CO (LiDCO) or pulse contour analysis CO (PiCCO or FloTrac). These systems use a pulse contour CO algorithm to estimate CO and systemic vascular resistance in the absence of invasive techniques. There is some evidence that the information garnered from such devices is most useful at a single point in time; when used for continuous assessment, the serial values show limited agreement or reproducibility.[200] In small clinical trials, devices that use arterial waveform analysis have shown some promise, but large multicenter trials looking at patient outcomes have yet to be reported.[201]

Near-infrared spectroscopy (NIRS) offers continuous, noninvasive bedside monitoring of tissue oxygenation. It measures oxygenation in the tissue's microvasculature and, thus, not only examines the adequacy of tissue perfusion, but also provides a window to noninvasively study tissue metabolism. In the clinical setting, NIRS has been used for continuous monitoring of metabolic variables including tissue oxygen availability, tissue oxygen consumption, tissue oxygen saturation (StO_2), and changes in StO_2 in diverse populations of patients (eg, injury, sepsis, heart failure).[194,202] However, the exquisite sensitivity of the technique and the rapid and

labile nature of peripheral perfusion in critically ill patients result in poor reproducibility; thus, the clinical utility of the technology has not been realized.

Recent reviews suggest that our lack of understanding of the effects of shock and resuscitation stem from a discrepancy between the need to identify effective strategies aimed at restoring normal oxygen delivery and the fact that most resuscitation research is aimed at controlling inflammation and coagulopathy. Although the degree of activation of the inflammatory mechanisms and coagulation derangements are directly related to the magnitude of the hypoxia-induced tissue injury, it is naïve to believe that by simply correcting oxygen delivery or modulating a specific pathway we could prevent the already established physiologic derangements and ensuing multiple organ injury.

Until more practical and quantitative methods are introduced to measure the cumulative effect of the oxygen deficit and subsequent host response, it is likely that we will continue to use a combination of surrogates of tissue perfusion to diagnose shock and guide resuscitation.

Trauma-Induced Coagulopathy

Hunter B. Moore • Ernest E. Moore

KEY POINTS

- The pathogenesis of trauma-induced coagulopathy is multifactorial and includes impaired thrombin generation, defective fibrinogen, platelet dysfunction, and dysregulated fibrinolysis.
- Metabolic acidosis has a more significant effect on trauma-induced coagulopathy than hypothermia at clinically relevant levels.
- Fibrinolysis is the active degradation of polymerized fibrin through the co-localization of tissue plasminogen activator or urine-type plasminogen activator with the lysine avid binding plasminogen and subsequent conversion to plasmin.
- Systemic hyperfibrinolysis occurs in 10% to 15% of those requiring a massive transfusion.
- Impaired fibrinolysis (shutdown) is present in the majority of severely injured patients and may result in microvascular occlusion and organ dysfunction.
- Tranexamic acid should be used selectively and only in patients with active bleeding and severe shock (systolic blood pressure <75 mm Hg or base deficit >6) and optimally with documented hyperfibrinolysis.
- Prehospital plasma improves survival in patients with transport times that are anticipated to exceed 20 minutes.
- Goal-directed hemostatic strategies employing viscoelastic assays improve survival.
- Cryoprecipitate contains fibrinogen, factor VIII, von Willebrand factor, fibronectin, factor XIII, and platelet microparticles.
- Weight-based low molecular weight heparin and antifactor Xa–guided dosing are advantageous in the prevention of venous thromboembolism.

INTRODUCTION

Despite advances in emergency medical systems (EMS) and trauma care, deaths from injury have increased in the United States over the past decade.[1] In both the civilian[2] and military[3] settings, uncontrolled hemorrhage is the leading cause of preventable death after injury. In civilian studies, more than 95% of deaths from hemorrhage occur within the first 24 hours at a median time of less than 3 hours.[2] Consequently, there is intense interest worldwide in the pathogenesis of trauma-induced coagulopathy (TIC) and its early management. Although there have been substantial insights, the words of Mario Stefanini in his address to the New York Academy of Medicine in 1954[4] remain applicable today:

> *The ponderous literature on the subject of hemostasis could perhaps be considered a classical example of the infinite ability of the human mind for abstract speculation. For several years, the number of working theories of the hemostatic mechanism greatly exceeded and not always respected the confirmed experimental facts. In recent years, however, the revived interest in this field has led to an accumulation of new findings which has been almost too rapid for their orderly incorporation into a logical working pattern. As a result, we have rapidly gone from a state of orderly ignorance to one of confused enlightenment.*

Although transfusion medicine has undergone enormous development over the past 60 years since the challenge issued by Stefanini, important gaps in scientific knowledge persist, and several fundamental issues involving the diagnosis and management of TIC remain unclear. The more we learn about TIC, the more we appreciate the contributions of surgical scientists from the past century who had the insight to form the basis of our current understanding of trauma-related bleeding. This chapter will review important historical landmarks in our evolution of understanding TIC, synthesize recent investigations into the pathophysiology underlying these processes, and provide a rationale for current diagnostic and resuscitation strategies in these patients.

HISTORICAL PERSPECTIVE

The evolution of our understanding of the complexities of TIC has been, in large part, the result of collaboration between civilian and military teams. The early reports of TIC were generated from military research teams, often including civilian consultants, during major wars. These novel observations intensified hemostasis research in civilian centers. Ultimately, the resulting findings improved coagulopathy management in subsequent conflicts and primed the civilian environment for making new observations. The specific contributions to our understanding of TIC, however, are somewhat difficult to ascertain from World War I through Vietnam because the primary focus was on optimizing shock resuscitation at a time when plasma or whole blood was employed to replace acute blood loss.[5] Nonetheless, several landmark contributions are well recognized.

In 1916, the US National Research Council formed a subcommittee on traumatic shock that collaborated with the British Medical Research Committee to study wounded soldiers in the front lines of France. Among them was Walter B. Cannon, MD, who was perplexed by the inconsistencies of the prevailing toxin theory of shock. Cannon documented experimentally that stress (ie, epinephrine infusion into animals) provoked hypercoagulability followed by hypocoagulability. Cannon stated that "shock is a loss of homeostasis, and without homeostasis the patient does not survive."[6] During World War II, experts recognized that bottled whole blood would be logistically impractical and enlisted the expertise of Edwin J. Cohen, a biochemist, to deconstruct blood to enable components to be used on the battlefield.[7] Cohen was successful in purifying albumin as well as preparing plasma. At the onset of World War II, the National Research Council's Committee on Transfusion recommended that dried plasma—not blood—would be used if combat occurred outside the continental United States because it was easy to prepare and transport, whereas whole blood had to be typed, cross-matched, and refrigerated. Based on the legendary work of consultant Edward D. Churchill, MD,[8] who concluded that "wound shock is blood volume loss," the policy was changed to whole blood administration and implemented in 1943.

During the 1950s, civilian investigators recognized that impaired coagulation was associated with severe injury; the culprits were believed to be fibrinolysis,[9] loss of labile clotting factors,[10] disseminated intravascular coagulopathy (DIC),[11] and platelet dysfunction.[12] The labile factor depletion hypothesis was supported during the Korean War. Scott and Crosby[13] reported that the prothrombin time (PT) was doubled in combat casualties, while platelet count and fibrinogen were increased. Artz and Fitts[14] observed that severely injured soldiers in the Korean conflict required both return of shed blood and crystalloid for optimal survival. The recognition of the high incidence of acute renal failure further stimulated the classical experimental work of Shires et al,[15] who demonstrated the intracellular accumulation of sodium in hypoxic cells. These studies ultimately led to the routine practice of initial crystalloid loading for shock resuscitation.[16] During the Vietnam War, crystalloid resuscitation was used to such excess that it led to acute lung dysfunction, similar to the civilian description of acute respiratory distress syndrome.[16]

The factor depletion component of coagulopathy was proposed by Simmons et al[17] and attributed to a DIC-like phenomena. During the 1970s, coagulation research in civilian centers began to accelerate; the recurring theme was trauma patients with liver injury bleeding to death despite control of mechanical hemorrhage. From these clinical observations, the concept of preemptive plasma resuscitation was introduced[18,19]: "If the patients remain hypotensive after the second unit of blood—FFP [fresh frozen plasma] should be administered then and with every fourth unit thereafter" and "fresh whole blood should be given if bleeding persists despite normal PT, PTT [partial thromboplastin time], and bleeding times."[19] The bloody viscous cycle, later known as the lethal triad, was introduced in 1981 as it was observed that refractory bleeding was associated with hypothermia, acidosis, and coagulopathy, and experimental work supported this construct.[20] The frequent recognition of this scenario led to the concept of damage control resuscitation in which definitive repair of injuries was delayed in favor of optimizing the patient's physiologic status.[21] Coagulation research during this period was further complicated by the practice of aggressive crystalloid resuscitation targeting supraphysiologic oxygen delivery. This resulted in an epidemic of compartment syndromes, and in retrospect, much of the coagulopathies were generated by clotting factor dilution with overzealous infusion of crystalloid.[22]

The first decade of the 21st century provided perhaps the most significant insights into TIC in modern history. Progress was unquestionably inspired by the revolutionary concept of the cell-based model of coagulation proposed by Hoffman and Monroe,[23] who emphasized the fundamental role of platelets as a platform for clotting factor assembly and thrombin generation on damaged endothelium. In 2003, MacLeod et al[24] from the University of Miami and Brohi et al[25] from the Royal London Hospital independently reported that 25% of severely injured patients had prolonged plasma clotting times, and this abnormality was independent of fluid administration. Consequently, the London group termed the syndrome the *acute coagulopathy of trauma* (ACOT).[25] Stimulated by his observations of ACOT, Brohi pursued a trauma research fellowship with Cohen, Pittet, and colleagues in San Francisco. Together, in 2007, this civilian research team provided evidence suggesting that activation of protein C was an integral component of ACOT.[25] Simultaneous with these provocative civilian findings, the US military analyzed combat casualties in Iraq and concluded that uncontrolled hemorrhage was the predominant source of preventable death.[3] Armand and Hess[26] suggested the solution was to replace the lost blood with component therapy that replicated the composition of whole blood, initiating the concept of 1:1:1 (fresh frozen plasma [FFP]:red blood cells [RBCs]:platelets). Remarkably, in the same year as the proposed protein C hypothesis, Borgman et al[27] reported that resuscitation with FFP:RBC approaching 1:1 improved combat survival. These

landmark civilian and military reports prompted a literal explosion of coagulation research. Recognizing the ongoing controversies, the National Institutes of Health responded with a workshop on postinjury hemostasis in 2010 and achieved consensus in renaming this challenge *trauma-induced coagulopathy* (TIC).

Cell-Based Model of Hemostasis

Hoffman and Monroe[23] enhanced our understanding of the mechanisms of coagulation by shifting from a simple enzymatic cascade to a cell-based paradigm with tightly regulated events (Fig. 16-1). The key concept underlying the paradigm of "cell-mediated hemostasis" is that cells play active roles in regulating and localizing the coagulation reactions. Many cells participate in hemostasis and thrombosis, but two critical players are platelets and endothelial cells. This model consists of three overlapping phases: initiation, amplification, and propagation. A breach of the endothelium promotes clot formation via exposed collagen and tissue factor. Collagen localizes platelets via their glycoprotein (GP)-VI receptor. Circulating von Willebrand factor also binds collagen, and this complex further promotes platelet adherence through their GP-Ib-V-IX receptors, particularly important under high-stress flow. Tissue factor (TF) binds circulating factor VII; the resulting TF/factor VIIa complex activates factors IX and X. The initial amount of thrombin generated is insufficient to cleave fibrin, but activates platelets through their PAR-1 and PAR-4 receptors and also activates factors V and VIII. In the ensuing amplification phase, these activated factors form the prothrombinase (Va/Xa) and tenase (VIIIa/IXa) complexes on the surface of platelets. Tenase (VIIIa/IXa) generates sufficient amounts of factor Xa to support thrombin generation through prothrombinase (Va/Xa). These coagulation complexes require phospholipid and calcium for their activity. Prothrombinase and tenase then potentiate the "thrombin burst" in the propagation phase, which cleaves fibrinogen. The resulting fibrin polymerizes and integrates platelets by binding via their GP-IIb–IIIa receptors. This thrombin further generates Va and VIIIa that promote prothrombinase and tenase assembly and activate XIII, which cross-links fibrin to stabilize the evolving clot. Activated platelets release adenosine diphosphate (ADP) and thromboxane A2 that further recruit platelets to form an outer shell to stabilize the clot. The various proteins known to be active in the clotting system are summarized in Table 16-1.

DRIVERS OF TRAUMA-INDUCED COAGULOPATHY

Impaired Clot Formation (Part I)

ACTIVATED PROTEIN C

The activated protein C (APC) pathway attenuates coagulation activation, serving as an anticoagulant restraint on the multiple physiologic processes that promote clot formation. Independent of these anticoagulant properties, APC has been shown to have multiple cytoprotective effects as well, acting as an anti-inflammatory agent and preventing endothelial barrier leakage.[28] By these two mechanisms, the APC pathway serves to maintain vascular flow by preventing excessive thrombosis and also protects cells from damage associated with inflammatory insults, such as sepsis and trauma. Once activated, APC achieves its primary anticoagulant function through proteolytic cleavage of activated factors Va and VIIIa, the major drivers of thrombin formation.[29] Activation of protein C is achieved via thrombin-mediated cleavage.[30] Following injury, thrombin binds to upregulated thrombomodulin, activating the endothelial receptor for protein C, culminating in the release of protein C (Fig. 16-2). Thrombomodulin can increase this activity by 20,000-fold.[31] Thrombomodulin is a transmembrane protein that is found predominantly on the surface of endothelial cells and is heavy concentrated in the microvasculature.[32] Protein S also increases APC complex adherence to the phospholipid membrane, further enabling the inactivation of factor Va.[33] Krishnaswamy et al[34] have shown that meizothrombin released from stored RBCs can also bind to thrombomodulin and activate protein C.

As previously mentioned, data from the San Francisco general group suggested that APC has a central role in pathogenesis of TIC. The hypothesis is that this event is related to an evolved but maladaptive response to severe injury. In the setting of severe trauma and tissue hypoperfusion, an excess of protective anti-inflammatory APC is released in an attempt to prevent local microvascular thrombosis and mitigate cellular dysfunction. This hypothesis is supported by data from a trauma cohort demonstrating that poor outcomes associated with increased levels of inflammatory histones are abrogated by simultaneous increases in endogenous APC, implying a protective effect of APC in the setting of widespread inflammation.[35] The role of APC in the pathogenesis of TIC, however, remains controversial.[36]

AUTOHEPARINIZATION FROM GLYCOCALYX DEGRADATION

Shortly after the proposed role of APC in TIC, Johansson et al[37] from Copenhagen added evidence implicating endothelial glycocalyx degradation, emphasizing the endotheliopathy component of TIC. The vascular endothelium comprises a single layer of cells that line blood vessels and lymphatics in every organ, covering a surface area of 4000 to 7000 m^2 with a weight of 1 kg.[38] The luminal surface of the endothelial cells is covered by a 0.2- to 1.0-μm-thick, negatively charged, carbohydrate-rich surface layer, the endothelial glycocalyx, which represents a large component of the vascular system by containing a fixed noncirculating plasma volume of approximately 1 L in adults, corresponding to one-third of the vascular plasma volume.[38] The glycocalyx is an antiadhesive and anticoagulant structure that protects endothelial cells and maintains vascular barrier function.[39] It is bound to the underlying endothelial cells through various backbone

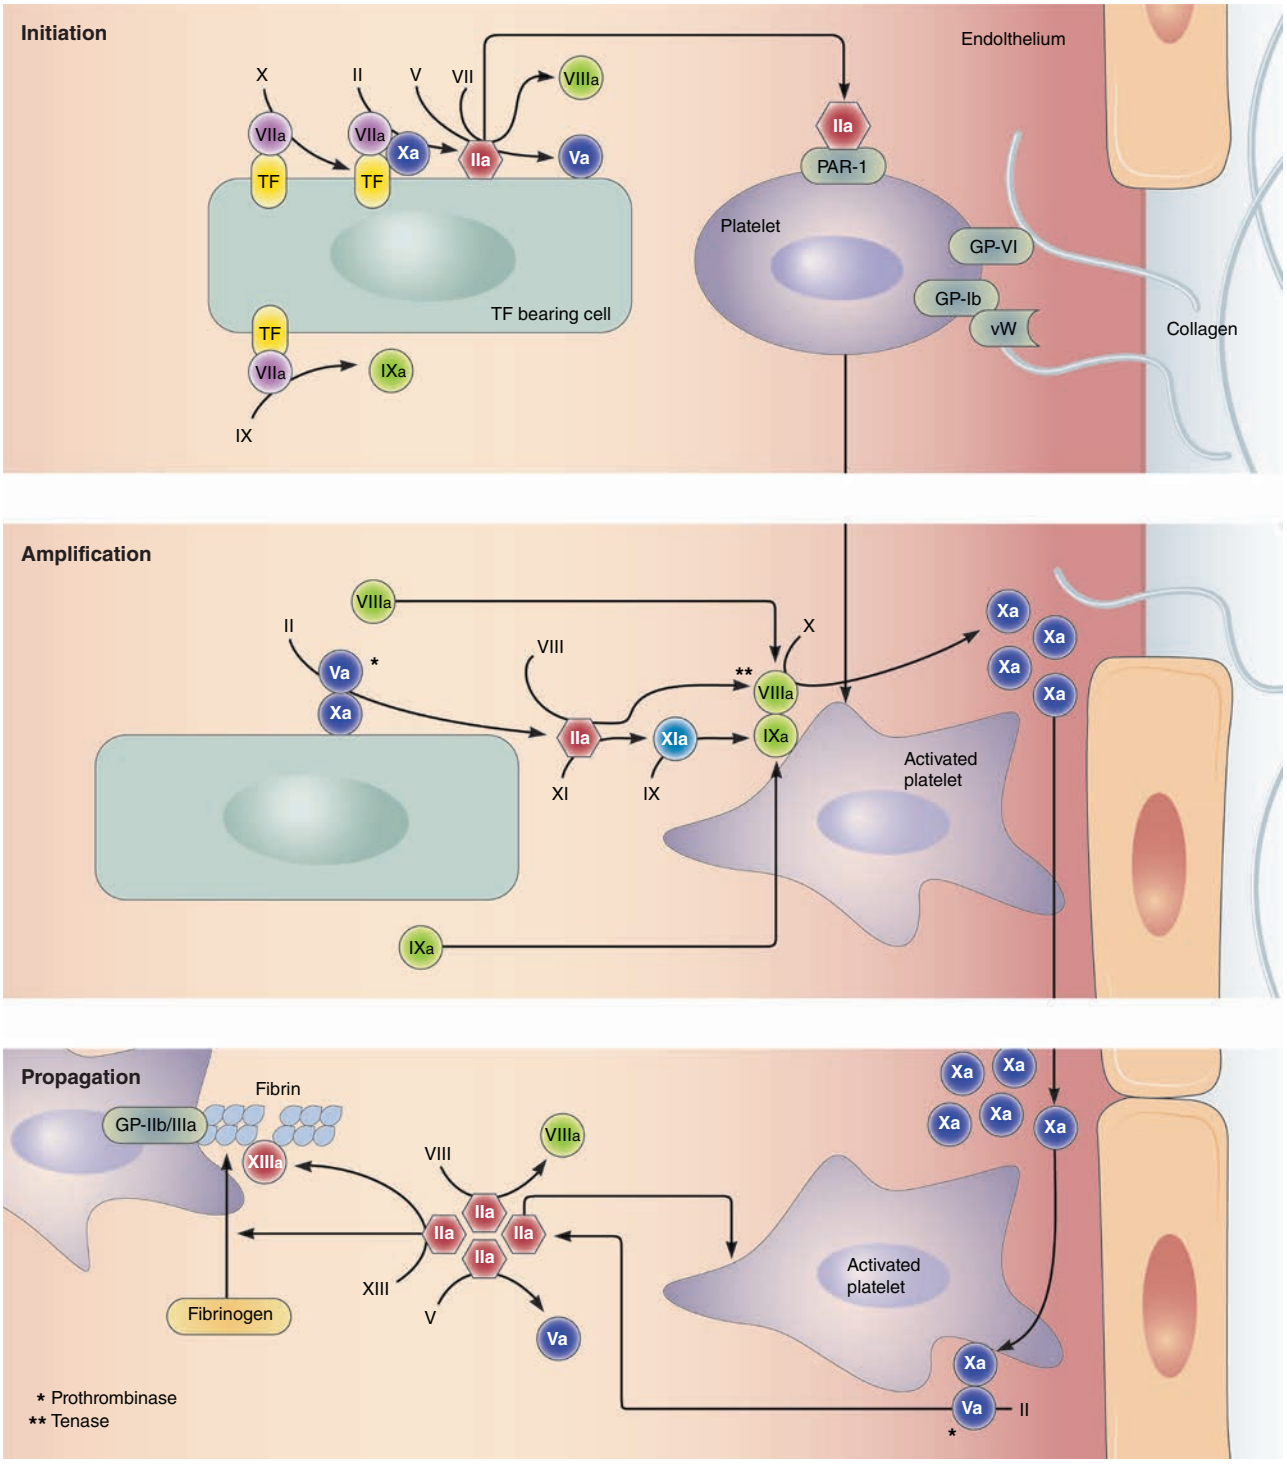

FIGURE 16-1 Cell-based model of hemostasis. Initiation is triggered by subendothelial tissue factor (TF) that binds circulating factor VII; the TF/factor VIIa complex activates factor X, generating thrombin. This initial thrombin activates platelets and factors V and VIII. During amplification, the prothrombinase (Va/Xa) complex generates additional thrombin, which activates the tenase (VIIIa/IXa) complex on the platelet surface. The tenase complex generates sufficient Xa to maintain prothrombinase-mediated thrombin, which cleanses fibrinogen into fibrin and activates factor XIII, which then cross-links fibrin to form a stable clot. TABLE 16-1: Proteins Involved in Coagulation, Anticoagulation, and Fibrinolysis

Protein	Source	Activated by	Function
Procoagulant			
Tissue factor (TF)	Subendothelium, monocytes	Binding to circulating platelets	Complexes with VII to initiate clot formation
Fibrinogen (factor I)	Activated platelets	Thrombin	Clot formation
Factor V	Activated platelets	Thrombin	Cofactor that accelerates conversion of prothrombin to thrombin
Factor VII	Liver	Thrombin, Xa, XIa, XIIa	Complexes with TF to convert X to Xa Activates TAFI
Factor VIII	Endothelial cell, liver	Thrombin	Cofactor, activates factor X
Factor IX	Liver	Factor XI	Cofactor, activates factor X
Factor X	Liver	Factors VIII and IX	Converts ~ prothrombin to thrombin
Factor XI	Liver	Thrombin	Activates IX
Factor XIII	Liver	Thrombin	Crosslinks fibrin
Kallikrein	Liver		Activates contact system
Anticoagulants			
Heparan sulfate	Endothelial cells	Ischemia	Activation of ATIII
Antithrombin III	Liver	Thrombin	Inhibition of thrombin, Xa, XIa, XIIa
Protein C	Liver	Thrombin, TM, EPCR	Irreversibly inactivates Va and VIIIa
Protein S	Liver		Cofactor for protein C
Thrombomodulin (TM)	Endothelial cell	Ischemia	Complexes with thrombin to activate protein C; inhibits TAFI
Endothelial protein C receptor (EPCR)	Endothelial cell		Complexes with thrombin and TM to activate protein C
Tissue factor pathway inhibitor (TFPI)	Liver	Thrombin	Inhibits TF–VII complex from converting X → Xa
Meizothrombin	Red blood cells		Precursor of thrombin
Fibrinolytic system			
Plasminogen	Liver	t-PA	Converted to plasmin
Tissue plasminogen activator (t-PA)	Endothelial cell	Ischemia, thrombin	Converts plasminogen to plasmin
Urine-type plasminogen activator (u-PA)	Epithelium, monocytes	Kallikrein	Converts plasminogen to plasmin
Plasminogen activator inhibitor 1 (PAI-1)	Endothelium, platelets, adipocytes		Binds t-PA and u-PA
Plasminogen activator inhibitor 2 (PAI-2)	Placenta, adipocytes, monocytes		Binds t-PA and u-PA
Thrombin-activatable fibrinolysis inhibitor (TAFI)	Liver, platelets	Thrombin–thrombomodulin complex	Inhibits plasminogen binding to fibrin
α-2 antiplasmin	Liver, platelets		Binds plasmin and inactivates
α-2 macroglobulin	Endothelium, platelets		Binds plasmin and inactivates
C1-esterase inhibitor	Liver		Binds t-PA and inactivates

Platelet activation = adhesion/aggregation/degranulation/shape change

Agonists	Platelet receptors
Thrombin	PAR-1 and PAR-4
Collagen	GP1a-IIa and GPVI
von Willebrand factor	GP1ba-IX-V
Adenosine diphosphate	P2Y1 and P2Y12
Thromboxane A2	TRα and TRβ
Fibrinogen	GPIIb-IIIa
Epinephrine	
Serotonin	

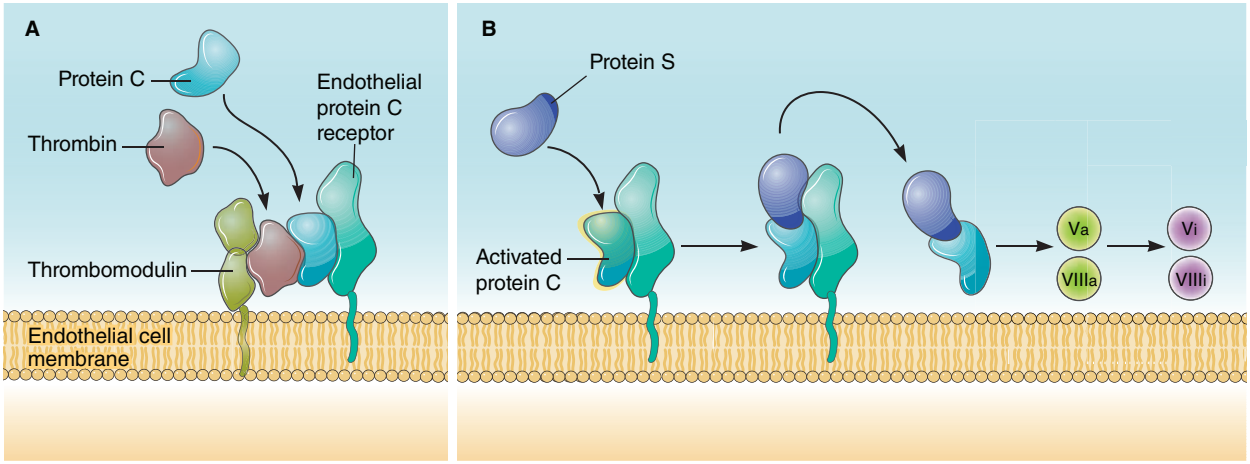

FIGURE 16-2 Protein C activation. Increased expression of the transmembrane endothelial protein thrombomodulation binds thrombin, which activates protein C (**A**). The endothelial protein C receptor localizes protein, facilitating this activation (**B**). Activated protein C cleaves peptide bonds of factor Va and factor VIIIa, preventing their assembly into the prothombinase (Va/Xa) and tenase (VIIIa/IXa) complexes.

molecules of proteoglycans (the most abundant is syndecan-1) and glycoprotein. The proteoglycans have long glycosaminoglycan side chains composed mainly of heparan sulfate that has heparin-like functions.[39] Glycocalyx damage can range from discrete disturbances in the composition of the most luminal layer to degradation with loss of the entire glycocalyx. Upon shedding, the glycocalyx glycosaminoglycans retain their anticoagulant (heparin-like) activity and promote measurable hypocoagulability in the circulating blood through endogenous autoheparinization.[39] Rehm et al[40] provided the first evidence of acute destruction of the endothelial glycocalyx in patients undergoing vascular surgery associated with ischemia/reperfusion injury. This study reported that syndecan-1 and heparan sulphate levels increased after ischemia/reperfusion injury during vascular surgery and that this increase correlated to shedding of glycocalyx as detected by electron microscopy. Despite 40- to 60-fold increases in syndecan-1 postischemia, the levels of the classical endothelial adhesion molecules ICAM-1 and VCAM-1 did not change, emphasizing the occurrence of selective glycocalyx disruption. Ostrowski and Johansson[41] translated these observations to trauma when their group demonstrated reversibility of prolonged clotting time by heparinase-thromboelastography in critically injured trauma patients. These patients had syndecan-1 levels fourfold higher than noncoagulopathic patients in this study, in addition to a higher injury severity and transfusion requirements. However, the role of glycocalyx degradation in the pathogenesis of vascular barrier function remains unclear.[42] Furthermore, the Copenhagen group has failed to translate a clinical strategy to reduce bleeding by blocking circulating glycocalyx products. The use of protamine or antiheparin in the resuscitation of trauma patients cannot be advocated at this time. Although this group continues to publish multiple papers on syndecan-1 levels and poor outcomes, they ultimately have identified a biomarker of endothelial activation/injury after trauma that is associated with poor outcomes.[43]

DIC AND CONSUMPTIVE COAGULOPATHY

The role of DIC in depleting circulating clotting factors resulting in impaired thrombin generation remains debated.[44] The distinction is that DIC occurs systemically within the vessel lumen, whereas factor consumption from disrupted endothelium exposing tissue factor and collagen is a localized process at the site of injury. Most investigators do not believe DIC is a dominant mechanism in TIC but acknowledge its potential contribution. The innate immune response to injury has been implicated in the genesis of DIC, particularly with the release of damage-associated molecule patterns (DAMPs). However, beyond increased tissue factor expression on monocytes and microparticles, the mechanism remains unclear. Among those with procoagulant implications are HMGB1, histone DNA complexes,[45] polyphosphates,[46] and myosin.[47] In addition, neutrophils are believed to contribute to a procoagulant state via degranulation of elastase, which can act as an indiscriminate protease.[48] Human neutrophil elastase mediates fibrinolysis shutdown through competitive degradation of plasminogen and generation of angiostatin.[49] With extensive tissue disruption, there is undoubtedly some element of coagulation factor consumption at the site of injury to achieve hemostasis.

HYPOTHERMIA AND ACIDOSIS

Hypothermia and acidosis were initially considered the primary drivers of TIC. Although hypothermia is usually not a major factor, acidosis may play a more important role than recognized. In vitro[50] and in vivo[51] work indicates that hypothermia affects hemostasis when the temperature is below 33°C. Below this temperature, hypothermia inhibits the initiation phase of clotting. This would be anticipated as most of the coagulation enzymes are slowed by hypothermia. However, although moderate hypothermia delays the onset of thrombin generation, the total amount of thrombin generation is unaffected.[51] The effect of hypothermia on platelet function

is contradictory due to limitation in the ability to replicate platelet function under physiologic conditions.[52] Some investigators have indicated enhanced platelet activation (priming) and aggregation,[53] whereas others indicate decreased adhesion and aggregations.[51] Profound hypothermia has long been recognized for promoting hepatic sequestration of platelets, but the clinical relevance outside of cardiac surgery is minimal, as a temperature below 30°C is needed for this phenomenon.

Metabolic acidosis has a more significant effect on TIC than hypothermia at clinically relevant levels.[54] A reduction of pH from 7.4 to 7.0 has been shown in vitro to reduce factor VIIa activity by 90%, prothrombin complex (Xa/Va) activity by 70%, and factor VIIa/TF complex activity by 55%.[55] In vitro work has confirmed a pronounced inhibition of the propagation phase of thrombin generation at a pH of 7.1, resulting in a marked reduction in clot strength.[50] These studies also suggest this degree of acidosis increases fibrinogen degradation twofold. Although impaired platelet aggregation and adhesion at a pH of less than 7 has been appreciated for decades, more recently the mechanism has been linked to the store-operated calcium entry (SOCE) channels. Perhaps more worrisome, the correction of pH with bicarbonate[50] or trishydroxymethylaminomethane (THAM)[56] does not restore platelet function. This may have implications for the optimal timing of platelet transfusion in the critically injured patient.

HEMODILUTION

Hemodilution is no longer the dominant mechanism for TIC, but overzealous crystalloid resuscitation can exaggerate an existing coagulopathy. Reduced levels of coagulation proteins have been documented in healthy volunteers after administration of crystalloids, colloids, and stored RBCs[57] and remain a fundamental rationale for permissive hypotensive resuscitation (see Chapter 15). Interestingly, acute hemodilution to 50% in vitro does not impair clot formation,[58] but this magnitude of hemodilution enhances the sensitivity to tissue plasminogen activator (t-PA) due to the dilution of endogenous antifibrinolytics.[59]

In sum, impaired clot formation is central in the pathogenesis of TIC, but the mechanism is complex and time dependent and can be exacerbated by acidosis, factor consumption, and hemodilution (Fig. 16-3).

PHENOTYPES OF TIC

With the multiple mechanisms and time dependence that drive TIC, it is not surprising that patients manifest coagulopathy, with unique phenotypes of coagulopathy warranting patient-specific management. Trauma is a combination of tissue injury and shock, and no two patients have an identical injury pattern and magnitude of shock. These variables in combination with genetic variability, preexisting medical conditions, and age-related changes in coagulation make every trauma patient unique when they arrive at the emergency department (Fig. 16-4). In the early description of TIC, two components were proposed: (1) impaired blood clot formation (hypocoagulation) and (2) increased clot degradation (hyperfibrinolysis).[60] These two processes appear to be mechanistically unique based on principal component analyses, which also implicate a third mechanistic variant of coagulopathy.[61,62] To make it more complicated, the extremes of the phenotypes can be pathologic. Recently it has been identified that trauma patients can present with a spectrum of fibrinolysis within 12 hours of injury and those patients on either extreme with excessive or impaired fibrinolysis have increased mortality.[63]

Dysregulation of Fibrinolysis (Part II)

Stafford's review on fibrinolysis and hemostasis in 1964[64] established a logical understanding for why coagulation becomes pathologic: "a general assumption has developed that clotting is not episodic but a continuous process which is normally never allowed to progress to a physical end point." In the previous section, we stressed that APC and the glycocalyx serve physiologic functions to localize thrombin-generated clot and that fibrinolysis serves a physiologic role to control clot burden. The recurring theme of biologic systems is germane to TIC; coagulation is a balance, and preventing the extremes should be the resuscitation goal (Fig. 16-5).

HYPERFIBRINOLYSIS

Although proposed in 1948,[9] during the 1960s, a number of investigators emphasized that fibrinolysis was a physiologic process to counterbalance thrombosis and was occurring perpetually.[64,65] Fibrinolysis is the active degradation of polymerized fibrin through the lysine avid binding protease plasmin.[66] The conversion of plasminogen to plasmin is accomplished by proteolytic cleavage by one of its activators (t-PA or urine-type plasminogen activator [u-PA]). Plasmin activity is highly dependent on its local environment, and its proenzyme plasminogen binds numerous receptors, indicating the process occurs on cell surfaces and not in circulation.[67] The regional distribution of specialized endothelial cells contributory to the fibrinolytic system is reflective of the importance of localizing this process.[68] The primary driver of intravascular fibrinolysis, t-PA, is released from precapillary arteriole and postvenular endothelial cells; u-PA is considered a secondary source derived from epithelial cells, but its relative importance is likely tissue specific, including the brain.[69] Release of t-PA into the circulation results in complex formation with its most abundant serine protease inhibitor, plasminogen activator inhibitor 1 (PAI-1), and secondary inhibitors such as C-1 inhibitor. These t-PA complexes are cleared by the liver.[70] There are a number of additional proteins present in plasma that either inhibit t-PA directly, inhibit plasmin, or impair plasmin access to fibrin (see Fig. 16-5). These proteins are normally in relatively high abundance in the plasma, including α-2 antiplasmin (α-2AP), α-2 macroglobulin, α-1 antitrypsin, and histidine-rich glycoprotein.[71] In addition, there are potent inhibitors integrated into the fibrin clot, including α-2AP and thrombin-activatable fibrinolysis inhibitor (TAFI), which are directly released from platelets to ensure a tight regulation of the system. TAFI cleaves lysine binding

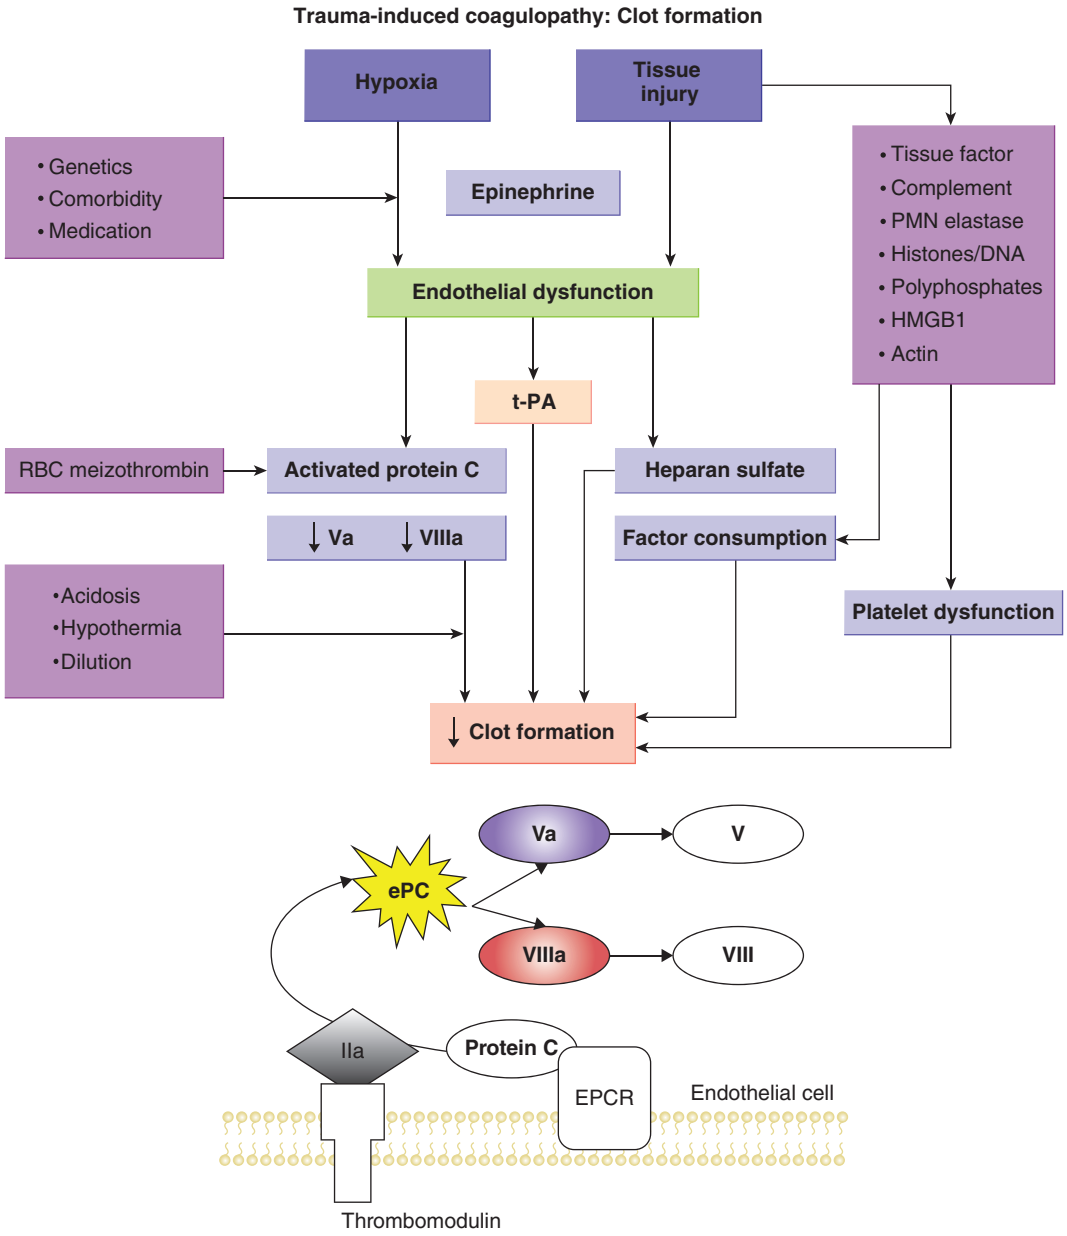

FIGURE 16-3 Ineffective clot formation is the dominant manifestation of trauma-induced coagulopathy. Hypoxia and tissue injury provoke endothelial dysfunction, which activates protein C and releases anticoagulants from the glycocalyx. Platelet dysfunction, factor consumption, and acidosis further impair thrombin generations and clot formation. EPCR, endothelial cell protein C receptor; PMN, neutrophil; t-PA, tissue plasminogen activator.

sites on fibrinogen, inhibiting plasminogen and t-PA binding. Plasma can buffer the effects of t-PA in vivo,[72] and in vitro exogenous t-PA mixed in whole blood of healthy volunteers requires supraphysiologic concentrations to reproduce hyperfibrinolysis. While fibrinolysis is constitutively occurring at a microvascular level to maintain vascular patency, pathologic systemic hyperfibrinolysis is the result of both an increase in circulating t-PA and a reduction of its circulating inhibitors. Fibrinolysis shutdown is associated with a fivefold increase in mortality in trauma patients lacking hypersensitivity to tissue t-PA.[73]

Interest in fibrinolysis as a component of TIC was stimulated by the proposal of Brohi et al,[60] who suggested APC degraded PAI-1. However, recognition of systemic fibrinolysis following injury did not occur until the widespread use of viscoelastic assays. Recent clinical studies indicate that systemic hyperfibrinolysis occurs in 2% to 5% of critically injured patients and 10% to 15% of those requiring a massive transfusion.[74,75] In our experience, the highest rate of hyperfibrinolysis in trauma occurs in those undergoing emergency department resuscitative thoracotomy. Currently, the only established mechanistic factor for hyperfibrinolysis is inadequate tissue perfusion,

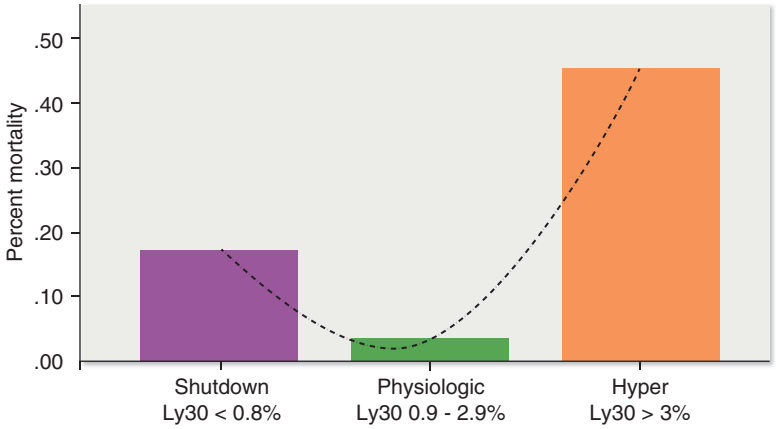

FIGURE 16-4 Systemic fibrinolysis phenotypes. The *y*-axis represents mortality, the *x*-axis is the fibrinolysis phenotype based on the LY30 measured by thromboelastography. There is a U-shaped distribution of mortality, with a nadir evident in the physiologic group. LY30 above (hyperfibrinolysis) and below (fibrinolysis shutdown) this range had increased mortality. (Reproduced with permission from Moore H, Moore E, Gonzalez E, et al. Hyperfibrinolysis, physiologic fibrinolysis, and fibrinolysis shutdown: the spectrum of postinjury fibrinolysis and relevance to antifibrinolytic therapy. *J Trauma Acute Care Surg.* 2014;77:811-817.)

suggested by a number of retrospective studies[63,75] and further strengthened by the fact that the only patients in the CRASH II trial who benefited from antifibrinolytics had a systolic blood pressure of less than 75 mm Hg.[76] Supporting this observation is that blood taken from patients who have nontraumatic cardiac arrest has a high prevalence of hyperfibrinolysis.[77] Shock may also generate metabolic disturbances that enhance fibrinolysis. For example, taurocholic acid increases fibrinolysis in vitro and is markedly elevated following shock.[78] Recent animal work indicates that t-PA levels increase substantially in animals undergoing hemorrhagic shock, whereas tissue injury does not increase systemic t-PA levels.[79]

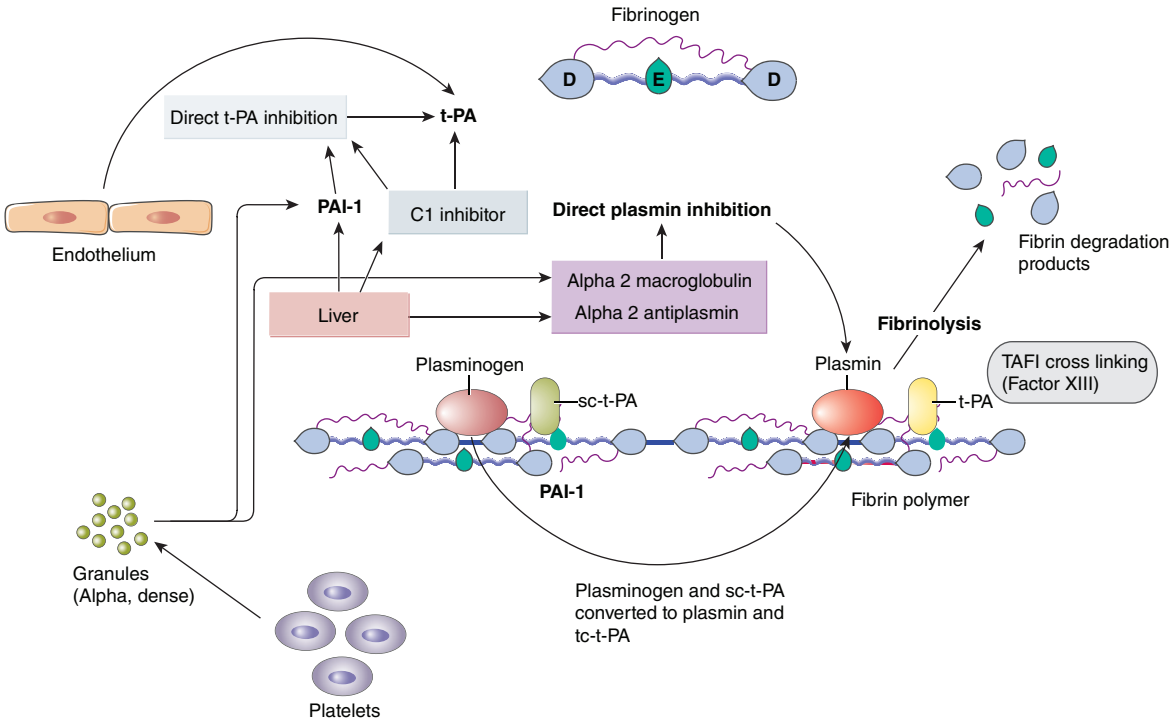

FIGURE 16-5 Fibrinolysis regulation. Systemic fibrinolysis is controlled conceptually at three levels. The first is direct inhibition of the predominant plasminogen activator, tissue plasminogen activator (t-PA). The major inhibitor is the serine protease plasminogen activator inhibitor 1 (PAI-1). The next is direct inhibition of plasmin, with antiplasmin the major circulating factor. The third is access to fibrin for degradation via factors that stabilize the clot (factor XIIIa) or prevent plasmin binding to fibrin (thrombin-activatable fibrinolysis inhibitor [TAFI]). (Reproduced with permission from Moore H, Moore E, Gonzalez E, et al. Postinjury fibrinolysis shutdown: rationale for selective tranexamic acid. *J Trauma Acute Care Surg.* 2015;78:S65-S69.)

FIBRINOLYSIS SHUTDOWN

The mortality rate of injured patients with impaired fibrinolysis (shutdown) has been reported to be nearly four times greater than that of patients with a physiologic level of fibrinolysis.[63] Death is primarily from organ failure, attributed to microvascular fibrin deposition. The term *fibrinolysis shutdown* was first used in 1969[80] in a review describing the effects of electroplexy, myocardial infarction, and elective surgery on fibrinolysis, but was originally described by Innes and Sevitt in 1964.[81] Animal work prior to this time suggested microemboli in visceral small vessels led to irreversible shock that was later found to be survivable with a profibrinolytic.[82] Hardaway et al[83] further translated these findings to humans and implicated trauma and shock in producing microvascular occlusion. Confusion arises as the nomenclature of describing impaired removal of vascular thrombi is often referred to as either the syndrome of DIC or pathologic impairment of fibrinolysis (shutdown). As mentioned previously, some investigators consider DIC to have two distinct phenotypes; that is, hyperfibrinolysis and fibrinolysis shutdown,[44] which is somewhat difficult to reconcile because diffuse intravascular thrombus should not exist in the presence of systemic hyperfibrinolysis.

It is well known that trauma patients are prone to thrombotic events. The prevalence has been reported to approach 60% with Duplex screening for postinjury venous thrombosis.[84] There is evidence for thrombosis in the pulmonary vasculature in nearly one in four seriously injured patients within 48 hours of their injury.[85] Furthermore, microvascular clot has been implicated in organ dysfunction.[86] Therefore, it is intuitive that maintaining adequate fibrinolysis to clear the microvasculature of excessive fibrin deposition would be beneficial.

In 1991, Enderson et al[87] described that the majority of multisystem trauma patients in their study had elevated D-dimers but low fibrinolytic activity. Subsequently, Raza et al[88] showed minimal fibrinolysis activity measured by rotational thromboelastometry (ROTEM) and high plasmin-antiplasmin (PAP) complexes in 57% of their patients. It is important to recognize the circulating half-life of PAP and D-dimer exceed 12 hours.[89] Raza et al[88] misinterpreted their data to question the validity of viscoelastic test for fibrinolysis, which the London group appears to remain confused about,[90] as they propose elevated D-dimer levels as evidence of active "occult fibrinolysis." Although D-dimer and PAP levels after injury correlate to poor outcomes, it is important to remember that these are measurements of what has occurred over the past 12 hours in the patient, and at one point the fibrinolytic system was activated, but a one-time plasma level does not accurately reflect the patient's current systemic fibrinolytic activity.

The seemingly paradoxical condition of elevated PAP or D-dimer levels has also been described in the United States[91] and Canada.[92] These patients have elevated mortality that occurs days after injury,[90,91] but they require early blood product resuscitation,[91] indicating that fibrinolysis shutdown is not a universally hypercoagulable state. In contrast, patients who manifest hyperfibrinolysis require significantly more blood products, and the majority of deaths occur within 24 hours of admissions.[90] Recent evidence supports that trauma patients with low fibrinolytic activity on presentation to the hospital classified as fibrinolysis shutdown can be stratified into subphenotypes.[73] One subphenotype has elevated D-dimer levels and can harbor additional coagulation derangements that can cause bleeding, whereas the other subphenotype has minimal bleeding and delayed mortality from head injury. Regardless of the subphenotype of shutdown, antifibrinolytic use has not been shown to improve clot strength when tested ex vivo.[93]

The transition from a wide range of fibrinolysis activity to fibrinolysis resistance within hours of injury has been observed for several decades[81,94] and further verified within the past 5 years.[95] These transitions make research and treatment challenging, as patients can shift between different states of fibrinolytic activity from injury through resuscitation. Although single blood draws can capture ephemeral fibrinolytic states, delays from injury to blood sampling increase the probability of detecting low fibrinolytic activity by viscoelastic hemostatic assay. This is evident in several studies where prevalence of shutdown ranges from 22% with field draws[73] to 58% with samples from the first 2 hours[90,96] to as high as 65% when the first sample is obtained up to 12 hours from injury.[63] Comparing similar patient populations at similar times from injury is essential for advancing our understanding of fibrinolysis following injury. It is likely that a significant number of patients in the reports by Moore et al,[63] Meizoso et al,[96] and Gall et al[90] were misclassified as being in acute shutdown due to the timing from injury to blood draw as samples obtained within an hour of injury indicate that the prevalence is 20% to 40%.[92,97-99]

Decades of research have demonstrated a transition to fibrinolysis resistance (not necessarily shutdown) several hours after injury or elective surgery,[80,81,94,100,101] which is thought to be an acute phase response via PAI-1 upregulation.[94] In a study of hyperfibrinolytic trauma patients who did not receive antifibrinolytics, fibrinolysis was significantly inhibited within 4 hours of injury, correlating to a several thousand–fold PAI-1 upregulation during this time frame.[95] With an endogenous transition to increased fibrinolysis resistance with PAI-1 production following resuscitation, differentiating pathologic early fibrinolysis shutdown from a physiologic acquired shutdown becomes difficult. Tissue injury appears to play a role in impairing fibrinolysis in animal models,[79,102,103] which is consistent with the association of blunt injuries with acute shutdown.[98] This endogenous impairment of fibrinolysis followed by a PAI-1 surge after resuscitation could be responsible for persistent shutdown.

The duration of shutdown following resuscitation may be the critical insult leading to organ injury and thrombotic complications. Specifically, fibrinolysis activation followed by a delayed upregulation of inhibitors would be an expected physiologic response to prevent excessive bleeding but at the cost of increased thrombotic risks. Although upregulation of inhibitors after activation is appreciated in thrombolytic

therapy, PAI-1 levels become upregulated in the post-lytic period.[104] This elevation of PAI-1 after reperfusion is presumably a physiologic response, since the prevalence of low fibrinolytic activity between 4 and 6 hours after injury exceeds 80%, yet only patients with persistently low fibrinolysis at 24 hours from injury have adverse outcomes.[95] A study from Miami suggests an eightfold mortality increase in trauma patients who retain low fibrinolytic activity for 7 days following injury compared to patients who recover from shutdown.[97] Similarly, persistent fibrinolysis shutdown following resuscitation has also been associated with adverse outcomes in pediatric trauma patients.[105] The mechanism for persistent fibrinolysis shutdown is presumed to be related to PAI-1. Prospective observation data in patients with sepsis show improved survival with recovery of fibrinolytic activity associated with decreases in PAI-1 levels.[106]

In sum, enhanced clot degradation (hyperfibrinolysis) (Fig. 16-6) can be a major component of bleeding in TIC, but the incidence is relatively low. On the other hand, impaired fibrinolysis (shutdown) is present in the majority of severely injured patients and may result in microvascular occlusion and organ dysfunction.

Platelet Dysfunction (Part III)

PLATELET ROLE IN HEMOSTASIS

Platelets are anucleated cell fragments from megakaryocytes (MKs). Maturation of platelets occurs in two phases.[107] The first phase is MK maturation in the bone marrow that takes several days. In the second phase, mature MKs grow pedicles that project into the sinusoids of bone marrow blood vessels and fragment into circulation as platelets, a process that only requires several hours. The circulating count of platelets in normal subjects is around 250,000/mcL with a half-life of 9 days, representing a turnover rate of 35,000 platelets per day.

Successful hemostasis requires the rapid accumulation of platelets to occlude the site of blood extravasation (Fig. 16-7). In animal models, platelets can seal a small wound in approximately 30 seconds and can form a fibrin-rich core within minutes.[108] Contracted platelets free of fibrin have decreased permeability. This work suggests that activated platelets serve as the primary sealant, with fibrin acting as a secondary stabilization of the platelet plug. In addition, platelets form a complex around fibrin clots that provides a unique microenvironment that is both prothrombotic and antifibrinolytic.[109] Furthermore, platelets have multiple roles in initiating and maintaining hemostasis due to their myriad of receptors and complex granule contents. The interplay of platelet auto and paracrine signaling from release of granules and the local environment optimize clot formation and resist degradation.

Effects of Trauma on Platelet Dysfunction

Endogenous activators of platelets have been well characterized in both the arterial and venous systems, with a focus on collagen and thrombin in the inner core of a platelet hemostatic plug and platelet-released ADP and thromboxane for

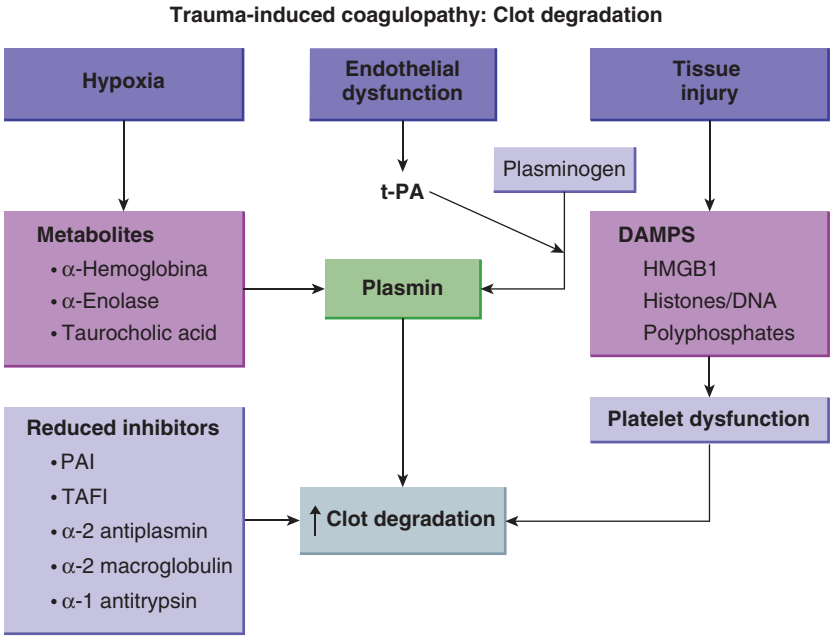

FIGURE 16-6 Clot degradation. Degradation of the clot is an important component of trauma-induced coagulopathy in some patients, particularly those with hypoperfusion. Degradation is primarily via the action of plasmin on fibrin, although platelet dysfunction can contribute to clot instability. The mechanisms responsible for postinjury fibrinolysis are complex and include the depletion of circulating antifibrinolytic agents. DAMPs, damage-associated molecule patterns; PAI-1, plasminogen activator inhibitor 1; TAFI, thrombin-activatable fibrinolysis inhibitor; t-PA, tissue plasminogen activator.

the outer core. However, the precise roles of these platelet activation pathways during TIC are not well defined. Interestingly, the TIC patient is more likely to display platelet dysfunction as opposed to platelet consumption.[110,111] Platelet dysfunction occurs early after injury and has been documented with isolated traumatic brain injury.[112] In the context of TIC, the molecular definitions of the desensitized, stunned, inactive, postactivated, dysfunctional, degranulated, exhausted, or zombie platelets are still emerging. For example, DAMPs have been shown to bind the toll-like 4 (TL4) receptor of platelets, leading to platelet dysfunction–related coagulopathy.[113] Circulating platelets may experience combinations or sequential exposures of agonists to trigger modes of activation as indicated by shape change, degranulation, and receptor expression, activation, or shedding.[114] As mentioned earlier, the optimal timing of platelet transfusion in the severely injured patient remains unclear as platelets may be rendered dysfunctional in a metabolically suboptimal environment. Furthermore, unnecessary platelet transfusion may result in adverse consequences.

COAGULATION ASSESSMENT

Traditional Laboratory Tests

Lack of an accurate tool to identify and track coagulopathy remains a major limitation surrounding both postinjury hemostatic derangements and empiric blood component replacement therapy. Traditional laboratory tests of coagulation function, such as PT and partial thromboplastin time (PTT), are plasma based and designed originally for the assessment of coagulation function with isolated factor deficiencies in hemophiliacs and, later, for the effects of warfarin. To date, the performance characteristics of these tests in the trauma patient are questionable, and they do not appear to represent clotting factor deficiency.[115]

Furthermore, because both the PT and PTT are performed on platelet-poor plasma, they are sensitive only to the earliest initiation of clot formation (estimated to represent 5% of the thrombin generation during clot formation) and do not incorporate cellular contributions, including platelets, red cells, and neutrophils. Finally, these tests are performed in an artificial environment, irrespective of the patient's core body temperature and pH. Measurements of individual pro- and anticoagulant factors, such as protein C, are both costly and time consuming. Diagnosis of fibrinolysis is also problematic. The euglobulin lysis time is a complex and time-consuming procedure that requires more than 180 minutes, reduces some of the inhibitors, and does not include platelets that regulate fibrinolysis. Other techniques suggested to identify hyperfibrinolysis, such as plasmin–antiplasmin complex, fibrin monomers, and D-dimers, are only reflective of the footprint of fibrinolysis; that is, due to their prolonged half-lives, they do not represent the patient's current systemic fibrinolytic activity.[89] Thus, partitioning the components of a patient's blood and testing them independently in an artificial environment that requires a lengthy assay time is not clinically optimal to manage coagulopathy in the critically injured patient.

Viscoelastic Hemostatic Assays

In response to the shortcomings of conventional measurements of coagulopathy, point-of-care, viscoelastic, hemostatic assays are emerging as the standard of care for both the diagnosis and treatment of postinjury coagulopathy in many trauma centers throughout the world. Viscoelastic assays quantify whole blood clot formation and degradation based on the resistance created by liquid blood solidifying and degrading after reaching maximum strength. The time and rate to achieve output of the device correlate with coagulation factor status, fibrinogen function, and platelet function and quantify fibrinolysis. Interpretation of the two most clinically employed viscoelastic assays is described in the following discussion.

THROMBOELASTOGRAPHY

The various components of the thromboelastography (TEG) tracing are depicted in Fig. 16-8, and the viscoelastic output measured by TEG is summarized in Table 16-2. The rapid TEG is designed to provide the quickest results by using both extrinsic (tissue factor) and intrinsic (kaolin) pathway activators. The downside of maximizing clot initiation is the resulting amplification of the coagulation system, which may mask

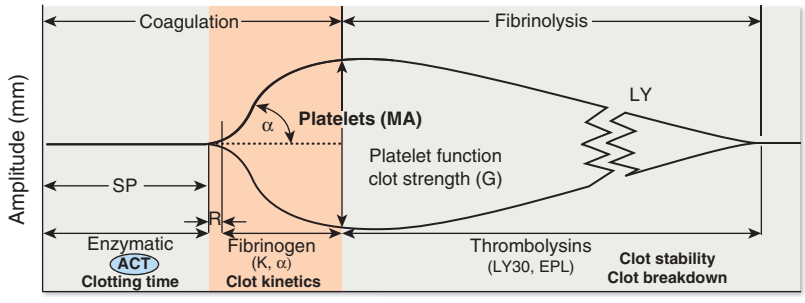

FIGURE 16-8 Thromboelastography (TEG). The TEG tracing depicts the temporal phases of clot assembly: ACT (activated clotting) represents the enzymatic component (initiation), α (angle) reflects fibrin crosslinking (propagation), and MA (maximum amplitude) is the final clot strength resulting from fibrin and platelet interaction (amplifications). Clot dissolution is quantified by LY30, which is percent lysis at 30 minutes following time of MA. EPL, estimated percent lysis.

TABLE 16-2: TEG Parameters

Parameter	Significance
SP time	Earliest activity of enzymatic factors, causing tracing to split
R time	Initiation phase of enzymatic factor activity
K time	Potentiation phase of enzymatic factors yielding clot strengthening
Alpha-angle	Rate of clot strengthening through polymerization of available fibrinogen
MA	Platelet functional contribution to clot strength through IIb–IIIa receptor interaction with fibrin
G	Overall total clot strength resulting from all coagulation interactions, calculated from amplitude (*A*), $G = (5000 \times A)/(100 \times A)$
EPL	Fibrinolytic activity, derived from percent decrease in clot strength after MA is reached

Alpha-angle, degrees; EPL, estimated percent lysis, %; *G*, clot strength, dynes/cm^2; *K*, coagulation time, minutes; MA, maximum amplitude, millimeters; *R*, reaction time, minutes; SP, split point, minutes.

more subtle changes in coagulation, particularly in the hypercoagulable setting or when quantifying fibrinolysis. Kaolin activation is used for the later indications. A native TEG is performed without activators for subtle changes in the coagulation system and is primarily used for research. The reaction time (*R*, minutes) is defined as the time elapsed from the initiation of the test to the point where the onset of clotting provides enough resistance to produce a 2-mm amplitude reading on the TEG tracing.[116] Of note, in the R-TEG assay (discussed later), due to the acceleration of clotting initiation, the *R* time is represented by a TEG-derived activated clotting time (TEG-ACT). The *R* time and TEG-ACT are most representative of the initiation phase of clotting due to enzymatic factors. A prolonged *R* time or TEG-ACT is diagnostic of hypocoagulability, whereas shortened times suggest hypercoagulability. The alpha-angle (α, degrees) is the angle formed by the slope of a tangent line traced from the *R* to the time required to reach 20-mm amplitude (*K* time) measured in degrees. Alpha-angle represents the rate at which the clot strengthens and is most representative of thrombin's cleavage of available fibrinogen into fibrin. The maximum amplitude (MA, mm) is the point at which clot strength reaches its maximum on the TEG tracing, reflects the end result of maximal platelet–fibrin interaction, and is often used to guide platelet transfusions. The LY30 variable represents the percentage of clot degradation 30 minutes after the clot reaches MA and is used to quantify fibrinolysis. The functional fibrinogen (FF-TEG) assay is a more specific method to quantify fibrinogen contribution to clot strength and is performed by using a monoclonal antibody to glycoprotein IIb–IIIa to eliminate the contribution of platelets to clot formation.[117] One of the limitations of the viscoelastic assay is the generation of abundant thrombin, which masks the effects of antiplatelet therapy or potential platelet dysfunction by activating platelets via the robust protease activating receptors (PAR) 1 and 4. To quantify platelet dysfunction, a platelet mapping assay (PM-TEG) relies on heparin to eliminate thrombin activation and employs reptilase and factor XIII to cross-link fibrin and, thus, eliminate the fibrin contribution to clot strength. The contribution of the P2Y12 or thromboxane receptors to clot formation is measured by the addition of ADP or arachidonic acid, respectively. There are additional TEG variables that are not routinely used clinically that also provide information on clot strength and fibrinolysis, but at this time, these are mostly used in experimental work.

ROTEM

ROTEM is the other commonly employed viscoelastic assay[118] and is based on the same fundamental principles as TEG. Consequently, the graphical output appears similar to that obtained with TEG (Fig. 16-9). In the TEG system,

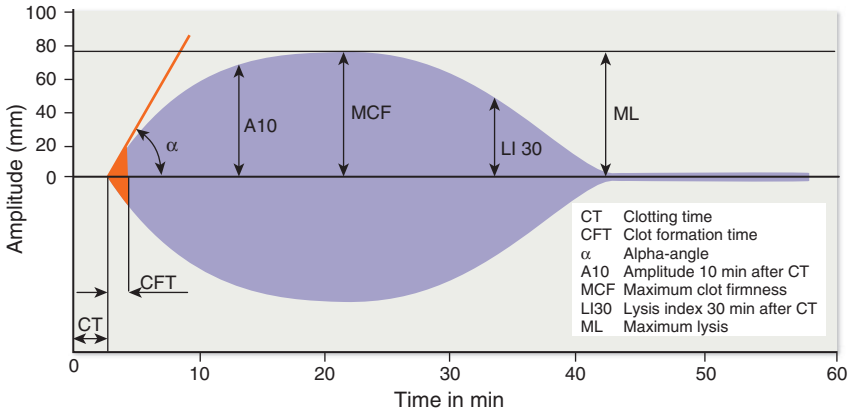

FIGURE 16-9 Rotational thromboelastometry (ROTEM). The ROTEM tracing depicts the temporal phases of clot assembly: CT (clotting time) represents the enzymatic component (initiation), α (angle) reflects fibrin crosslinking (propagation), MCF (maximum clot firmness) is the final clot strength resulting from fibrin and platelet interaction (amplification). Clot dissolution is quantified by CL30, which is percent clot lysis at 30 minutes following initiation of clot formation.

the sample cup oscillates and a pin on a torsion wire is suspended in the blood sample. In the ROTEM system, the sample cup remains fixed while the pin oscillates. ROTEM and TEG provide essentially the same information on clot formation kinetics and strength (Table 16-2). EXTEM is activated with tissue factor (external) and INTEM with ellagic acid (internal). FIBTEM is a modified EXTEM with the added platelet inhibitor cytoclasin D to provide an estimate of functional fibrinogen,[119] and APTEM is a modified EXTEM with the addition of tranexamic acid (TXA) to guide antifibrinolytic therapy. The NATEM is recalcified without activators. Another assay, approved in Europe, is ECATEM using the viper venom ecarin (prothrombin activator) to measure the effect of direct thrombin inhibitors. Because of differences in operating characteristics, the results of ROTEM and TEG are not interchangeable. Furthermore, the two tests use different nomenclature to describe the same variables, although the sensitivity of TEG and ROTEM variables to detect coagulopathy is comparable.[120] Limits of agreement between TEG and ROTEM variables from multiple institutions have been reported. However, newer generation TEG and ROTEM devices, currently undergoing clinical validation for US Food and Drug Administration (FDA) approval, are operator-independent, vibration-resistant, and smaller devices. Thus, these devices facilitate point-of-care capabilities, including prehospital use.

Clinical Implementation of Viscoelastic Hemostatic Assays

A recent prospective randomized trial has shown that viscoelastic assays are superior compared to PT/international normalized ratio (INR), activated PTT (aPTT), platelet count, fibrinogen level, and D-dimer for the management of TIC.[121] Furthermore, a retrospective cohort study indicated that viscoelastic assays are better than a fixed ratio (1:1:1) strategy.[122] TEG is also capable of detecting hypercoagulability (increased MA), whereas the PT and aPTT are not.[123] Perhaps the greatest advantage of viscoelastic assays is to individualize management of patients based on their phenotype of TIC. Considering the diverse mechanisms driving TIC (Figs. 16-3 and 16-6), severely injured patients manifest unique patterns of TIC (Fig. 16-4).[61,62] Patients with predominately impaired thrombin generation have a prolonged *R* and low MA. Depressed MA has been associated with an increased risk of bleeding and mortality.[124,125] The ROTEM A5 (5 minutes after clot initiation) and A10 have also been accurate in early identification of patients with advanced TIC.[126]

MANAGEMENT OF TIC

Blood Components

RBC TRANSFUSION

RBC transfusion is lifesaving in the setting of critical anemia associated with hemorrhagic shock. However, the optimal target hematocrit during resuscitation remains unknown (see Chapter 15). Elimination of oxygen debt involves optimization of oxygen delivery, which is the product of cardiac output and arterial oxygen content. The arterial oxygen content, in turn, is dependent primarily on the hemoglobin concentration and oxygen saturation. During resuscitation, a balance must occur between the competing goals of maximal oxygen content (hematocrit = 100%) and minimal blood viscosity (hematocrit = 0%). Furthermore, beyond a role in oxygen delivery, erythrocytes are integral to hemostasis via their involvement in platelet function as well as thrombin generation. The hematocrit is thus relevant to hemorrhagic shock as it relates to both oxygen availability and hemostatic integrity. As the hematocrit rises, platelets are displaced laterally toward the vessel wall, placing them in contact with the injured endothelium; this phenomenon is referred to as margination. Platelet adhesion via margination appears optimal at a hematocrit of 40%.[127] Erythrocytes are also involved in the biochemical and functional responsiveness of activated platelets. Furthermore, RBCs participate in thrombin generation through exposure of procoagulant phospholipids and generation of meizothrombin.[34] Interestingly, animal studies suggest that a decrease of the platelet count of 50,000 is compensated for by a 10% increase in hematocrit.[128] At this point, we continue to target a hemoglobin of greater than 10 g during hemorrhage control.[129]

PLASMA TRANSFUSION

As discussed previously, the role of preemptive plasma transfusion was introduced in the late 1970s to manage coagulopathy associated with major liver injuries.[19,130] Several decades later, Borgman et al[27] evaluated the military data and identified that a high ratio of plasma to RBCs has a survival advantage. This report prompted ongoing debate in the civilian setting in regard to the optimal empiric ratios of plasma to RBC.[131] Plasma is obtained via whole blood centrifugation or apheresis. Despite plasma's acellular composition, this blood product contains hundreds of biologically active proteins that have considerable variability between individuals.[132] Although blood banks have minimal requirements for concentrations of certain coagulation factors, it is becoming clear that not all plasma is the same. AB plasma is the universal donor, but it is limited in supply because less than 2% of the population qualify as donors. Appreciation of the calcium binding capacity due to citrate in stored plasma is essential to prevent iatrogenic hypocalcemia, which exacerbates coagulopathy. Pooled plasma with pathogen reduction, such as Octaplas and Uniplas, may have a role in early plasma resuscitation in trauma patients because they have a more standardized composition and do not require the calcium-chelating anticoagulant citrate.[133]

Plasma containing the highest concentration of coagulation factors is currently FFP that represents plasma frozen at –18°C within 8 hours of blood draw. Alternatively, plasma can be frozen within 24 hours, termed FP24, which has a small reduction in coagulation factors. Frozen plasma

requires 20 to 40 minutes to thaw prior to transfusion by conventional devices. For this reason, many trauma centers have prethawed plasma available in the emergency department. Thawed FFP is required to be transfused within 24 hours or becomes relabeled as thawed plasma. Thawed plasma can be stored at 4°C for up to 5 days and can be useful in the setting of trauma resuscitations. Thawed plasma retains many functioning proteins but is depleted of the more labile factors V, VII, and VIII.[134] In plasma resuscitation, it is important to appreciate that patients are receiving more than just coagulation factors. Plasma contains abundant proteins with diverse regulatory functions related to inflammation, coagulation, and fibrinolysis, in addition to being an effective colloid. The levels of these proteins have high variability person to person and between sexes.[132] Plasma-first resuscitation in animal models has been shown to repair the endothelium,[135] improve platelet function,[136] and attenuate fibrinolysis.[72]

Animal, in vitro, and retrospective clinical data have been supportive of using plasma for prehospital resuscitation, which has been confirmed by the recently completed Prehospital Air Medical Plasma (PAMPer) trial.[137] This randomized clinical study allocated patients to standard of care (crystalloid) prehospital helicopter resuscitation versus 2 units of plasma. The overall mortality was reduced by nearly 10% in the plasma arm of the study. Although these results were encouraging for adopting plasma's role in early prehospital resuscitation, the same benefit in mortality was not appreciated in an urban ambulance study, the Control of Major Bleeding After Trauma (COMBAT) trial.[138] Major differences in these trials included a higher rate of penetrating trauma in the COMBAT study and much shorter transport times compared to PAMPer. Thus, the patients who appear to benefit the most from prehospital plasma resuscitation are patients with blunt injury and greater than 40 minutes of transport time. Both of these studies provide critical data on the evolving role of plasma in the resuscitation of trauma patients; we originally believed that every patient benefited from early plasma, but in reality, clotting factor deficiency may not be the critical factor driving TIC. Perhaps plasma is more important for volume restoration, minimizing the duration of shock during transport. Ongoing research is needed to identify a more defined role of plasma in the prehospital setting, in addition to cost and potential complications. The prohibitive logistics of thawing plasma for ground transportation, however, have now been resolved with the availability of lyophilized plasma.

CRYOPRECIPITATE/FIBRINOGEN REPLACEMENT

Fibrinogen levels are decreased early after injury in coagulopathic trauma patients (<1.5 g/L in 15%, <1.0 g/L in 5%, and <0.5 g/L in 2%). Although plasma units contain fibrinogen, the low concentration requires a large volume of transfusion; hence, cryoprecipitate has remained the main source of fibrinogen supplementation in the United States. Cryoprecipitate also contains factor VIII, von Willebrand factor, fibronectin, factor XIII, and platelet microparticles, which may all be important in hemostasis. The European experience suggests recombinant fibrinogen concentrate is effective in the management of TIC. Each 10-unit pool of fibrinogen contains approximately 5 g of fibrinogen or a median 500 mg per unit. Most trauma centers administer fibrinogen dosed by 10-unit pools (one fibrinogen "pack" = 10 pooled units). A 10-pooled unit of fibrinogen transfusion is expected to increase fibrinogen by 0.5 to 0.9 g/L; however, dose response varies in the setting of ongoing bleeding and may require redosing. Several retrospective studies in trauma patients, civilian and military, suggest that more aggressive use of fibrinogen replacement improves outcome.[139,140] Consensus guidelines recommend a fibrinogen threshold of greater than 1.5 to 2.0 g/L for transfusing for hemostasis.[141] Recent studies using a viscoelastic assay to administer cryoprecipitate as part of a goal-directed transfusion strategy use the alpha-angle or FF assay of TEG or FIBTEM of ROTEM as a trigger for transfusion. Randomized clinical trials are underway to evaluate the impact of empiric cryoprecipitate administration on outcomes in patients requiring massive transfusion, as well as prehospital administration of cryoprecipitate. Label indications for recombinant fibrinogen concentrate use in Europe allow for its use in both congenital and acquired coagulopathies (eg, TIC); however, in the United States, its use is restricted to congenital coagulopathies. On the other hand, cryoprecipitate has been removed from most blood banks in Europe due to transfusion-related infectious concerns given that transfusion of one dose (or "pack") of cryoprecipitate exposes the patient to 10 random donors, hence the surge in use of fibrinogen concentrate in Europe. To date, retrospective reviews of the use of fibrinogen concentrate in trauma patients suggest it has been associated with reduced blood product requirement, but no conclusions can be drawn for the impact on mortality.

PLATELET TRANSFUSION

Before the development of platelet concentrates in the second half of the 20th century, platelets were administered through whole blood transfusion. When blood component therapy became the standard, transfusion of platelets focused on treating thrombocytopenia; in trauma, this was often the result of dilution from crystalloid and RBC transfusion. But platelet dysfunction has been shown to occur following injury despite platelet numbers exceeding these traditional threshold levels.[110-112] The strategy of early transfusion of hemostatic blood components has improved outcomes after injury; however, whether this is due to the early administration of platelets or of plasma is difficult to distinguish. Perkins et al[142] reported that platelet administration was independently associated with survival in combat casualties. In a review of civilian trauma patients requiring transfusion of 5 or more RBC units in 24 hours, Brasel et al[143] reported that a higher ratio of platelets to RBC (≥1:2) units was independently associated with improved 30-day survival among patients with traumatic brain injury, whereas a higher ratio of plasma to RBC (≥1:2) units was independently associated with improved 30-day survival only in non–traumatic brain injury patients. On the other hand, more recent data suggest

that presumptive platelet administration does not improve outcome for patients with blunt traumatic brain injury.[144] Holcomb et al[145] reported that in civilian trauma patients transfused 10 or more RBC units in 24 hours, using a time-dependent analysis of survival, a higher plasma:platelet:RBC unit ratio (≥1:1:2) was associated with improved survival, compared to lower ratios. However, survival was not significantly different between patients with lower plasma but higher platelet to RBC unit ratio and higher plasma but lower platelet to RBC unit ratio. A drawback of these retrospective studies is that the collinearity between plasma and platelet ratios obscures the relative contribution of each component to patient outcomes. This is further compounded by the fact that all platelet concentrates are suspended in plasma; for apheresis platelets, each unit contains 1 unit of plasma. The recent multicenter, randomized, controlled PROPPR (Pragmatic, Randomized, Optimal Platelet and Plasma Ratios) trial to assess the impact on survival of 1:1 versus 1:2 FFP:RBC did not show a survival benefit for a higher ratio of platelets to RBCs.[146] Perhaps one of the reasons for conflicting results is the timing of platelet administration. Previous experimental work indicates that platelets given to acidotic animals are irreversibly impaired.[56] Furthermore, a recent multicenter trial of patients with cerebral hemorrhage indicated increased mortality with preemptive platelet transfusion (ie, the Platelet Transfusion Versus Standard Care After Stroke due to Spontaneous Cerebral Haemorrhage Associated With Antiplatelet Therapy [PATCH] trial, a recently completed multinational study). Finally, to add to the confusion, there is evidence that cold stored platelets may be superior for reversing coagulopathy.[147]

Warm Fresh Whole Blood

After the introduction of whole blood fractionation into blood components for clinical use in the late 1970s, several civilian trauma centers continued to transfuse warm fresh whole blood for severely injured patients with a refractory coagulopathy.[19] This concept was resurrected in the recent military conflict in Iraq, where plasma and platelets were not immediately available.[148] The concept of fresh whole blood transfusion is becoming the international standard for far-forward care,[149] and the reported experience has prompted its reconsideration in the civilian setting.

Low Titer O-Negative Whole Blood

The success with fresh whole blood in the military setting has rejuvenated interest in the administration of stored low titer O-negative whole blood (LTOWB) for civilian use. The American Association for Blood Banking approved LTOWB for civilian trauma use in 2018, and a number of trials are underway to determine its optimal application.[150]

PROTHROMBIN COMPLEX CONCENTRATE

Prothrombin complex concentrate (PCC) contains the vitamin K–dependent coagulation factors II, VII, IX, and X, as well as the anticoagulants protein C and protein S. As such, its main indication is for rapid reversal of the anticoagulant effects of warfarin in bleeding patients. Importantly, PCC provides these factors in a concentrated form as compared to FFP (approximately 50 mL vs 300 mL, respectively). The efficacy of PCC for urgent reversal of warfarin in the perioperative period has been well documented,[151] and use in this setting has been recommended by expert panels in the United States and Europe. The role of PCC in the bleeding patient not on anticoagulants continues to be studied. Bruce and Nokes[152] reported favorable outcomes following PCC administration for uncontrolled hemorrhage after cardiac surgery, exclusive of warfarin use. Several animal studies of hemodilutional coagulopathy have reported superior achievement of hemostatic resuscitation using PCC as compared to FFP.[153] Although the reduced time and volume necessary to achieve coagulation factor replacement are appealing, transfusion of PCC represents only a limited number of coagulation proteins and likely carries the same immunomodulatory risks as those of FFP. Controlled trials in injured patients are necessary to define recommendations.[154]

RECOMBINANT FACTOR VIIA

Treatment of postinjury coagulopathy with supraphysiologic doses of recombinant factor VIIa (rVIIa) was proposed to amplify coagulation through generation of a thrombin burst in the presence of both tissue factor and functional platelets and in the absence of either hypothermia or acidosis. Due to continued concerns over efficacy, thrombotic risk, and cost, two parallel randomized controlled trials, one of penetrating and one of blunt trauma patients, were conducted among 32 international institutions (exclusive of the United States) from 2003 to 2004.[155] Eligibility criterion was transfusion of 6 or more units of RBCs in 4 hours. Subjects were randomized to receive either placebo or three doses of rVIIa (200, 100, and 100 mcg/kg), with the first dose given after the eighth unit of RBC was transfused. A reduction in RBC transfusion requirement for both blunt (median 7.0 vs 7.5) and penetrating (3.9 vs 4.2) groups was observed among those alive 48 hours after the first dose of the study drug. However, these relatively small differences were eliminated when the analysis was expanded to include patients who had died within the first 48 hours of injury. In another multicenter trial of rVIIa in trauma, including the United States, there was also no evidence of significant clinical benefit.[156] Thus, the role for rVIIa in trauma care is considered limited. If rVIIa therapy is contemplated, several pharmacokinetic properties of the drug warrant consideration. The activity of rVIIa is both pH and temperature dependent, with a 60% decrement at a pH of 7.20 and a 20% decrement at a temperature less than 34°C.[55] Furthermore, physiologic concentrations of calcium, fibrinogen, and platelets are required, such that replacement of these clotting factors is essential prior to rVIIa administration. Dosages range from 50 to 200 mcg/kg, with redosing recommended for continued coagulopathy beyond the half-life of 2 hours.

FACTOR XIIIA

Factor XIII acts to stabilize the fibrin clot once formed, and a relationship between XIII concentration and maximal clot firmness has been demonstrated experimentally.[157] Early depletion of the limited endogenous XIII stores has been documented following major hemorrhage and is believed to contribute to coagulopathy.[158] Although prospective data are lacking, recombinant factor XIIIa should be considered for postinjury coagulopathy that is refractory to conventional factor replacement therapy. As discussed previously, factor XIII is abundant in cryoprecipitate.

ANTIFIBRINOLYTICS

The role of antifibrinolytics in trauma remains controversial and has been fueled by the recognition that the majority of severely injured patients manifest fibrinolysis shutdown.[98] Antifibrinolytic agents include the lysine analogue inhibitors of plasminogen binding to fibrin, aminocaproic acid (Amicar) (dosing, 150 mg/kg, followed by 15 mg/kg/h) and TXA (dosing, 10 mg/kg, followed by 1 mg/kg/h), as well as the direct plasmin inhibitor aprotinin (dosing, 280 mg, followed by 70 mg/h). In addition to its effect on plasmin, aprotinin also inhibits kallikrein, factor XIIa, and trypsin. Aprotinin, however, is not currently approved in the United States due to increased mortality in a randomized trial during cardiac surgery.[159] The CRASH II trial suggested improvement in survival with TXA,[76] but this trial has many limitations,[160] particularly when applied to care at US Level I trauma centers. Furthermore, there is compelling investigative work suggesting that indiscriminate use of antifibrinolytics can have adverse effects.[161] Retrospective studies in civilian centers in the United States have failed to identify a survival advantage,[162] and several studies have suggested increased mortality.[163,164] On the other hand, inhibiting plasminogen activation may have benefits beyond coagulation considering the diverse cellular receptors for plasminogen.[67] There are a number of ongoing randomized trials evaluating the efficacy of TXA in trauma patients that will be completed over the next several years that will better define the role of antifibrinolytics in trauma. The most recent randomized trial evaluating 180 patients with traumatic brain injury identified no survival advantage and a fivefold increased rate of pulmonary embolism in patients who received TXA compared to controls.[165] The same association of no benefit in mortality with TXA and increased thrombotic complications was also appreciated in the most recent military experience.[166]

Resuscitation Strategies for TIC

PREDICTING MASSIVE TRANSFUSION

Massive transfusions require a predetermined plan to rapidly deliver blood products to the exsanguinating patients. One of the major challenges in trauma resuscitation is correctly identifying patients at risk of massive transfusion. Several scoring strategies have been proposed to rank patients at risk of life-threatening hemorrhage. Many of these scores use a combination of physiologic measurements, laboratory values, and physical findings. The Trauma-Associated Severe Hemorrhage (TASH) score was developed from a regression analysis that identified seven independent predictors of massive transfusion in trauma patients based on retrospective data.[167] The score takes into consideration the patient's systolic blood pressure, hemoglobin, focused assessment with sonography in trauma (FAST) examination, pelvic/long-bone fracture, gender, and base deficit. The TASH score has a range from 0 to 28, making it somewhat complex to calculate. The Assessment of Blood Consumption (ABC) score was proposed and was developed as a minimalist score not requiring laboratory values to predict massive transfusions.[168] The ABC score incorporates four variables that are simplified by dichotomous point scoring, rather than ordinal grouping as used in TASH. These include a positive FAST, penetrating mechanism, heart rate >120 bpm, and systolic blood pressure less than 90 mm Hg. In consideration of these scoring systems, the timing of when a decision can be made to activate a massive transfusion is critical. The optimal goal is early communication to the blood bank of the urgent need of a large volume of blood products. The majority of the scoring systems have a high negative predictive value but universally lack a strong positive predictive value, which is likely best determined at this time by experience.[169] Using clinical variables will continue to be problematic due to their dynamic nature, and an objective measure to identify those at risk of massive transfusion is needed. We are optimistic that the t-PA challenge TEG assay may prove to have clinical utility, as results to risk stratify patients for massive transfusion can be obtained within 15 minutes[170] while providing additional information on the patients' coagulation status. Our current massive transfusion protocol using rapid TEG emphasizing goal-directed approach is shown in Fig. 16-10.

HYPOTENSIVE CRYSTALLOID RESUSCITATION

Permissive hypotension was proposed as a deliberate tolerance of lower arterial pressures in the face of uncontrolled hemorrhagic shock in order to minimize further bleeding. This strategy is based on the notion that decreasing perfusion pressure will maximize the body's natural mechanisms for hemostasis, such as arteriolar vasoconstriction, increased blood viscosity, and in situ thrombus formation (see Chapter 15). In the first large-scale trial, Bickell et al[171] randomized patients in hemorrhagic shock (systolic blood pressure [SBP] <90 mm Hg) who had sustained penetrating torso trauma to either crystalloid resuscitation or no resuscitation prior to operative intervention. Mean SBP was significantly decreased on arrival for the delayed resuscitation group as compared to the immediate resuscitation group (72 mm Hg vs 79 mm Hg, respectively, $P = .02$), with a corresponding increase in survival (70% vs 62%, respectively, $P = .04$). A subsequent subgroup analysis, however, indicated that these benefits were limited to patients who had cardiac injury with tamponade. Furthermore, prehospital crystalloid resuscitation in severely injured patients with sustained hypotension appears to be

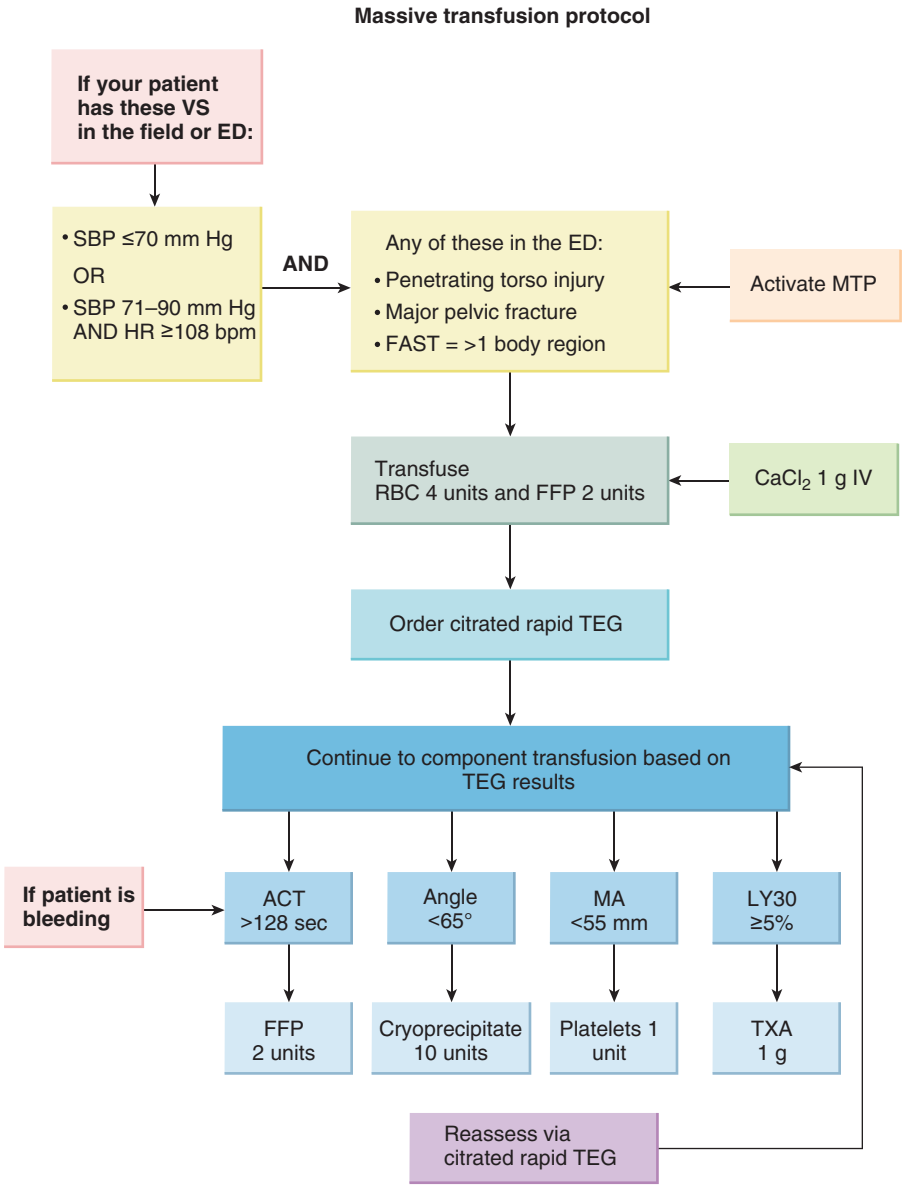

FIGURE 16-10 Massive transfusion protocol (MTP). The Denver Health MTP is primed by the Research Outcomes Consortium (ROC) prehospital physiologic criteria (systolic blood pressure [SBP] ≤70 mm Hg or SBP 71–90 mm Hg and heart rate [HR] >108 bpm) and activated at emergency department (ED) arrival with the anatomic findings of a penetrating torso injury, major pelvic fracture, or a focused assessment with sonography in trauma (FAST) = >1 body region. Upon activation, 1 g of calcium chloride ($CaCl_2$) is administered, and resuscitation is initiated with a fresh frozen plasma (FFP) to red blood cell (RBC) ratio of 1:2. Subsequent blood components are delivered based on thromboelastography measurements. ACT, activated clotting time; IV, intravenous; LY30, percent lysis at 30 minutes; MA, maximum amplitude; TXA, tranexamic acid; VS, vital signs.

beneficial. Brown et al[172] observed a survival benefit with increased crystalloid use in blunt injured trauma patients with prehospital hypotension. Schreiber et al[173] reported a survival advantage using limited crystalloid resuscitation in the prehospital setting in a prospective phase II trial. In this study, patients with an SBP of less than 70 mm Hg were randomized either to resuscitation with a 250-mL bolus of crystalloid with repeated doses to maintain an SBP of greater than 70 mm Hg or palpable radial pulse or to standard care of 2 L. In blunt injury, mortality was reduced from 18% in the standard-of-care group to 3% in the controlled resuscitation group, whereas in penetrating trauma, there was no difference in survival. In considering the dominant factors for TIC, hypoperfusion and associated metabolic acidosis are associated with impaired thrombin generation and hyperfibrinolysis. Overzealous crystalloid dilution dilutes whole blood and results in the depletion of the critical balance of regulatory proteins.[72]

Goal-Directed Management of TIC

Although there is no debate in the United States that early blood component resuscitation is warranted for the severely injured patient at risk, there is substantial debate as how to best deliver the optimal quantity of plasma and platelets; that is, fixed ratios or point-of-care guided resuscitation with clinical assays. The large Prospective, Observational, Multicenter, Major Trauma Transfusion (PROMMTT) trial suggested the beneficial effects of early plasma administration during trauma resuscitation and indicated platelets were given late.[2] These findings were then translated into the multicenter randomized controlled PROPPR trial to assess the impact on survival of 1:1 versus 1:2.[146] The PROPPR study also included a different platelet:RBC transfusion target, which confounded the results. The important finding from this study was that the ratios did not make a difference in the primary study end points of 24-hour or 30-day mortality. However, there have been no randomized trials to address the important issue of fixed-ratio versus goal-directed management, although a retrospective cohort evaluation suggested that TEG-driven resuscitation is superior.[122] Our current TEG-driven protocol[174] is outlined in Fig. 16-10. In the injured patient considered at risk of TIC, a citrated rapid TEG is performed and 1 g of calcium chloride is administered, followed by transfusion of 2 units of FP24 and 4 units of RBCs. Subsequent blood products are delivered based on the initial rapid TEG output, and serial TEG-directed transfusions are continued until hemostasis is achieved. If TEG results are not available after 4 units of RBCs with the first hour, we administer empiric platelets and cryoprecipitate.[175]

Novel Resuscitation Strategies to Mitigate TIC

New resuscitation strategies are continually being developed and tested.[176] The most recent to fail was hypertonic saline, which was ultimately believed to enhance coagulopathy. The most recent promising solution is adenosine-lidocaine-magnesium (ALM). Originally designed for cardioplegia in cardiothoracic surgery based on an induced hibernation state for myocytes, ALM has now been shown to attenuate TIC in experimental models of postinjury shock.[177]ALM fluid therapy attenuates systemic inflammation, platelet dysfunction, and coagulopathy after noncompressible truncal hemorrhage.[178]

MANAGEMENT OF ANTICOAGULATION/ANTIPLATELET THERAPY

Antiplatelet Therapy

Antiplatelet therapy, which consists predominantly of acetylsalicylic acid (ASA) and clopidogrel (P2Y12 inhibitors), has revolutionized the care of patients with atherosclerotic cardiovascular disease. Although via independent mechanisms, both ASA and clopidogrel irreversibly inhibit platelet aggregation. The average lifespan of a platelet is roughly 9 days, and platelet function recovers gradually following cessation of antiplatelet agents, as the bone marrow generates approximately 30,000 platelets per day. Data comparing the incidence of intracerebral hemorrhage (ICH) between patients using antiplatelet therapy and controls are sparse. However, several matched case series of head-injured patients have indicated an increased severity of hemorrhage, as well as mortality, among patients using antiplatelet therapy as compared to controls.[179,180] These reports are limited primarily by confounding comorbidity, as patients using antiplatelet therapies tend to be sicker. Despite an apparent increased morbidity associated with preinjury antiplatelet agents among head-injured patients, little data exist to support routine platelet transfusion in this setting.[144] Prospective randomized data are warranted, preferably incorporating serial platelet functional assessment. These studies are particularly timely as both the elderly demographic and prevalence of antiplatelet therapy are increasing exponentially. Interestingly, the deleterious effects of antiplatelet therapy do not appear to extend to the non–head-injured trauma patient. In a recent report, no mortality difference was noted for patients using antiplatelet therapies as compared to controls among a cohort of trauma patients with no evidence of ICH.[181]

Warfarin

Warfarin is an oral anticoagulant that inhibits synthesis of the vitamin K–dependent clotting factors II, VII, IX, and X, as well as the anticoagulant protein C and protein S. It is the most common drug prescribed to achieve chronic anticoagulation. Several studies have documented an increased likelihood of traumatic ICH, as well as severity of injury and mortality, among trauma patients using warfarin as compared to nonanticoagulated patients. Importantly, the increased likelihood of adverse outcomes is observed only among patients who have achieved therapeutic anticoagulation (INR >2).[182] Rapid identification of patients on therapeutic warfarin and at risk for traumatic ICH is paramount to minimize hemorrhage progression with resultant irreversible neurologic consequences. Most authors advocate empiric transfusion of FFP prior to laboratory documentation of therapeutic anticoagulation. In such patients, it is argued that the morbidity of a delay in reversal of patients with a supratherapeutic INR outweighs that of unnecessary factor administration to patients with a subtherapeutic INR. Although up to one-half of trauma patients on warfarin present with a subtherapeutic INR,[183] the morbidity of an expanding ICH renders this argument reasonable. However, a striking amount of variability exists among trauma surgeons as to the INR above which reversal of anticoagulation should be implemented, the rapidity with which the PT is normalized, or the target INR following reversal. As mentioned previously, reversal of warfarin-induced anticoagulation using PCC may be particularly beneficial in patients at high risk for cardiopulmonary complications secondary to the large-volume plasma administration to correct the INR.[151,153,154] The risk of warfarin anticoagulation in the

non–head-injured trauma patient is less clear. A recent study of blunt injured patients age 60 years or older who sustained trauma to the abdomen or thorax, in the absence of intracranial injury, demonstrated no difference in outcome.[182]

Direct Thrombin and Factor Xa Inhibitors

Chronic anticoagulation has changed substantially in the United States since the introduction of the oral direct thrombin inhibitor dabigatran (Pradaxa) in 2010.[184] Subsequently, the FDA has approved two oral factors Xa (FXa) inhibitors, rivaroxaban (Xarelto) and apixaban (Eliquis), and no doubt others are on the horizon. Dabigatran binds to free and clot-bound thrombin, preventing the conversion of fibrinogen to fibrin and platelet aggregation via the PAR receptors. Peak plasma levels occur in 1 to 2 hours. Clearance is predominantly renal, with a half-life of 14 to 17 hours. In addition, 20% is metabolized in the liver. Laboratory assessment of the anticoagulation effects are problematic. PT, PTT, and thrombin time are flat dose response (ie, useful for screening only). Rapid TEG results are erratic, but trends appear to correlate with circulating drug levels.[185] Ecarin clotting time has a dose response to dabigatran in therapeutic ranges but is not currently available in most hospitals. ROTEM is anticipated to have a channel to accomplish this testing soon. Reversal has been challenging until recently, and hemodialysis was recommended for emergent settings. The only promising universal reversal agent has been factor eight inhibitor bypass (FEIBA).[186] The antibody fragment idarucizumab appears to be clinically effective in reversing dibigitran,[187] but results have been variable.[188] Rivaroxaban reversibly binds the active site of FXa, preventing the formation of thrombin and subsequent fibrinogen cleavage.[189] The plasma half-life is 2 to 4 hours. Clearance is 66% renal and 33% hepatic; the half-life is 5 to 9 hours.[184] As expected, the most accurate assay for circulating levels is the anti-FXa assay. PT is prolonged in a linear fashion but is variable depending on the test reagents. The response to PTT is nonlinear, and the reliability of TEG remains unclear.[190] Dialysis is not useful for reversal because rivaroxaban is highly protein bound. A new reversal agent for FXa inhibitors, andexanet alfa, is now available.[191] Apixaban is another competitive inhibitor of FXa.[184] Peak circulating levels are achieved in 3 to 4 hours; clearance is 50% renal and 50% hepatic. At this point, there are insufficient data to recommend testing and reversal agents, but similarities to rivaroxaban are anticipated.

Hypercoagulability

VENOUS THROMBOEMBOLISM

The incidence of proximal lower extremity deep venous thrombosis (DVT) in injured patients without preventive measures has been reported at 18% to 32%, and the risk of significant pulmonary embolism (PE) ranges from 0.3% to 2%.[192] These figures are confounded by the fact that surveillance duplex will identify a higher incidence of asymptomatic DVT, but postinjury PE occurs in the absence of DVT in the majority of patients.[192] Furthermore, asymptomatic PE has been identified in more than 25% of severely injured patients on admission chest computed tomography scanning,[85] yet early symptomatic PE has been associated with extremity trauma but not thoracic injuries.[193] Consequently, it is not surprising that the prevention of postinjury venous thromboembolism (VTE) remains controversial, underscoring the critical need to understand the pathophysiology and fundamental mechanisms to design effective preventive strategies.

Virchow's Triad and Beyond

A century ago, Cannon recognized that the initial response to severe trauma is hypercoagulability, quickly followed by hypocoagulability. Severely injured patients who survive their injury subsequently transition to a hypercoagulable state as early as 24 hours following injury.[194] In fact, patients presenting with advanced TIC requiring a massive transfusion are at the greatest risk for VTE in the surgical intensive care unit. The etiology of this hypercoagulability is likely multifactorial, involving endothelial injury, circulatory stasis, platelet activation, hyperfibrinogenemia, decreased levels of endogenous anticoagulants, and impaired fibrinolysis. Furie and Furie[195] emphasize the role of the endothelium in maintaining blood flow via the generation of anticoagulants, nitric oxide, prostacyclin, and receptor expression. But even intact endothelium, when activated, can provoke thrombus formation. Furthermore, circulating leukocytes and microparticles can express tissue factor. Obesity[196] and traumatic brain injury[197] are independent risk factors for postinjury VTE, although the responsible mechanisms remain speculative.

Diagnosis of Hypercoagulability

The diagnosis and, thus, treatment of hypercoagulability following injury have been limited by the lack of accurate laboratory testing addressing the pathogenesis. Degradation products of fibrin (eg, D-dimer; Fig. 16-11) are not reliable in the acutely injured patient because these products merely indicate that a clot has been formed, since the half-life is greater than 12 hours.[89]

Conventional coagulation tests (ie, aPTT and PT/INR) are not able to diagnose hypercoagulability or delineate the relative contributions of enzymatic and platelet components. Previous trials investigating the benefit of various mechanical and pharmacoprophylactic regimens among injured patients have neither documented hypercoagulability nor monitored the efficacy of prophylaxis. Furthermore, current guidelines do not address the contribution of platelets or fibrinogen to hypercoagulability. Severely injured patients develop inflammation-driven hyperfibrinogenemia within days of injury,[198] and there is a growing body of evidence implicating platelet activation in the development and propagation of VTE.[199] Our work indicates that platelet hyperactivity contributes substantially to hypercoagulability beyond 48 hours of injury.[200] Antiplatelet therapy may have additional effects on attenuating hypercoagulability.[201] Finally, there is recent

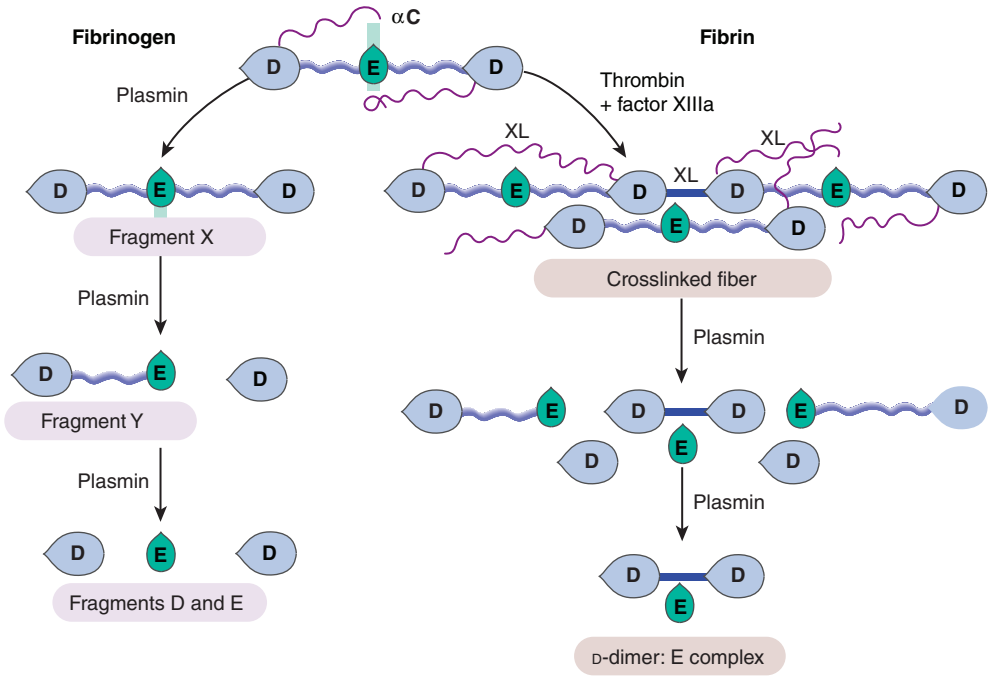

FIGURE 16-11 Fibrin degradation products. Plasmin initially cleaves the AC domains in fibrinogen generating fragment X. The subsequent cleavage step is at the central D and terminal D domains, resulting in fragment Y. Ultimately plasmin can cleave D from E. Plasmin cleaves fibrin protofibrils by removing the crosslinked α chains, followed by release of a number of fibrin degradation products, the smallest being DD/D, which is D-dimer. The persistence of the DD link is due to crosslinking of fibrin by thrombin activated factor XIII.

evidence documenting fibrinolysis shutdown in severely injured patients.[202] In light of these limitations, it is not surprising that most VTEs among trauma patients occur because of prophylaxis failure rather than failure to provide prophylaxis. In a recent comprehensive international analysis of medical and surgical intensive care units, the rate of DVT was 7.7% and the PE rate was 1.3%.[203]

Viscoelastic hemostatic assays may provide a breakthrough in managing hypercoagulability. A TEG-shortened *R* time, increased alpha-angle, and enhanced MA are indicative of hypercoagulability (Fig. 16-8). Our group documented a strong correlation between hypercoagulability indicted by TEG measurements and subsequent VTE. In the face of standard chemoprophylaxis, 60% of patients displayed evidence of hypercoagulability. Furthermore, TEG and ROTEM can distinguish platelet versus fibrinogen contribution to clot formation as well as calibrate fibrinolysis shutdown.[182] We have recently documented that persistent fibrinolysis shutdown (>24 hours) is a risk factor for postinjury VTE and have developed a t-PA sensitivity test (Fig. 16-12) to further

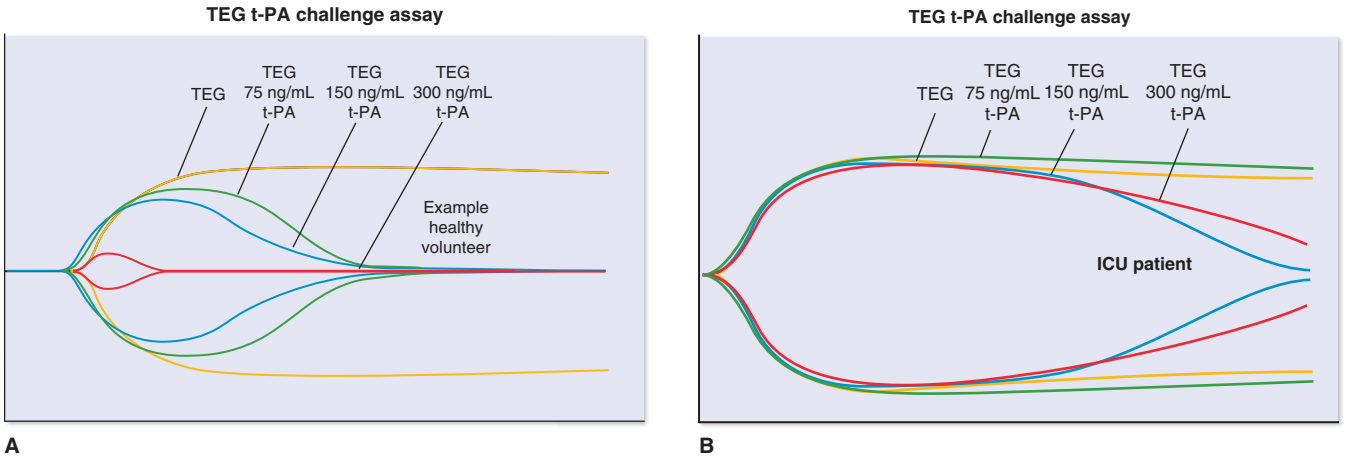

FIGURE 16-12 The tissue plasminogen activator (t-PA) challenge assay. (**A**) The objective of the t-PA assay is to determine sensitivity to exogenous t-PA added to a native thromboelastography (TEG). (**B**) Patients in fibrinolysis shutdown demonstrate reduced LY30 with high concentrations of exogenous t-PA. ICU, intensive care unit.

risk stratify and manage patients at risk. Despite the theoretical advantages of TEG-driven chemoprophylaxis protocols, prospective data remain sparse.

Prevention of Venous Thromboembolism

Early use of preventive measures is critical to prevent postinjury VTE, but identifying the high-risk population has been difficult. The two most widely used scores, Risk Assessment Profile (RAP) and Trauma Embolic Scoring System (TESS), miss a third of the patients who develop VTE.[204] Paradoxically, patients presenting with advanced TIC requiring a massive transfusion are at the greatest risk for subsequent VTE. Mechanical compression devices should be applied as soon as possible in all seriously injured patients. Heparin remains the cornerstone of pharmacologic VTE prophylaxis, and low molecular weight heparin (LMWH) is superior to unfractionated heparin.[201] Furthermore, weight-based LMWH or anti-factor Xa-guided dosing appears to be advantageous.[205] The use of novel oral anticoagulants is now being evaluated as an alternative to LMWH.[206]

The most controversial issue is timing of preventive agents with central nervous system injury.[205] The current debate is 48 versus 72 hours in patients without progressive intracranial hemorrhage. We currently believe aspirin should be routinely added at 72 hours in patients at high risk of VTE and should be dosed according to platelet mapping targeting arachidonic acid receptor inhibition at greater than 80%. Statin therapy may also become routine in the surgical intensive care unit for VTE prophylaxis,[207] via reducing PAI-1 to attenuate t-PA resistance. The role of inferior vena cava filters remains controversial, and at best, these devices have a limited role.[208]

In sum, the prevention of postinjury VTE remains a challenge because we do not currently understand the responsible biologic mechanisms.[209] A number of prospective trials are underway including the Department of Defense–supported Consortium of Leaders in the Study of Traumatic Thromboembolism (CLOTT) program. We currently believe TEG- or ROTEM-driven protocols should be employed, and the combination of a LMWH, aspirin, and a statin appears to be the optimal benefit-to-risk strategy at this moment.

Resuscitative Thoracotomy

Clay Cothren Burlew • Ernest E. Moore

KEY POINTS

- Resuscitative thoracotomy (RT) refers to an emergent thoracotomy, most commonly performed in the emergency department for patients arriving in extremis; RT may also be performed in the operating room or intensive care unit within hours after injury for physiologic deterioration.
- The primary objectives of RT are to release pericardial tamponade, control cardiac or intrathoracic hemorrhage, evacuate bronchovenous air embolism, perform open cardiac massage, and temporarily occlude the descending thoracic aorta.
- The critical determinants of survival following RT include the injury mechanism, anatomic location of injury, and the patient's physiologic condition at the time of thoracotomy.
- The highest survival rate following RT is in patients with penetrating cardiac wounds, especially when associated with pericardial tamponade.
- Based on the literature to date, RT should be performed for (1) penetrating nontorso trauma with cardiopulmonary resuscitation (CPR) of less than 5 minutes, (2) blunt trauma with CPR of less than 10 minutes, and (3) penetrating torso trauma with CPR of less than 15 minutes.
- RT is unlikely to yield productive survival when patients (1) sustain blunt trauma and require more than 10 minutes of prehospital CPR, (2) have penetrating wounds and undergo more than 15 minutes of prehospital CPR, (3) have isolated extremity trauma with more than 5 minutes of prehospital CPR, or (4) manifest asystole without pericardial tamponade.
- Outcome following RT in the adolescent population is largely determined by injury mechanism and physiologic status on presentation to the emergency department; for patients under 15 years of age, there are only isolated cases of survival following penetrating trauma and no apparent survival benefit following blunt trauma.

INTRODUCTION

The number of patients arriving at hospitals in extremis, rather than dying in the prehospital setting, has increased due to the maturation of regionalized trauma systems (see Chapter 4). Salvage of individuals with imminent cardiac arrest or those already undergoing cardiopulmonary resuscitation (CPR) often requires immediate thoracotomy as an integral component of their initial resuscitation in the emergency department (ED). The optimal application of a resuscitative thoracotomy (RT) requires a thorough understanding of its physiologic objectives, technical maneuvers, and the cardiovascular and metabolic consequences. Although resuscitative endovascular balloon occlusion of the aorta (REBOA) has been advocated as a resuscitation maneuver that should replace RT, there is a paucity of objective data to clarify the precise role of REBOA versus RT. In fact, aortic occlusion can be achieved quicker with RT than REBOA in patients arriving with CPR in progress.[1] Furthermore, RT is indicated for life-threatening thoracic injuries. However, we believe REBOA is ideal for unstable pelvic fractures with advanced hemorrhagic shock (see Chapter 39), and we have placed a REBOA in patients who have recovered perfusion following RT when it is evident that a pelvic fracture is the source of acute blood loss. This chapter reviews the features of RT and highlights the specific clinical indications, all of which are essential for the appropriate use of this potentially lifesaving yet costly procedure.

HISTORICAL PERSPECTIVE

Emergent thoracotomy came into use for the treatment of heart wounds and anesthesia-induced cardiac arrest in the late 1800s and early 1900s.[2] The concept of a thoracotomy

as a resuscitative measure began with Schiff's promulgation of open cardiac massage in 1874.[2] Block first suggested the potential application of this technique for penetrating chest wounds and heart lacerations in 1882.[3] Following use of the technique in animal models, the first successful suture repair of a cardiac wound in a human was performed at the turn of the century.[4] Subsequently, Igelsbrud described the successful resuscitation of a patient sustaining cardiac arrest during a surgical procedure using emergent thoracotomy with open cardiac massage.[2] The utility of the emergent thoracotomy was beginning to be tested in a wide range of clinical scenarios in the early 1900s.

With improvement in patient resuscitation and an ongoing evaluation of patient outcomes, the indications for emergent thoracotomy shifted. Initially, cardiovascular collapse from medical causes was the most common reason for thoracotomy in the early 1900s. The demonstrated efficacy of closed-chest compression by Kouwenhoven et al[5] in 1960 and the introduction of external defibrillation in 1965 by Zoll et al[6] virtually eliminated the practice of open-chest resuscitation for medical cardiac arrest. Indications for emergent thoracotomy following trauma also became more limited. In 1943, Blalock and Ravitch[7] advocated the use of pericardiocentesis rather than thoracotomy as the preferred treatment for postinjury cardiac tamponade. In the late 1960s, however, refinements in cardiothoracic surgical techniques reestablished the role of immediate thoracotomy for salvaging patients with life-threatening chest wounds.[8] The use of temporary thoracic aortic occlusion in patients with exsanguinating abdominal hemorrhage further expanded the indications for emergent thoracotomy.[9,10] In the past two decades, critical analyses of patient outcomes following postinjury RT has tempered the unbridled enthusiasm for this technique, allowing a more selective approach with clearly defined indications.[11-16]

DEFINITIONS

The literature addressing RT appears confusing, likely due to widely varying terminology. As a result, there is a lack of agreement among physicians regarding the specific indications for RT as well as the definition of "signs of life."[17] In this chapter, RT refers to an emergent thoracotomy, most commonly performed in the ED for patients arriving in extremis. At times, an RT is performed in the operating room (OR) or intensive care unit (ICU) within hours after injury for delayed physiologic deterioration or an acute anatomic disruption or physiologic change. The value of RT for acute resuscitation may also be confusing because of the variety of indices used to characterize the patient's physiologic status prior to thoracotomy. Because there have been a wide range of indications for which RT has been performed in different trauma centers, comparisons in the literature are difficult. The authors define "no signs of life" as no detectable blood pressure, respiratory or motor effort, cardiac electrical activity, or pupillary activity (ie, clinical death). Patients with "no vital signs" have no palpable blood pressure but demonstrate electrical activity, respiratory effort, or pupillary reactivity.

PHYSIOLOGIC RATIONALE FOR RESUSCITATIVE THORACOTOMY

The primary objectives of RT are to (1) release pericardial tamponade, (2) control cardiac hemorrhage, (3) control intrathoracic bleeding, (4) evacuate bronchovenous air embolism, (5) perform open cardiac massage, and (6) temporarily occlude the descending thoracic aorta. Combined, these objectives attempt to address the primary issue of cardiovascular collapse from mechanical sources or extreme hypovolemia.

Release Pericardial Tamponade and Control Cardiac Hemorrhage (See Atlas Figure 25)

The highest survival rate following RT is in patients with penetrating cardiac wounds, especially when associated with pericardial tamponade.[8] Early recognition of cardiac tamponade, prompt pericardial decompression, and control of cardiac hemorrhage are the key components to successful RT and patient survival following penetrating wounds to the heart (see Chapter 30).[18] The egress of blood from the injured heart, regardless of mechanism, results in tamponade physiology. In acute conditions with a nondistendable pericardium, only 100 to 150 mL of pericardial blood results in tamponade. Rising intrapericardial pressure produces abnormalities in hemodynamic and cardiac perfusion that can be divided into three phases.[19] Initially, increased pericardial pressure restricts ventricular diastolic filling and reduces subendocardial blood flow.[20] Cardiac output under these conditions is maintained by compensatory tachycardia, increased systemic vascular resistance, and elevated central pressure (ie, ventricular filling pressure). In the intermediate phase of tamponade, rising pericardial pressure further compromises diastolic filling, stroke volume, and coronary perfusion, resulting in diminished cardiac output. Although blood pressure may be maintained deceptively well, subtle signs of shock (eg, anxiety, diaphoresis, and pallor) become evident. During the final phase of tamponade, compensatory mechanisms fail as the intrapericardial pressure approaches the ventricular filling pressure. Cardiac arrest ensues as profound coronary hypoperfusion occurs.

The classic description of clinical findings, Beck's triad (muffled heart sounds, distended neck veins, and hypotension), is rarely observed in the ED; therefore, a high index of suspicion in the at-risk patient sustaining penetrating torso trauma is crucial, with prompt intervention essential. In the first two phases of cardiac tamponade, patients may be aggressively managed with volume resuscitation to increase preload and pericardial drainage (via pericardiocentesis, pericardial window, or median sternotomy). The patient in the third phase of tamponade, with profound hypotension (systolic blood pressure [SBP] <60 mm Hg), should undergo RT rather than pericardiocentesis as the management for evacuation of pericardial blood. Following release of tamponade, the source of tamponade can be directly controlled with appropriate interventions based on the underlying injury

(see later section titled Technical Details of Resuscitative Thoracotomy).[21]

Control Intrathoracic Hemorrhage

Life-threatening intrathoracic hemorrhage occurs in less than 5% of patients following penetrating injury presenting to the ED, and in an even lower percentage of patients sustaining blunt trauma.[22] The most common injuries include penetrating wounds to the pulmonary hilum and great vessels; less commonly seen are torn descending thoracic aortic injuries with frank rupture or penetrating cardiac wounds exsanguinating into the thorax through a traumatic pericardial window. There is a high mortality rate for injuries to the pulmonary hilar vasculature or thoracic great vessels due to the lack of hemorrhage containment by adjacent tissue tamponade or by lack of vessel spasm (see Chapters 29 and 30). Either hemithorax can rapidly accommodate more than half of a patient's total blood volume before overt physical signs of hemorrhagic shock occur. Therefore, a high clinical suspicion is warranted in patients with penetrating torso trauma, particularly in those with hemodynamic decompensation. Patients with exsanguinating wounds require RT with rapid control of the source of hemorrhage if they are to be salvaged.

Perform Open Cardiac Massage

External chest compression provides approximately 20% to 25% of baseline cardiac output, with 10% to 20% of normal cerebral perfusion.[23] This degree of vital organ perfusion can provide reasonable salvage rates for 15 minutes, but few normothermic patients survive 30 minutes of closed-chest compression. Moreover, in models of inadequate intravascular volume (hypovolemic shock) or restricted ventricular filling (pericardial tamponade), external chest compression fails to augment arterial pressure or provide adequate systemic perfusion; the associated low diastolic volume and pressure result in inadequate coronary perfusion.[24] Therefore, closed cardiac massage is ineffective for postinjury cardiopulmonary arrest. The only potential to salvage the injured patient with ineffective circulatory status is immediate RT with subsequent open cardiac massage.

Achieve Thoracic Aortic Cross-Clamping (See Atlas Figure 24)

The rationale for temporary thoracic aortic occlusion in the patient with massive hemorrhage is twofold. First, in patients with hemorrhagic shock, aortic cross-clamping redistributes the patient's limited blood volume to the myocardium and brain.[10] Second, patients sustaining intra-abdominal injury may benefit from aortic cross-clamping due to reduction in subdiaphragmatic blood loss.[9] Temporary thoracic aortic occlusion augments aortic diastolic and carotid SBP, enhancing coronary as well as cerebral perfusion.[25] Experimental work has shown that the left ventricular stroke-work index and myocardial contractility increase in response to thoracic aortic occlusion during hypovolemic shock.[26] These improvements in myocardial function occur without an increase in the pulmonary capillary wedge pressure or a significant change in systemic vascular resistance. Thus, improved coronary perfusion resulting from an increased aortic diastolic pressure presumably accounts for the observed enhancement in contractility.[27]

These experimental observations suggest that temporary aortic occlusion is valuable in patients with either shock due to nonthoracic trauma or continued shock following the repair of cardiac injuries or other thoracic exsanguinating wounds. Indeed, occlusion of the descending thoracic aorta appears to increase the return of spontaneous circulation following CPR.[28] Reports of successful resuscitation using RT in patients in hemorrhagic shock exist, including patients sustaining cardiac arrest due to exsanguinating extremity or cervical injuries.[29] In these situations, RT may be a temporizing measure until the patient's circulating blood volume can be replaced by blood product transfusion. However, once the patient's blood volume has been restored, the aortic cross-clamp should be removed. Thoracic cross-clamping in the normovolemic patient may be deleterious because of increased myocardial oxygen demands resulting from the increased systemic vascular resistance.[30] Careful application of this technique is warranted as there is substantial metabolic cost and a finite risk of paraplegia associated with the procedure.[31-33] However, in carefully selected patients, aortic cross-clamping may effectively redistribute the patient's blood volume until external replacement and control of the hemorrhagic source are possible. Complete removal of the aortic cross-clamp or replacement of the clamp below the renal vessel should be performed within 30 minutes; the viscera's tolerance of normothermic ischemia is 30 to 45 minutes. As mentioned previously, there may be a role for REBOA in the patient with ongoing pelvic bleeding from either pelvic fracture or gunshot wound.

Evacuate Bronchovenous Air Embolism

Bronchovenous air embolism can be a subtle entity following thoracic trauma and may be much more common than is recognized.[34-36] The clinical scenario typically involves a patient sustaining penetrating chest injury who precipitously develops profound hypotension or cardiac arrest following endotracheal intubation and positive-pressure ventilation. Traumatic bronchovenous communications produce air emboli that migrate to the coronary arterial systems; any impedance in coronary blood flow causes myocardial ischemia and resultant shock. The production of air emboli is enhanced by the underlying physiology—there is relatively low intrinsic pulmonary venous pressure due to associated intrathoracic blood loss and high bronchoalveolar pressure from assisted positive-pressure ventilation. This combination increases the gradient for air transfer across bronchovenous channels.[37] Although more often observed in penetrating

trauma, a similar process may occur in patients with blunt lacerations of the lung parenchyma (see Chapter 28).

Immediate thoracotomy with pulmonary hilar cross-clamping prevents further propagation of pulmonary venous air embolism. Pericardotomy provides access to the coronaries and cardiac ventricles; with the patient in the Trendelenburg position (done to trap to air in the apex of the left ventricle), needle aspiration is performed to remove air from the cardiac chamber. Additionally, vigorous cardiac massage, done by running a finger along the coronary vessel, may promote dissolution of air already present in the coronary arteries.[36] Aspiration of the aortic root is done to alleviate any accumulated air pocket, and direct needle aspiration of the right coronary artery may be effective.

CLINICAL RESULTS FOLLOWING RESUSCITATIVE THORACOTOMY

The value of RT in resuscitation of the patient in profound shock who is not yet dead is unquestionable. Its indiscriminate use, however, renders it a low-yield and high-cost procedure.[15,38-40] In the past three decades, there has been a significant clinical shift in the performance of RT, from a nearly obligatory procedure before declaring any trauma patient dead to very few patients undergoing RT. During this swing of the pendulum, several groups have attempted to elucidate the clinical guidelines for RT. In 1979, we conducted a critical analysis of 146 consecutive patients undergoing RT and suggested a selective approach to its use in the moribund trauma patient, based on consideration of the following variables: (1) location and mechanism of injury, (2) signs of life at the scene and on presentation to the ED, (3) cardiac electrical activity at thoracotomy, and (4) SBP response to thoracic aortic cross-clamping.[40]

To further delineate these clinical parameters, we established a prospective study in which these data were carefully documented in all patients at the time of thoracotomy. In 1982, the first 400 patients were analyzed.[39] In 1998, the second analysis of 868 patients was reported.[41] The most recent review has summarized the data on 1708 patients who have undergone RT at the Denver Health Medical Center.[42] Of these, 1289 (78%) were dead in the ED, 272 (16%) died in the OR, and 41 (2%) succumbed to multiple organ failure in the surgical ICU. Ultimately, 106 patients (6%) survived. Although, this yield may seem low, it is important to emphasize that thoracotomy was done on virtually every trauma patient delivered to the ED in the early years of the study period. Additionally, 79% were without vital signs in the field and underwent prehospital CPR. In contrast, it is equally important to stress that patients without signs of life at the scene but who responded favorably to resuscitation were excluded from this analysis because they did not require RT; these patients remind the practitioner that prehospital clinical assessments may not always be reliable in triaging these severely injured patients. Indeed, the authors have salvaged a number of individuals sustaining blunt and penetrating trauma who were assessed to have no signs of life at the scene of injury. The importance of guidelines for RT is evident in the improved survival rate in recent years: in 1974 to 1979, survival was only 5%, compared to 14% survival in 2010 to 2014.[42]

The survival rate and percentage of neurologic impairment following RT vary considerably, due to the heterogeneity of patient populations reported in the literature. As previously discussed, critical determinants of survival include the mechanism and anatomic location of injury and the patient's physiologic condition at the time of thoracotomy.[43-46] We have attempted to elucidate the impact of these factors in ascertaining the success rate of RT by collating data from a number of clinical series reporting on 50 or more patients (Table 17-1). Unfortunately, inconsistencies in patient stratification and a paucity of clinical details limit objective analysis of these data. Although some reviews provide a specific breakdown of the injury mechanism and clinical status of patients presenting to the ED, others combine all injury mechanisms. We believe it is crucial to stratify patients according to the anatomic location (cervical/extremity vs torso) and mechanism of injury (penetrating vs blunt), as well as the presence of signs of life (ie, blood pressure, respiratory effort, cardiac electrical activity, and pupillary activity).

The data summarized to date confirm that RT has the highest survival rate following isolated cardiac injury (Table 17-1). An average of 35% of adult patients presenting in shock, defined as an SBP less than 70 mm Hg, and 20% without vital signs were salvaged after isolated penetrating injury to the heart if RT was performed. In contrast, 1% to 15% of blunt trauma patients undergoing RT survive. Following penetrating torso injuries, 14% of patients requiring RT are salvaged if they are hypotensive with detectable vital signs, whereas 8% of those who have no vital signs but have signs of life at presentation and 1% of those without signs of life are salvaged. These findings are reiterated by a recent report incorporating all patients undergoing RT for either blunt or penetrating mechanism from 24 separate studies[44]; survival rates for patients undergoing RT for penetrating injuries and blunt mechanisms were 8.8% and 1.4%, respectively. Additionally, more patients survive RT for isolated cardiac wounds (19.4%), followed by stab wounds (16.8%) and gunshot wounds (4.3%).

Although there is a clear role for RT in the patient presenting in shock but with measurable vital signs, there is disagreement about its use in the patient population undergoing CPR prior to arrival in the ED. Although there have been multiple reports with low survival rates and dismal outcomes following prehospital CPR, termination of resuscitation in the field should not be performed in all patients.[47] Our most recent evaluation, spanning 40 years of experience, indicates that RT does play a significant role in the critically injured patient undergoing prehospital CPR.[42] The majority of patients arriving in extremis who survived to discharge sustained a stab wound to the torso, consistent with previous reports. Additionally, the majority of patients were neurologically intact at discharge.

To further define the limits of RT, a prospective, multicenter trial was performed by the Western Trauma Association (WTA).[13] The WTA data substantiate that injury mechanism alone is not a discriminator of futility. Specifically, with the exception of an overtly devastating head injury, blunt trauma does not prohibit meaningful survival, even with requirements for CPR. This multicenter experience, combined with prior reports, suggests current indications for RT (Table 17-2). RT should be performed for penetrating nontorso trauma with CPR of less than 5 minutes, blunt trauma with CPR of less than 10 minutes, and penetrating torso trauma with CPR of less than 15 minutes. RT is unlikely to yield productive survival when patients (1) sustain blunt trauma and require more than 10 minutes of prehospital CPR, (2) have penetrating wounds and undergo more than 15 minutes of prehospital CPR, (3) have isolated extremity trauma with more than 5 minutes of prehospital CPR, or (4) manifest asystole without pericardial tamponade. We recognize, however, that there will invariably be exceptions to the recorded literature.[29,43,48,49]

Emerging data indicate the clinical results in the pediatric population mirror those of the adult experience for penetrating injury (Table 17-3). One might anticipate that children would have a more favorable outcome compared to adults; however, this has not been borne out in multiple studies.[50-56] A recent review of RT in the pediatric population encompassed eight published reports with 2336 pediatric trauma patients[57]; 269 RTs were performed in this study population. Overall survival rate was 1.7% in blunt trauma and 14% following RT for penetrating trauma. According to this review, in the past 25 years, no published series of RT has demonstrated a survivor following blunt trauma in the pediatric age group. In the published literature over the past four decades, only two blunt trauma patients are reported to have undergone

TABLE 17-2: Current Indications and Contraindications for Emergency Department Thoracotomy

Indications:

Salvageable postinjury cardiac arrest
- Penetrating thoracic trauma patients with <15 min of prehospital CPR
- Penetrating nonthoracic trauma patients with <5 min of prehospital CPR
- Blunt trauma patients with <10 min of prehospital CPR

Persistent severe postinjury hypotension (SBP <60 mm Hg) due to:
- Cardiac tamponade
- Hemorrhage: intrathoracic, intra-abdominal, extremity, cervical
- Air embolism

Contraindications:
- CPR >15 min following penetrating injury and no signs of life (pupillary response, respiratory effort, or motor activity)
- CPR >10 min following blunt injury and no signs of life
- Asystole is the presenting rhythm and there is no pericardial tamponade

CPR, cardiopulmonary resuscitation; SBP, systolic blood pressure.

RT and survived; each of these patients was over the age of 15. Beaver et al[52] reported no survivors among 27 patients, from 15 months to 14 years of age, undergoing postinjury RT at Johns Hopkins Hospital. Powell et al,[55] at the South Alabama Medical Center, described an overall survival of 20% (3 of 15 patients) in patients ranging from 4 to 18 years old. A review using the National Trauma Data Bank of all pediatric blunt trauma patients with no sign of life in the field identified a 1.3% survival rate for those undergoing RT.[56] In a study at Denver Health Medical Center, encompassing an 11-year experience with 689 consecutive RTs, we identified 83 patients (12%) who were under 18 years old.[53] Survival by injury mechanism was 9% (1 of 11 patients) for stab wounds, 4% (1 of 25 patients) for gunshot wounds, and 2% (1 of 47 patients) for blunt trauma. Among 69 patients presenting to the ED without vital signs, only 1 patient (1%) survived (with a stab wound). This contrasted to a salvage of 2 (14%) of 14 patients with vital signs. The outcome in blunt trauma, the predominant mechanism of lethal injury in children, was disappointing, with only 2% salvage, and there were no survivors when vital signs were absent. A more recent analysis spanning 40 years identified a similar rate of RT in the pediatric population[58]; of 179 trauma patients undergoing RT, there were 6 survivors (3.4%). In the adolescent age group (15–18 years old), survival rate was 4.8%, whereas in the group younger than age 15 years, there were no survivors. Thus, as in adults, outcome following RT in the adolescent population is largely determined by injury mechanism and physiologic status on presentation to the ED; for patients under 15 years of age, there are only isolated cases of survival following penetrating trauma and no apparent survival benefit following blunt trauma.

In sum, overall analysis of the available literature indicates that the success of RT approximates 35% in the patient arriving in shock with a penetrating cardiac wound and 15% for all penetrating wounds. Patients undergoing CPR upon arrival to the ED should be stratified based on injury and transport time to determine the utility of RT. Conversely, patient outcome is relatively poor when RT is done for blunt trauma: 2% survival in patients in shock and less than 1% survival with no vital signs. A clear understanding of the indications for RT combined with available expertise will hopefully improve compliance with commonly accepted clinical practice and result in reduced mortality rates.[59]

INDICATIONS FOR RESUSCITATIVE THORACOTOMY

Based on our successive years of RT prospective analysis[42] and the recent WTA multicenter trial,[12] we propose current indications for RT (Table 17-2). Clearly, the specific application of these guidelines must include signs of life, mechanism of injury, and logistic issues such as qualified personnel. Our current decision algorithm for resuscitation of the moribund trauma patient and use of RT was formulated based on these analyses (Fig. 17-1). At the scene, patients in extremis without electrical cardiac activity are declared dead.[60] Patients in extremis but with electrical cardiac activity are intubated, supported with cardiac compression, and rapidly transported to the ED.

On arrival to the ED, the time from initiation of CPR is reported by the prehospital personnel to the trauma surgeon; blunt trauma patients with greater than 10 minutes of prehospital CPR and no signs of life are declared, whereas penetrating torso trauma patients with greater than 15 minutes or isolated extremity/cervical trauma patients with greater than 5 minutes of prehospital CPR and no signs of life are pronounced. Patients within the time guidelines or those with signs of life trigger ongoing resuscitation and RT. After performing a generous left anterolateral thoracotomy and subsequent pericardotomy, the patient's intrinsic cardiac activity is evaluated. Patients in asystole without associated cardiac tamponade are declared. Patients with a cardiac wound, tamponade, and associated asystole are aggressively treated; the cardiac wound is repaired first, followed by manual cardiac compressions, intracardiac injection of epinephrine, and defibrillation. Following treatment and blood product resuscitation, one should reassess salvageability, typically defined as the patient's ability to generate an SBP greater than 70 mm Hg.

Patients with an intrinsic rhythm following RT should be treated according to underlying pathology. Those with tamponade should undergo cardiac repair, either in the trauma bay or in the OR (see Chapter 30). Control of intrathoracic hemorrhage may entail hilar cross-clamping, digital occlusion of the direct injury, or even packing of the apices for subclavian injuries. Treatment of bronchovenous air embolism includes cross-clamping of the hilum, putting the patient in Trendelenberg position, aspirating the left ventricle and aortic root, and massaging the coronaries. Finally, cross-clamping of the descending aorta is performed to decrease the required effective circulating volume, increase cerebral and coronary blood flow, reduce infradiaphragmatic blood loss, and facilitate resuscitation. In all of these scenarios, reassessment of the patient following intervention and aggressive resuscitation efforts is performed, with the goal SBP of 70 mm Hg used to define salvageability.

TECHNICAL DETAILS OF RESUSCITATIVE THORACOTOMY

The optimal benefit of RT is achieved by a surgeon experienced in the management of intrathoracic injuries. The emergency physician, however, should not hesitate to perform the

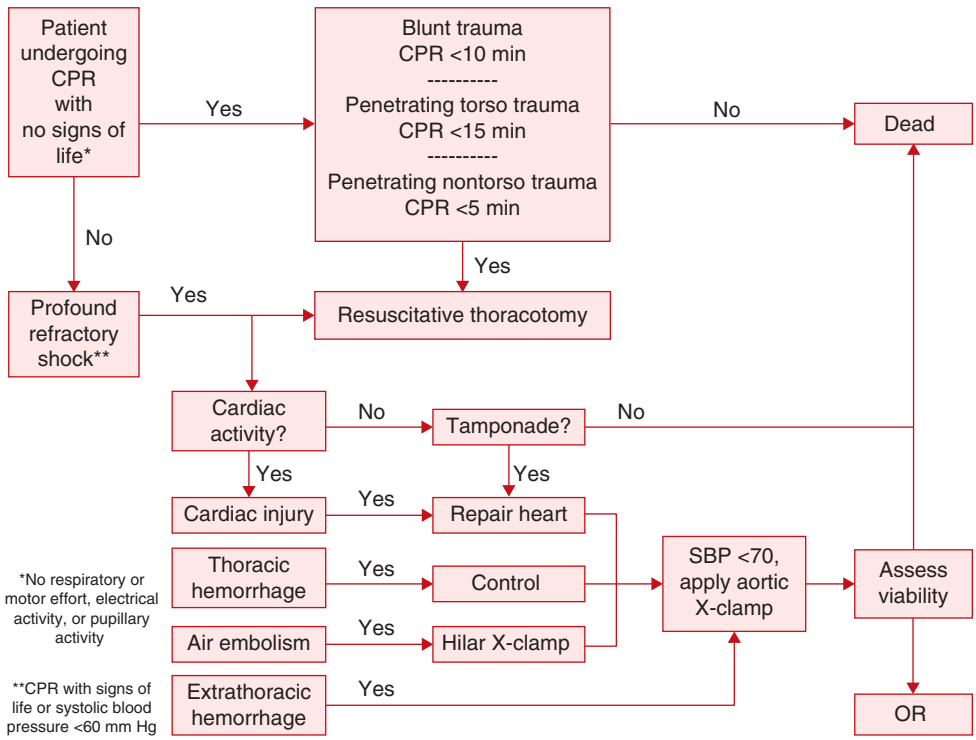

FIGURE 17-1 Algorithm directing the use of resuscitative thoracotomy in the multiply injured trauma patient. CPR, cardiopulmonary resuscitation; OR, operating room; X-clamp, cross-clamp.

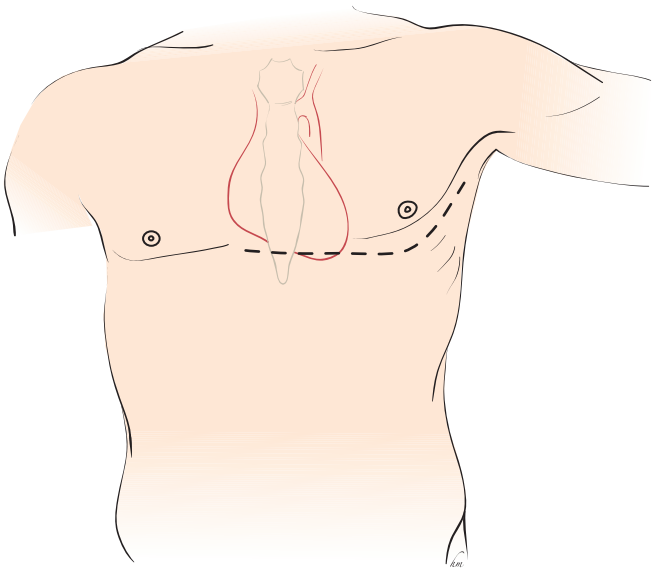
procedure in the moribund patient with a penetrating chest wound when thoracotomy is the only means of salvage. The technical skills needed to perform the procedure include the ability to perform a rapid thoracotomy, pericardiotomy, cardiorrhaphy, and thoracic aortic cross-clamping; familiarity with vascular repair techniques and control of the pulmonary hilum are advantageous. Once life-threatening intrathoracic injuries are controlled or temporized, the major challenge is restoring the patient's hemodynamic integrity and minimizing vital organ reperfusion injury.

Thoracic Incision

A left anterolateral thoracotomy incision is preferred for RT. Advantages of this incision in the critically injured patient include (1) rapid access with simple instruments, (2) the ability to perform this procedure on a patient in the supine position, and (3) easy extension into the right hemithorax, a clamshell thoracotomy, for exposure of both pleural spaces and anterior and posterior mediastinal structures. The key resuscitative maneuvers of RT, namely, pericardiotomy, open cardiac massage, and thoracic aortic cross-clamping, are readily accomplished via this approach. The initial execution of a clamshell thoracotomy should be done in hypotensive patients with penetrating wounds to the right chest. This provides immediate, direct access to a right-sided pulmonary or vascular injury while still allowing access to the pericardium from the left side for open cardiac massage. Clamshell thoracotomy may also be considered in patients with presumed air embolism, providing access to the cardiac chambers for aspiration, coronary vessels for massage, and bilateral lungs for obliteration of the source.

Preparation for RT should be performed well ahead of the patient's arrival. Set-up should include a 10-blade scalpel, Finochietto chest retractor, toothed forceps, curved Mayo scissors, Satinsky vascular clamps (large and small), long needle holder, Lebsche knife and mallet, and internal defibrillator paddles. Sterile suction, skin stapler, and access to a variety of sutures should be available (specifically 3-0 Prolene on a CT-1 needle, 3-0 silk ties, and Teflon pledgets). Upon patient arrival and determination of the need for RT, the patient's left arm should be placed above the head to provide unimpeded access to the left chest. The anterolateral thoracotomy is initiated with an incision at the level of the fifth intercostal space (Fig. 17-2). Clinically, this level for incision corresponds to the inferior border of the pectoralis major muscle, just below the patient's nipple. In women, the breast should be retracted superiorly to gain access to this interspace, and the incision is made at the inframammary fold. The incision should start on the right side of the sternum; if sternal transection is required, this saves the time-consuming step of performing an additional skin incision. As the initial incision is carried transversely across the chest and one passes beneath the nipple, a gentle curve in the incision toward the patient's axilla rather than direct extension to the bed should be performed; this curvature in the skin correlates with the natural curvature of the rib cage. The skin, subcutaneous fat, and



A

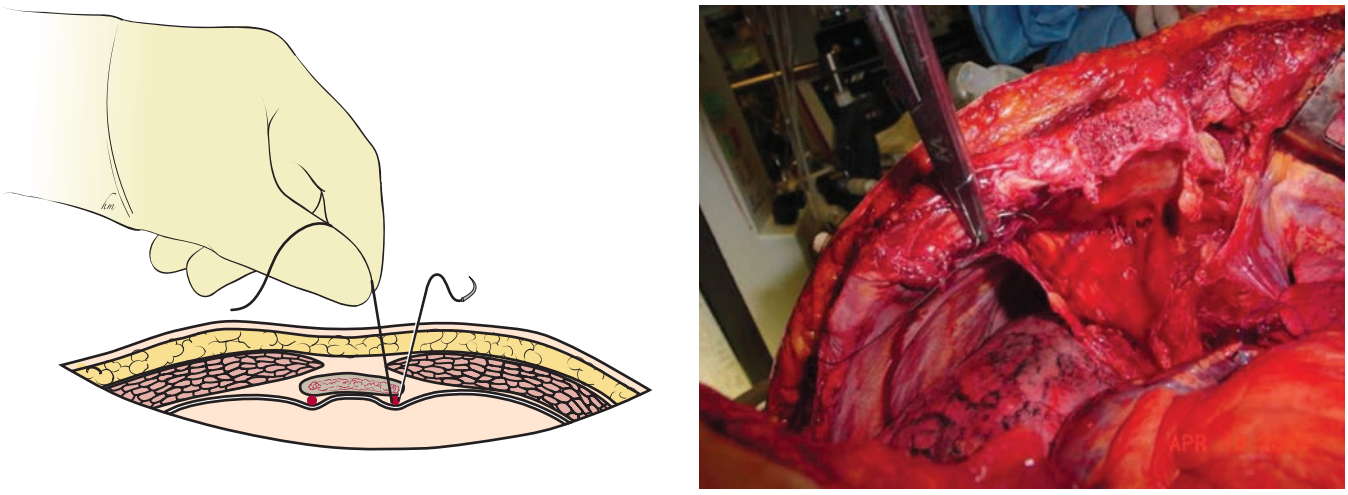
FIGURE 17-2 (**A, B**) The thoracotomy incision is performed through the fourth or fifth intercostal space; the incision should start to the right of the sternum, and begin curving into the axilla at the level of the left nipple. The Finochietto rib retractor is placed with the handle directed inferiorly toward the bed.



A B

FIGURE 17-3 (**A, B**) Transverse division of the sternum requires individual ligation of the internal mammary arteries.

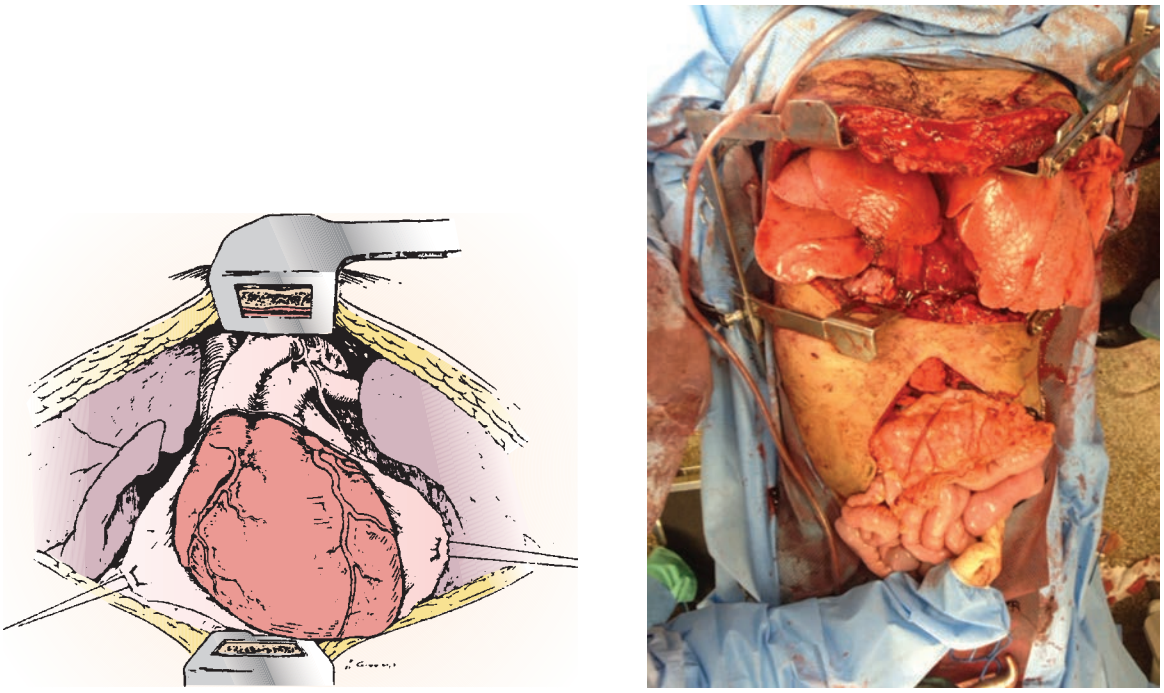
chest wall musculature are incised with a knife to expose the ribs and associated intercostal space. Intercostal muscles and the parietal pleura are then divided in one layer with curved Mayo scissors; the intercostal muscle should be divided along the superior margin of the rib to avoid the intercostal neurovascular bundle. Chest wall bleeding is minimal in these patients and should not be a concern at this point in the resuscitation. Once the incision is completed and the chest entered, a standard Finochietto rib retractor is inserted, with the handle directed inferiorly toward the axilla (Fig. 17-2) (see Atlas Figures 22 and 23). Placement of the handle toward the bed rather than the sternum allows extension of the left thoracotomy into a clamshell thoracotomy with crossing of the sternum without replacing the rib retractor.

If the left anterolateral thoracotomy does not provide adequate exposure, several techniques may be employed. The costal cartilages can be readily divided with heavy scissors. Alternatively, the sternum can be transected for additional exposure with a Lebsche knife; care must be taken to hold the Lebsche knife firmly against the underside of the sternum when using the mallet to forcefully transect the sternum, or the tip of the instrument may deviate and result in an iatrogenic cardiac injury. If the sternum is divided transversely, the internal mammary vessels must be ligated when perfusion is restored; this may be performed using either a figure of eight suture with 3-0 silk or by clamping the vessel with a tonsil and individually ligating it with a 3-0 silk tie (Fig. 17-3). A concomitant right anterolateral thoracotomy produces a "clamshell" or "butterfly" incision and achieves wide exposure to both pleural cavities and anterior and posterior mediastinal structures (Fig. 17-4). Once the right pleural space is opened, the rib retractor should be moved to more of a midline position to enhance separation of the chest wall for maximal exposure. When visualization of penetrating wounds in the aortic arch or major branches is needed, the superior sternum is additionally split in the midline.

Pericardiotomy and Cardiac Hemorrhage Control

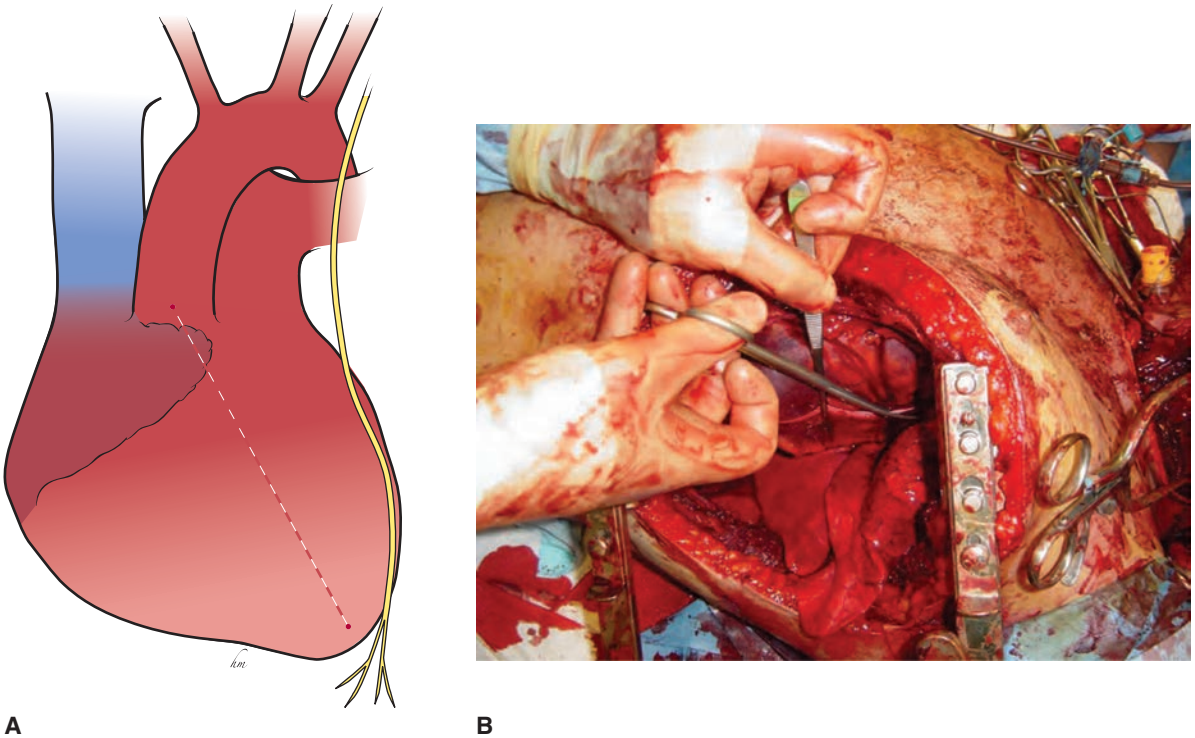
The pericardium is incised widely, starting at the cardiac apex and extending toward the sternal notch, anterior and parallel to the phrenic nerve (Fig. 17-5). If the pericardium is not tense with blood, it may be picked up at the apex with toothed forceps and sharply opened with scissors. If tense pericardial tamponade exists, a knife or the sharp point of a scissors is often required to initiate the pericardiotomy incision. Blood and blood clots should be completely evacuated from the pericardium. The heart should be delivered from the pericardium by placing the right hand through the opening in the pericardium posterior to the heart, encircling the right side of the heart and pulling it into the left chest. This effectively places the left side of the pericardium behind the heart allowing access to the cardiac chambers for repair of cardiac wounds and access for effective open cardiac massage.

Prompt hemorrhage control is paramount for a cardiac injury. In the beating heart, cardiac bleeding sites should be controlled immediately with digital pressure on the surface of the ventricle and partially occluding vascular clamps on the atrium or great vessels. Efforts at definitive cardiorrhaphy may be delayed until initial resuscitative measures have been completed. In the nonbeating heart, cardiac repair is done prior to defibrillation and cardiac massage. Cardiac wounds in the thin-walled right ventricle are best repaired with 3-0 nonabsorbable running or horizontal mattress sutures. Buttressing the suture repair with Teflon pledgets is ideal for the thinner right ventricle. When suturing a ventricular laceration, care must be taken not to incorporate a coronary vessel into the repair. In these instances, vertical mattress sutures should be used to exclude the coronary and prevent cardiac ischemia. In the more muscular left ventricle, control of bleeding can occasionally be achieved with a skin-stapling device if the wound is a linear stab wound whose edges coapt in diastole.



A B

FIGURE 17-4 (**A, B**) A bilateral anterolateral ("clamshell") thoracotomy provides access to both thoracic cavities including the pulmonary hila, heart, and proximal great vessels.



A B

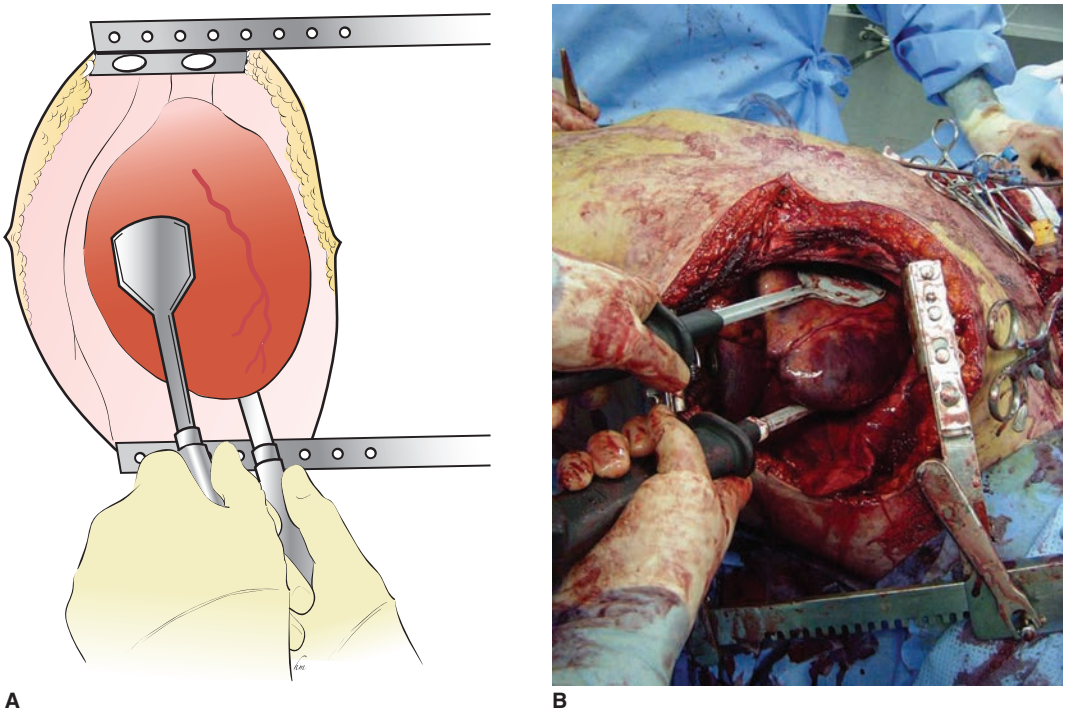
FIGURE 17-5 (**A, B**) Pericardiotomy is done with toothed pickups and curved Mayo scissors; the incision begins at the cardiac apex, anterior to the phrenic nerve, and extends on the anterior surface of the heart toward the great vessels.

Low-pressure venous, atrial, and atrial appendage lacerations can be repaired with simple running or purse string sutures of 3-0 Prolene. Posterior cardiac wounds may be particularly treacherous when they require elevation of the heart for their exposure; closure of these wounds is best accomplished in the OR with optimal lighting and equipment. For a destructive wound of the ventricle or for inaccessible posterior wounds, temporary inflow occlusion of the superior and inferior vena cava may be employed to facilitate repair (see Chapter 30). BioGlue may be used as a hemostatic agent in such cases. Use of a Foley catheter for temporary occlusion of cardiac injuries has been suggested; in our experience, this may inadvertently extend the injury due to traction forces.

Advanced Cardiac Life Support Interventions Including Cardiac Massage

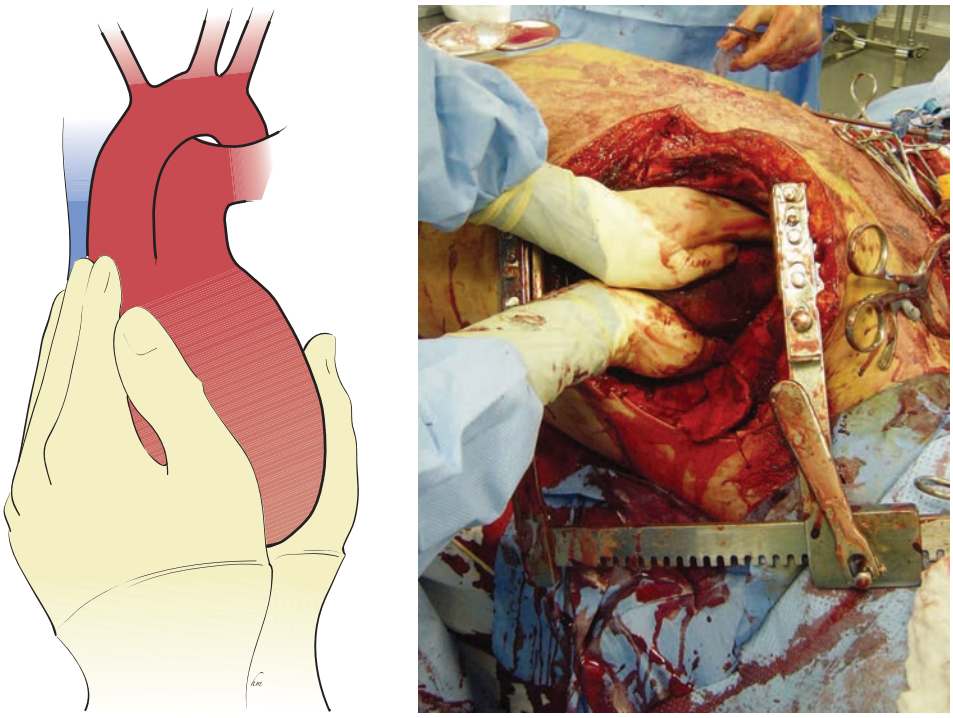
The restoration of organ and tissue perfusion may be facilitated by a number of interventions.[61] First, a perfusing cardiac rhythm must be established. Early defibrillation for ventricular fibrillation or pulseless ventricular tachycardia has proven benefit, and evidence supports the use of amiodarone (with lidocaine as an alternative) following epinephrine in patients refractory to defibrillation. Magnesium may be beneficial for torsades de pointes; other dysrhythmias should be treated according to current guidelines.[61] Familiarity with the internal cardiac paddles and appropriate charging dosages in joules are required (Fig. 17-6). In the event of cardiac arrest, bimanual internal massage of the heart should be instituted promptly (Fig. 17-7). We prefer to do this with a hinged clapping motion of the hands, with the wrists apposed, sequentially closing from palms to fingers. The ventricular compression should proceed from the cardiac apex to the base of the heart. The two-handed technique is strongly recommended, as the one-handed massage technique poses the risk of myocardial perforation with the thumb.

Pharmacologic adjuncts to increase coronary and cerebral perfusion pressure may be needed. The first agent in resuscitation at this juncture is intracardiac epinephrine. Epinephrine should be administered using a specialized syringe, which resembles a spinal needle, directly into the left ventricle. Typically, the heart is lifted up slightly to expose the more posterior left ventricle, and care is taken to avoid the circumflex coronary during injection. Although epinephrine continues to be advocated during resuscitation, there is a growing body of data suggesting that vasopressin may be superior to epinephrine in augmenting cerebral perfusion and other vital organ blood flow.[62] Administration of calcium, while theoretically deleterious during reperfusion injury, increases cardiac contractility and may be helpful in the setting of hypocalcemia produced by blood component transfusion (see Chapter 16). Although metabolic acidosis is common following RT and resuscitation,[63] the mainstay of therapy is provision of adequate alveolar ventilation and restoration of tissue perfusion. Sodium bicarbonate therapy has not been proven beneficial in facilitating defibrillation, restoring spontaneous circulation, or improving survival. However, it may be warranted following protracted arrest or resuscitation because catecholamine receptors may be desensitized with advanced metabolic acidosis.



A B

FIGURE 17-6 (**A, B**) Internal paddles for defibrillation are positioned on the anterior and posterior aspects of the heart.



A B

FIGURE 17-7 (**A, B**) Open cardiac massage is performed with a two-handed hinged technique; the clapping motion sequentially closes the hands from palms to fingers.

Thoracic Aortic Occlusion and Pulmonary Hilar Control

Following thoracotomy and pericardiotomy with evaluation of the heart, the descending thoracic aorta should be occluded to maximize coronary perfusion if hypotension (SBP <70 mm Hg) persists. We prefer to cross-clamp the thoracic aorta inferior to the left pulmonary hilum (Fig. 17-8). Exposure of this area is best provided by elevating the left lung anteriorly and superiorly. Although some advocate taking down the inferior pulmonary ligament to better mobilize the lung, this is unnecessary and risks injury to the inferior pulmonary vein. Dissection of the thoracic aorta is optimally performed under direct vision by incising the mediastinal pleura and bluntly separating the aorta from the esophagus anteriorly and from the prevertebral fascia posteriorly. Care should be taken in dissecting the aorta, and completely encircling it may avulse thoracic and other small vascular branches. Alternatively, if excessive hemorrhage limits direct visualization, which is the more realistic clinical scenario, blunt dissection with one's thumb and fingertips can be done to isolate the descending aorta. Once identified and isolated, the thoracic aorta is occluded with a large Satinsky or DeBakey vascular clamp. If the aorta cannot be easily isolated from the surrounding tissue, digitally occlude the aorta against the spine to effect aortic occlusion. Although occlusion of the thoracic aorta is typically performed after pericardiotomy, this may be the first maneuver upon entry into the chest in patients sustaining extrathoracic injury and associated major blood loss.

Control of the pulmonary hilum has two indications. First, if coronary or systemic air embolism is present, further embolism is prevented by placing a vascular clamp across the pulmonary hilum (Fig. 17-9). Associated maneuvers such as vigorous cardiac massage to move air through the coronary arteries and needle aspiration of air from the left ventricular apex and the aortic root are also performed (Fig. 17-10). Second, if the patient has a pulmonary hilar injury or marked hemorrhage from the lung parenchyma, control of the hilum may prevent exsanguination. Hilar control is best performed with a large Satinsky clamp or temporarily with digital control (see Chapter 30).

COMPLICATIONS AND CONSEQUENCES OF RESUSCITATIVE THORACOTOMY

Procedural Complications

Technical complications of RT involve virtually every intrathoracic structure. The list of such misadventures includes lacerations of the heart, coronary arteries, aorta, phrenic nerves, esophagus, and lungs, as well as avulsion of aortic branches to components of the mediastinum. Previous thoracotomy virtually assures technical problems from the presence of dense pleural adhesions and is therefore a relative contraindication to RT. Additional postoperative morbidity among ultimate survivors of RT includes recurrent chest bleeding; infection

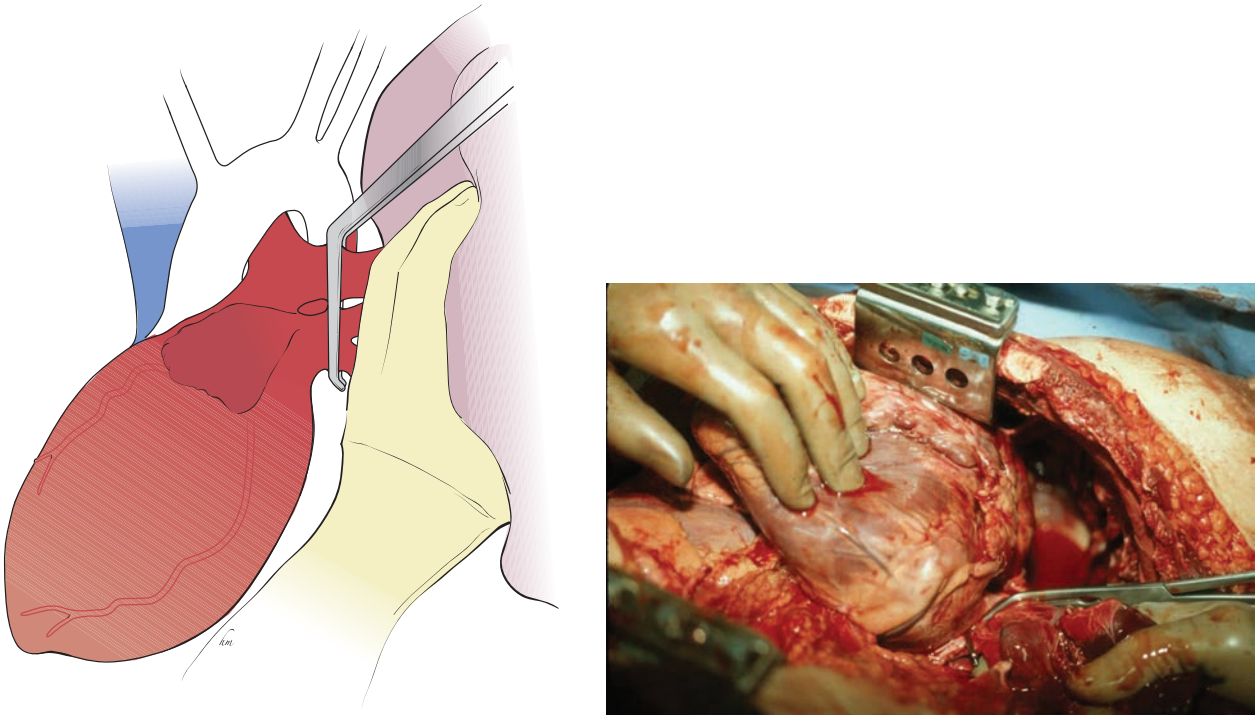
FIGURE 17-8 (**A, B**) Aortic cross-clamp is applied with the left lung retracted superiorly, below the inferior pulmonary ligament, just above the diaphragm. The flaccid aorta is identified as the first structure encountered on top of the spine when approached from the left chest.



A B

FIGURE 17-9 (**A, B**) A Satinsky clamp is used to clamp the pulmonary hilum for hemorrhage control or to prevent further bronchovenous air embolism.

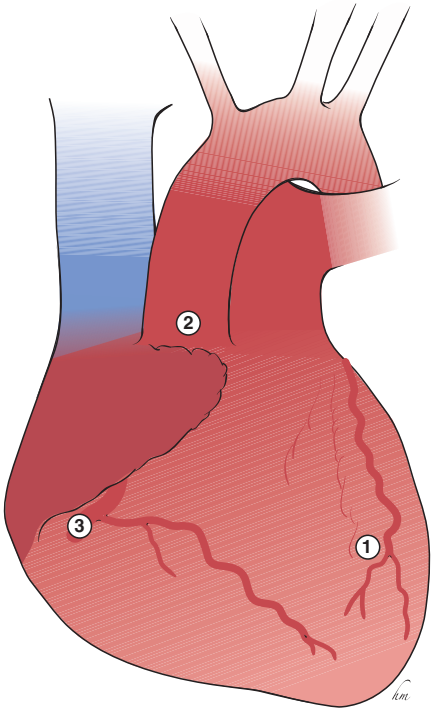


FIGURE 17-10 In cases of bronchovenous air embolism, sequential sites of aspiration include the left ventricle (1), the aortic root (2), and the right coronary artery (3).

of the pericardium, pleural spaces, sternum, and chest wall; and postpericardiotomy syndrome.

Importantly, there is a finite risk to the health care providers and trauma team performing an RT.[64] The use of RT by necessity involves the rapid use of sharp surgical instruments and exposure to the patient's blood. Even during elective procedures in the OR, the contact rate of patient's blood with the surgeon's skin can be as high as 50%, and the contact rate of patients' blood with health care workers' blood is as high as 60%. The overall seroprevalence rate of HIV among patients admitted to the ED for trauma is around 4%, but is much higher among the subgroup of patients most likely to require an RT, for example, 14% of penetrating trauma victims and nearly 30% of intravenous drug abusers. Caplan et al[65] found that 26% of acutely injured patients had evidence of exposure to HIV (4%), hepatitis B (20%), or hepatitis C virus (14%); there was no difference in the incidence comparing blunt to penetrating trauma. Thus, the likelihood of a health care worker sustaining exposure to HIV or hepatitis in the ED is substantial. The risk of contagion from exposures to HIV and other bloodborne pathogens can be minimized by the use of appropriate barrier precautions, minimizing the use of needles and scalpels, and selective use of RT.

Hemodynamic and Metabolic Consequences of Aortic Cross-Clamping

Aortic cross-clamping may be lifesaving during acute resuscitation, but there is a finite cost to the patient. Occlusion of the aorta results in an increase in blood pressure, but there is an associated 90% reduction in femoral artery SBP; in addition, abdominal visceral blood flow decreases to 2% to 8% of baseline values.[32,33] Therefore, cross-clamping magnifies the metabolic cost of shock by reducing local blood flow to abdominal viscera even further. This results in tissue acidosis and increased oxygen debt, and may ultimately contribute to postischemic multiple organ failure.[33] Additionally, return of aortic flow may not result in normalization of flow to vital organs; in animal models, blood flow to the kidneys remained at 50% of baseline despite a normal cardiac output. The metabolic penalty of aortic cross-clamping becomes exponential when the normothermic occlusion time exceeds 30 minutes, both in trauma and in elective thoracic aortic procedures.[66,67] Hypoxia of distal organs, white blood cells, and endothelium induces the elaboration, expression, and activation of inflammatory cell adhesion molecules and inflammatory mediators; this systemic inflammatory response syndrome has been linked to impaired pulmonary function and multiple organ failure[68] (see Chapter 63). Consequently, the aortic clamp should be removed as soon as effective cardiac function and adequate systemic arterial pressure have been achieved.

Removal of aortic occlusion may result in further hemodynamic sequelae.[69] Besides the abrupt reperfusion of the ischemic distal torso and washout of metabolic products and inflammatory mediators associated with aortic declamping, there are direct effects on the cardiopulmonary system. The return of large volumes of blood from the ischemic extremities, with its lower pH, elevated lactate, and other mediators, may exert a cardiodepressant activity on myocardial contractility.[70] Overzealous volume loading during aortic occlusion may also result in ventricular strain, acute atrial and ventricular dilatation, and consequently, precipitous cardiac failure.[34] Following release of aortic occlusion, there is impaired left ventricular function, systemic oxygen utilization, and coronary perfusion pressure in the postresuscitation period.[27,68] The transient fall in coronary perfusion may not be clinically relevant in patients with efficient coronary autoregulation; however, in patients with coronary disease or underlying myocardial hypertrophy, this increase in cardiac work may result in clinically critical ischemia.[27]

OPTIMIZING OXYGEN TRANSPORT FOLLOWING RT

Following RT, patients are frequently in a tenuous physiologic state. The combination of direct cardiac injury, ischemic myocardial insult, myocardial depressants, and pulmonary hypertension adversely impact postinjury cardiac function (see Chapter 58). Additionally, aortic occlusion induces profound anaerobic metabolism, secondary lactic academia, and release of other reperfusion-induced mediators. Consequently, once vital signs return, the resuscitation priorities shift to optimizing cardiac function and maximizing oxygen delivery to the tissues. The ultimate goal of resuscitation is adequate tissue oxygen delivery and cellular oxygen consumption (see Chapter 57). Circulating blood volume status is maintained

at the optimal level of cardiac filling in order to optimize cardiac contractility, and the oxygen-carrying capacity of the blood is maximized by keeping the hemoglobin above 7 to 10 g/dL. If these measures fail to meet resuscitative goals (eg, resolution of base deficit or clearance of serum lactate), inotropic agents are added to enhance myocardial function.

FUTURE CONSIDERATIONS

Defining Nonsalvageability

As clinicians faced with increasing scrutiny over appropriation of resources, it is critical to identify the patient who has permanent neurologic disability or death. Although there may be a widespread belief that survivors of RT have long-term functional or neurologic impairment, a recent analysis reports the majority have no long-term sequelae.[71] Resuscitative efforts should not be abandoned prematurely in the potentially salvageable patient, but field assessment of salvageability is unreliable.[43,72-76] Our clinical pathway attempts to optimize resource utilization, but outcomes must continue to be evaluated, searching for more definitive predictors of neurologic outcome. For example, markers of brain metabolic activity such as increased serum neuron-specific enolase activity appear to have prognostic significance for irreversible brain damage.[77] Although the optimal outcome of RT is undoubtedly the neurologically intact survivor, some have recognized the impact of RT on the potential salvageability of organs for donation.[78] The use of more advanced monitoring devices in the ED, together with further elucidation of the characteristics of irreversible shock, may permit a more physiologic prediction of outcome for these critically injured patients in the future.

Temporary Physiologic Hibernation

A potential adjunct in the care of traumatic arrest is the timely application of hypothermia. Recent randomized studies suggest the use of hypothermia for central nervous system protection after nontraumatic cardiac arrest.[79,80] In these studies, patients randomized to a period of mild-to-moderate hypothermia (32–34°C) after cardiac arrest had improved neurologic outcomes compared to those kept normothermic. This favorable effect was presumably due to a decrease in cerebral metabolic demand during hypothermia. In addition, hypothermia may reduce oxygen radical generation and inflammatory mediator production. By extension, then, if an injured patient in transport could be cooled to a minimal metabolic rate (ie, suspended animation), one can posit that transfer to definitive care might be possible.[81,82] Application of this principle to the multiply injured or bleeding patient, however, is problematic. Rapid cooling is not currently practical in the field, and there are legitimate concerns about the adverse effects of hypothermia on immune function and effective clot formation. Overall, although some[83] preclinical work supports the application of hypothermia after resuscitation from hemorrhage, other investigators have reached the opposite conclusion.[84]

Temporary Mechanical Cardiac Support

The concept of temporary mechanical cardiac support for the failing heart following injury is intuitively attractive. Unfortunately, experience with the intra-aortic balloon pump in this scenario has been unrewarding. The advent of centrifugal pumps (Bio-Medicus Pump; Bio-Medicus, Inc., Minneapolis, MN), which allow partial cardiac bypass without systemic anticoagulation, offers another potential means for increasing salvage of the moribund patient. Centrifugal pumps have become the standard approach for open repair of a torn descending thoracic aorta (see Chapter 30).[85,86] The adjunctive use of extracorporeal membrane oxygenation may also play a critical role in supporting the patient with massive injuries or early multiple organ failure.[87] Finally, hypothermia circulatory arrest may find utility in a broad spectrum of patients with injuries that are considered "irreparable."[88,89] Although a political issue, restoring perfusion in a patient with unsurvivable injuries is a potential source of organs for donation,[90] particularly with kidneys that can tolerate prolonged periods of warm ischemia.

Surgeon-Performed Ultrasound in Acute Care Surgery

Kazuhide Matsushima • Damon H. Clark • Heidi L. Frankel

KEY POINTS

- Medical diagnostic ultrasound imaging most often uses transducer frequencies between 2.5 and 10 MHz (1 megahertz = 1 million cycles per second).
- For the focused assessment with sonography for trauma (FAST) examination, either a sector- or convex-shaped transducer (low frequency: 2.5–5.0 MHz) is used to visualize the pericardial space and relatively deep regions in the abdominal cavity (hepatorenal fossa, splenorenal recess, pelvis).
- A negative FAST examination in the hypotensive patient with blunt trauma, particularly one with a pelvic fracture, should be followed by a second FAST examination in 15 to 30 minutes or a diagnostic peritoneal aspiration.
- The primary goal in the thoracic component of the extended FAST examination is to detect a pneumothorax or hemothorax in the pleural cavity.
- The assessment of intravascular volume status during resuscitation can be estimated by measuring the diameter and collapsibility of the inferior vena cava using ultrasound.
- The ultrasound diagnosis of acute calculous cholecystitis is made by visualizing cholelithiasis, thickening of the wall of the gallbladder, and the presence of pericholecystic fluid.
- The ultrasound diagnosis of acute appendicitis is made by visualizing an enlarged appendix with an appendicolith, lack of compressibility and diameter under compression of greater than 6 mm, and increased blood flow in the appendiceal wall.
- A high-frequency linear transducer is used to confirm the presence of a soft tissue infection or abscess and allow for percutaneous drainage.
- Cardiac goal-directed ultrasound includes the subxiphoid, parasternal long-axis, parasternal short-axis, and apical four-chamber views.
- During ultrasound-guided catheterization of the internal jugular vein, the transverse view is used to identify puncture of the vessel, whereas the longitudinal view is beneficial to localize the needle tip and wire.

INTRODUCTION

Ultrasound is routinely incorporated into the workup of patients with a variety of trauma, critical care, or emergency surgical disorders.[1-6] Despite advances in other imaging modalities such as multidetector-row computed tomography (MDCT), the ability to acquire real-time and repeatable data with ultrasound allows the surgeon to make critical decisions expeditiously and with minimal risk of complications. Surgeons are also capable of obtaining good-quality images and interpreting ultrasound examinations independently.[7-9] Given that medical students, surgical residents, and fellows have frequent opportunities to learn the technique of bedside ultrasound examination in patients with trauma and emergency general surgery problems, broad familiarity is typical.[10] Similarly, the use of ultrasound in critically ill patients for resuscitation, hemodynamic monitoring, and procedural guidance is now commonly performed.[11-18] These critical care ultrasound studies can also be completed at the bedside and, therefore, can avoid transportation of patients out of the intensive care unit (ICU). This chapter reviews the indications, techniques, and currently available data for ultrasound examinations in trauma, emergency general surgery, and critical care patients.

PHYSICS OF ULTRASOUND

Ultrasonography is operator dependent. Therefore, an understanding of select principles of ultrasound physics is necessary so that images may be acquired rapidly and interpreted correctly. Knowledge of these basic principles enables the acute care surgeon to select the appropriate transducer, optimize resolution of the image, and recognize artifacts. Basic terms and principles of physics relative to ultrasound imaging in the acute setting are defined in Tables 18-1, 18-2, and 18-3.

In general, an ultrasound system includes the following components: (1) a transmitter that controls electrical signals sent to the transducer; (2) a receiver or image processor that admits the electrical signal; (3) a transducer containing piezoelectric crystals to interconvert electrical and acoustic energy; (4) a monitor to display the ultrasound image; and (5) an image recorder or printer.[19,20] The ultrasound images themselves depend on the orientation of the transducer or probe relative to the structure or organ being imaged, with each transducer having an indicator that directs its orientation to the screen. The indicators on most probes are oriented such that placing the indicator cephalad in a coronal or sagittal plane or to the left in the transverse plane will orient the image correctly. This left-to-right convention is typically reversed in cardiac imaging presets that are employed in focused echocardiography examinations. As the image may be purposefully reversed by a machine adjustment, the surgeon should confirm the orientation of the probe by adding ultrasound gel to the probe's footprint and gently rubbing it to visualize where the motion is detected on the screen (Fig. 18-1). This will allow the surgeon to determine how the indicator orients the image. The orientations or scanning planes are described in Table 18-4.[21]

Although diagnostic ultrasound uses transducer frequencies ranging from 1 to 30 MHz (1 megahertz = 1 million cycles per second), medical diagnostic imaging most often uses frequencies between 2.5 and 10 MHz (Table 18-5). Accordingly, transducers are chosen on the basis of the depth of the structure or organ to be imaged. High-frequency transducers (≥5 MHz) provide excellent resolution for imaging superficial structures such as a thyroid nodule or an abscess in the soft tissue of an extremity. Lower-frequency transducers emit waves that penetrate deeply into tissue and are preferred for visualizing organs such as the liver or spleen.[19,22,23]

ULTRASOUND IN TRAUMA

Since the 1980s, ultrasound has been used to detect free fluid such as blood in the pericardial and intraperitoneal spaces in acutely injured patients.[24,25] This simple, rapid, and accurate ultrasound technique was adopted in the United States in the 1990s and subsequently named the focused assessment with sonography for trauma (FAST).[26] The application of ultrasound has expanded to other areas of the body to identify injuries and help to direct patient management in the prehospital setting and within the emergency room.

Technique of FAST: General Principles

The FAST examination is performed by a trauma team member (trauma surgeon, emergency medicine physician, trainee, or advanced practice provider) (Fig. 18-2). Although a designated examiner typically performs the FAST examination, the care provider who conducts the primary and secondary survey may also complete the FAST sequentially. The patient's chest and abdomen are exposed during the primary survey. Trauma patients are normally placed in the supine position during the primary and secondary survey of the Advanced Trauma Life Support (ATLS) algorithm.[27] Therefore, dependent portions in the abdominal cavity should be scanned to identify abnormal hypoechoic areas (ie, free fluid). In many institutions, a small-size portable ultrasound machine is attached to the bedside tower in the emergency department (Fig. 18-3). For the FAST examination, either a sector- or convex-shaped transducer (low frequency: 2.5–5.0 MHz) is used to visualize the pericardial space and relatively deep regions in the abdominal cavity. A linear-shaped transducer (high frequency: ≥7.5 MHz) is not suitable for this reason (Fig. 18-4). Before starting the examination, the image settings, including depth or gain, should be adjusted. Recording of real-time images is required for review to ensure quality of the FAST examination. The entire examination should not require more than 5 minutes, even in the hands of trainees. The goal of the FAST examination is to detect or exclude fluid in the pericardial space and abdominal cavity.

Pericardial Examination

The FAST examination typically begins with visualizing the heart so that the image settings, such as gain or depth, can be optimized (with a known fluid-filled structure). It is also the component of the examination that may illicit immediate surgical response (eg, thoracotomy). The intracardiac blood should be anechoic, and the posterior heart should be visualized on the screen. First, a transducer is placed in the subxiphoid region for a sagittal or transverse view of the heart. The transducer should be directed toward the head of the patient under the xiphoid process. In this position, the heart will be visualized beneath the left lobe of the liver. This sagittal view enables the examiner to view simultaneously the inferior vena cava and was prescribed in the original description of the FAST examination. A transverse view allows the provider to visualize more pericardial surface area, although more pressure is applied with consequent pain. A pericardial effusion is observed as an anechoic area around the heart (Fig. 18-5). Both the anterior and posterior walls of the heart should be visualized because a small effusion can otherwise be missed. For patients with severe injuries to the chest and/or abdominal wall, subcutaneous emphysema, a narrow costal angle, or a thick thoracoabdominal wall, appropriate views may not be obtainable through this window. Alternate views include the apical view or parasternal view in which the transducer is placed adjacent to the left nipple or along the sternum in the second intercostal space, respectively.

TABLE 18-1: Ultrasound Physics Terminology Relevant to Ultrasound Imaging

Term	Definition	Significance
Ultrasound	High-frequency (>20 kHz) mechanical radiant energy transmitted through a medium	Diagnostic ultrasound: 1–30 MHz Medical diagnostic ultrasound: 2.5–10 MHz
Frequency	Number of cycles per second (10^6 cycles/s = 1 MHz)	Increasing frequency improves resolution Higher-frequency transducers (eg, 7.5 MHz) provide better resolution of tissues.
Propagation speed	Speed with which wave travels through soft tissue (1540 m/s); propagation speed (determined by density and stiffness of medium) is greater in solids than in liquids and greater in liquids than in gases	To image an organ, the ultrasound wave must be emitted from the transducer, travel through a medium (soft tissue or liquid), strike the organ, and bounce back to the transducer. It is the reflected wave that forms the ultrasound image. Ultrasound waves travel better through solids and liquids (molecules are more compact, less interference) than through gas. Therefore, ultrasound waves do not travel well through air-filled structures (eg, lungs or bowel). These organs are visualized, however, when they are surrounded by fluid that acts as an acoustic window and allows the through transmission of waves. The formation of a good ultrasound image depends on two principles of physics: (1) how well sound waves are transmitted through the tissue (acoustic impedance, which equals the density of the material times the speed of sound through the material) and (2) the amount of sound waves reflected once they hit a target organ. A good ultrasound image, therefore, is formed when sound waves travel well through tissues of higher and similar density, such as the liver and kidney. In the presence of subcutaneous emphysema, a large impedance mismatch exists because of the difference in densities between the air-filled tissue and the soft tissue (liver). As a result, the waves travel poorly through the air-filled tissue, and not enough of them are reflected back to the transducer to form a good image. The air-filled lung is not normally visualized because the air within the lung reflects the sound waves too strongly, and therefore, no image is formed. When a hemothorax or pleural effusion is present, the differences in tissue acoustic impedance between fluid and the lung allow the lung to be visualized.
Acoustic impedance		Acoustic impedance = density of tissue × the speed of sound in tissue (sound velocity). The strength of the returning wave depends on difference in density between two organs imaged. Structures of different acoustic impedance (eg, bile and gallstone) are relatively easy to distinguish from one another. Those of similar acoustic impedance (eg, spleen and kidney) are more difficult to distinguish, although Gerota's fascia has a higher tissue acoustic impedance (more dense) and, therefore, allows the spleen and kidney to be visualized as two distinct organs.
Amplitude	Strength or height of wave	Amplitude and intensity are reduced (attenuated) as waves travel through tissue. The higher the frequency, the more the wave is attenuated. Therefore, higher-frequency transducers cannot visualize deep structures well. Increasing the gain setting on the machine enhances the amplitude of the returning or reflected ultrasound waves. If the gain setting is too high, echo amplification is too strong and the image appears too bright.
Attenuation	Decrease in amplitude and intensity of wave as it travels through a medium; attenuation is affected by absorption, scattering, and reflection	
Absorption	Conversion of sound energy into heat	
Scattering	Redirection of wave as it strikes a rough or small boundary	

(*continued*)

TABLE 18-1: Ultrasound Physics Terminology Relevant to Ultrasound Imaging (*Continued*)

Term	Definition	Significance
Reflection	Return of wave toward transducer	
Artifact	Error in imaging; features on the ultrasound image that do not have precise correspondence to the image being scanned	Examples include shadowing (gallstones), reverberation (comet tail, metallic fragment), and mirror image (diaphragm as strong reflector). In the normal sagittal ultrasound image of the lower thoracic cavity, the supradiaphragmatic area (lung) appears to have a similar echogenicity to the liver because of a mirror-image artifact. This artifact occurs because the diaphragm acts as a strong reflector of the ultrasound waves, sending them back to the transducer and then re-reflecting them as they return to the interface of the diaphragm and the liver. (It should be recalled that it is the *returning* or *reflected* wave that forms the ultrasound image on the screen.) These re-reflected or smaller waves return to the transducer *after* the original reflected waves and, therefore, "create" an image that appears to be deeper than the liver and diaphragm, hence the "mirror image."[76]

kHz. kilohertz; MHz, megahertz.

Abdominal Examination

There are three dependent spaces that are scanned in the abdominal portion of the FAST examination: the hepatorenal recess (Morison's pouch), the splenorenal recess, and the pelvis around the bladder. To obtain a longitudinal view in the hepatorenal recess, the transducer is placed in the right upper quadrant (RUQ) of the abdomen. Although this view is often called the RUQ view, optimal views typically are obtained in the right mid-to-posterior axillary line at the level of the 9th to 12th ribs. The right lobe of the liver and the right kidney should be visualized in the same view (Fig. 18-6). Fanning the transducer to visualize the right kidney from one side to the other is key to preventing a false-negative examination, and free fluid can be identified between the liver and kidney. For patients with a significant amount of intraperitoneal fluid, this fluid may also be visualized above the anterior surface of the liver. The longitudinal view of the splenorenal recess is obtained next in the left upper quadrant (LUQ). The transducer should be oriented more superiorly and posteriorly than in the RUQ (Fig. 18-7). Given that trauma patients often present with a full stomach that can be misread as free fluid, it is imperative to visualize the spleen and the left kidney in the same image (Fig. 18-8). Finally, sagittal and transverse views are obtained in the pelvis. The transducer is placed a few centimeters above the pubic symphysis. The FAST examination is ideally performed before an indwelling urinary catheter is placed. Fluid inside (urine) and outside (blood) of the bladder is visualized as an anechoic area separated by the bladder wall (Fig. 18-9).

TABLE 18-2: Essential Principles of Ultrasound

Principle	Explanation
Piezoelectric effect	Piezoelectric crystals expand and contract to interconvert electrical and mechanical energy.
Pulse-echo principle	When ultrasound waves contact an organ, some are reflected and some are transmitted through the organ or tissue. Reflected waves return to the transducer and generate electrical impulses that are converted to the image seen on the monitor.

TABLE 18-3: Terminology Used in Interpretation of Ultrasound Images

Term	Definition
Echogenicity	Degree to which tissue echoes the ultrasonic waves (generally reflected in ultrasound image as degree of brightness)
Anechoic	Showing no internal echoes; appearing dark or black
Isoechoic	Having appearance similar to that of surrounding tissue
Hypoechoic	Less echoic or darker than surrounding tissue
Hyperechoic	More echoic or brighter than surrounding tissue

Data in Blunt Trauma Using the FAST Examination

The utility of the FAST examination has been examined most extensively in patients with blunt torso injury.[2,7,28-35] Since the 1990s, many prospective and retrospective studies have been conducted in various patient populations. A significant disparity in data regarding the FAST examination is due to different inclusion criteria and outcomes of interest (intraperitoneal fluid vs any intra-abdominal injury).

TABLE 18-4: Scanning Planes Used in Ultrasound Imaging

Scanning plane (Fig. 18-2)	Definition	Transducer orientation
Sagittal	Divides body into right and left sections parallel to long axis	Transducer indicator points toward patient's head
Transverse	Divides body into superior and inferior sections perpendicular to long axis	Transducer indicator points toward patient's right side
Coronal	Divides body into anterior and posterior sections perpendicular to sagittal and parallel to long axis	Transducer indicator points toward patient's head when imaging exteriorly

Accuracy of the FAST examination can be affected by several factors, including hemodynamic stability (a likely surrogate for amount of fluid) or associated injuries.[36,37] Currently, the dominant indication for a FAST examination remains hypotensive patients with blunt torso injuries. A large prospective study conducted by Rozycki et al[38] demonstrated that surgeon-performed FAST was 100% sensitive and 100% specific for detecting hemoperitoneum in hypotensive patients with blunt abdominal trauma. Patients with a positive FAST examination (showing intra-abdominal free fluid) and persistent hypotension should be taken to the operating room for an emergent exploratory laparotomy. In contrast, a negative FAST examination should not be used to rule out a serious intra-abdominal injury in patients with unstable vital signs. Diagnostic options in these cases are to (1) repeat the FAST examination in 15 to 30 minutes or (2) perform a bedside diagnostic peritoneal aspiration to determine the presence of intraperitoneal hemorrhage.[39,40] Furthermore, it remains

unclear how sensitive the FAST examination can be for intraperitoneal fluid in patients with pelvic fractures. More specifically, Friese et al[36] reported that the sensitivity of the FAST examination performed by surgical residents for high-risk patients with a pelvic fracture (age >55 years, systolic blood pressure [SBP] <100 mm Hg, or unstable pattern fracture) was only 26.1% for detecting intraperitoneal fluid. Even for patients with an SBP of less than 100 mm Hg, the FAST examination was not reliable to rule out a hemoperitoneum (sensitivity, 36.4%). Another recent retrospective study, in contrast, concluded that the FAST is sensitive enough (96%) to rule out clinically significant hemoperitoneum associated with pelvic fracture in hemodynamically unstable patients.[41] Although several studies have been reported showing the utility of the FAST examination in the detection of intraparenchymal injuries involving solid organs, the FAST examination carries a low sensitivity in detecting intra-abdominal injuries that are not associated with intra-abdominal fluid.[8,42,43] In the series by Chiu et al,[8] 29% of patients with blunt abdominal injury had no hemoperitoneum. In these patients, the FAST examination was interpreted as negative, although computed tomography (CT) imaging identified grade 2 to 3 splenic and hepatic injuries.

Pericardial fluid secondary to a cardiac injury is rarely observed in patients with blunt trauma. As a result, data reflecting the accuracy of the FAST examination in detecting this fluid are scarce. A series early in the 1990s reported no patients with pericardial fluid after blunt trauma.[38] Press and Miller[44] focused on the cardiac component of the FAST examination in blunt trauma using institutional databases. Out of 29,236 patients with blunt trauma over 7 years, only 14 patients were identified with a hemopericardium and 3 patients with cardiac rupture, respectively. Further, the incidence of hemopericardium confirmed during the emergency cardiac ultrasound was only 0.13%.

Data in Penetrating Trauma Using the FAST Examination

Patients with penetrating injury to the anterior chest can potentially sustain life-threatening injuries. A cardiac injury with an associated hemopericardium should be identified rapidly and accurately regardless of a patient's hemodynamic stability, as early detection of these injuries improves the prognosis. Thus, using ultrasound for patients with penetrating wounds in the so-called "cardiac box" is another critical indication for the FAST examination. A prospective multicenter study by Rozycki et al[45] examining patients with precordial or transthoracic wounds at five Level I trauma centers suggested that a hemopericardium could be identified in all patients without any false-negative examinations (sensitivity 100%). Therefore, patients with a positive pericardial view should have an emergent sternotomy or thoracotomy based on the very high specificity (96.9%). These data were consistent with results from other series of the precordial FAST examination.[1,38] A pitfall in interpreting the pericardial FAST examination for patients with a suspected penetrating cardiac injury, however, is that pericardial blood can decompress into the thoracic cavity if there is an associated laceration of the pericardial sac.[46] In these cases, a patient could present with a hemothorax without evidence of hemopericardium on the FAST examination (Fig. 18-10).

The utility of the FAST examination is limited in patients with penetrating abdominal trauma as compared to blunt injuries. Hemodynamically unstable patients with a penetrating injury require operative intervention regardless of the result of a FAST examination. Similarly, patients with peritonitis should be explored independent of FAST examination results. Therefore, ultrasound examination is not included in the algorithm suggested by the Western Trauma Association to guide the management of patients with anterior abdominal stab wounds.[47] This is supported by multiple studies showing a low sensitivity of the FAST examination for intra-abdominal injuries.[48,49] Although Rozycki et al[7] showed comparable sensitivity and specificity for the FAST examination in patients with penetrating wounds (sensitivity, 83.8%; specificity, 97.4%), subsequent studies consistently failed to replicate this accuracy.[7] In the aforementioned multicenter study, the FAST examination was performed in half of hemodynamically stable and asymptomatic patients with abdominal stab wounds.[47] Of these, only 21% of patients who required therapeutic laparotomy had a positive FAST examination. Similarly, Soffer and Cohn[50] conducted a prospective cohort study to include patients with both stab and

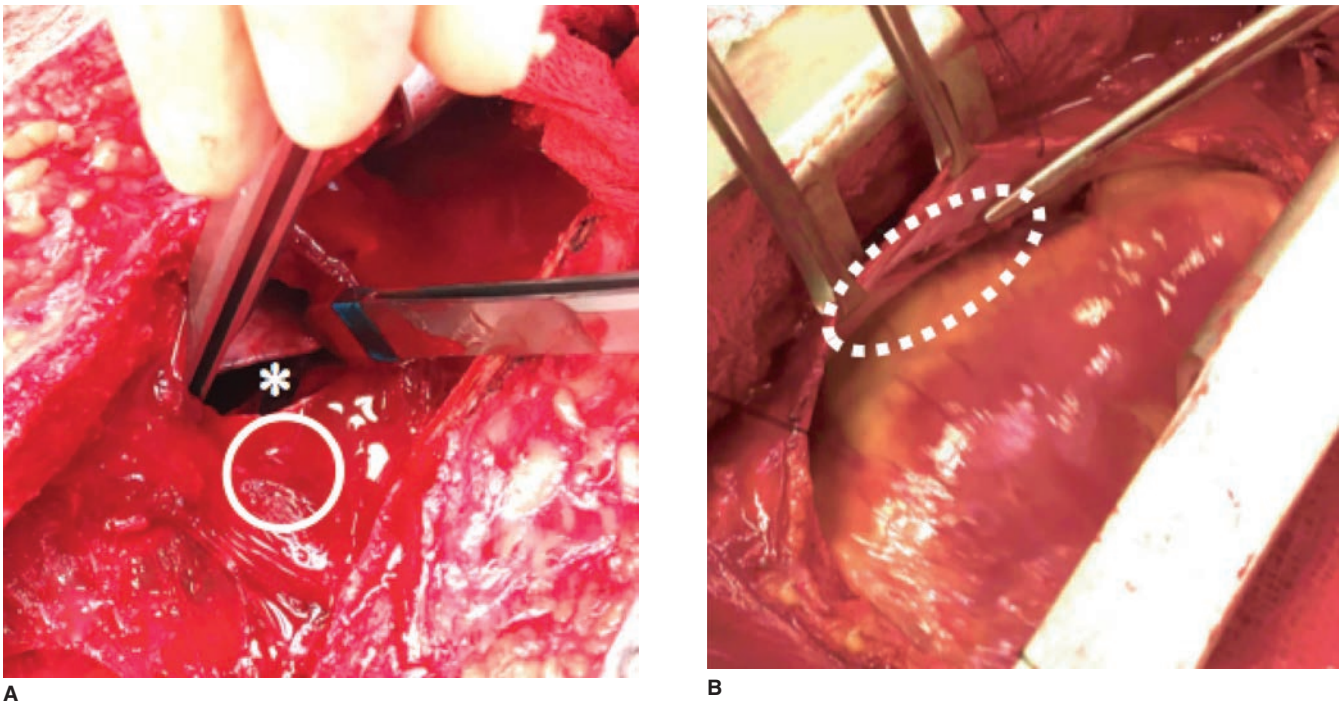

FIGURE 18-10 A case with false-negative pericardial-focused assessment with sonography for trauma (FAST). (**A**) Stab wound was penetrated through the right thorax into the heart (circle). Asterisk indicates lung. (**B**) A hole in the pericardium (dotted area) and injury to the right atrial appendage are identified.

gunshot wounds. A majority of the FAST examinations were performed by trauma surgeons or surgical trainees. Sensitivities of the FAST examination for therapeutic laparotomy in patients with stab and gunshot wounds were 47% and 49%, respectively. Approximately 40% of injuries to a hollow viscus, the most common injury identified at exploratory laparotomy, were missed by the FAST examination. Furthermore, authors have indicated that initial FAST findings rarely alter their management (3 of 177 cases). To date, there are scarce data to determine the role of the FAST examination in hemodynamically unstable patients with penetrating injury. For unstable patients with multicavitary penetrating injury (eg, thoracoabdominal injury), the FAST examination can be a useful tool to guide surgeons in their decision as to which cavity to explore first.[51]

Technique of Extended FAST

Thoracic injuries are common in multisystem blunt or penetrating trauma to the torso.[52] The ATLS protocol emphasizes the importance of identifying life-threatening thoracic injuries, including pneumothorax and hemothorax, during the primary and secondary survey.[27] Frequently, these injuries are missed on a physical examination as patients do not often present with classic signs. Although a chest x-ray (CXR) is considered the gold screening standard for these serious thoracic injuries, equipment or personnel may not be readily available in certain circumstances. Further, because of the patient's position (supine) and other interfering factors such as a backboard, foreign bodies, and/or associated injuries, the quality of the CXR is often inadequate for use as a screening tool (ie, 50% sensitive for detection of a pneumothorax).[53] The application of thoracic ultrasound in trauma patients was first reported as a part of the ultrasound examination in the 1990s.[54] Although inertia was evident, an extended FAST (E-FAST) examination is now typically performed in the trauma bay to detect thoracic injuries.

The E-FAST is normally performed as a continuation of the FAST examination. It is not necessary to change the position of the patient (supine) or the type of transducer (low-frequency sector or convex type). The primary goal in the thoracic component of the E-FAST examination is to detect air (pneumothorax) and/or fluid (hemothorax) in the thoracic cavity. After the pericardial and abdominal examination, the transducer is placed longitudinally in the mid-axillary line, a few costal spaces more cephalad than the area for the RUQ FAST examination. This view should include the right lobe of the liver and diaphragm, which has respiratory excursion. A hemothorax is observed above the diaphragm as an anechoic area (Fig. 18-11). In patients with a moderate to large hemothorax, passively collapsed lung parenchyma is detected as a hypoechoic structure. This maneuver is repeated on the left side to scan the entire thoracic cavity. The transducer should be placed more posteriorly and cephalad to visualize the left hemidiaphragm. The remainder of the E-FAST examination can be performed with either the same low-frequency transducer or a high-frequency (7.5–10 MHz) linear transducer. When a low-frequency transducer is used, the depth of image

FIGURE 18-11 Hemothorax (asterisk) is seen above the right diaphragm.

requires adjustment to focus on more superficial structures of the anterior thoracic wall. Patients should be maintained in the supine position as the goal of this maneuver is to identify a pneumothorax located anteriorly. The transducer is placed in the midclavicular or parasternal line longitudinally. In order to obtain an optimal view, the transducer should be placed in the intercostal spaces (superior, mid, and lower levels). In normal individuals, a "lung sliding" sign can be observed. This is the finding whereby the parietal and visceral pleurae (both hyperechoic linear structures) are moving in relation to each other. Similarly, "comet tails" are visualized in normal individuals due to artifacts generated by reverberation of the ultrasound waves. This sign is named for vertical, hyperechoic lines arising from the pleural line (Fig. 18-12).These two signs (sliding and comet tails) are *not* observed in patients

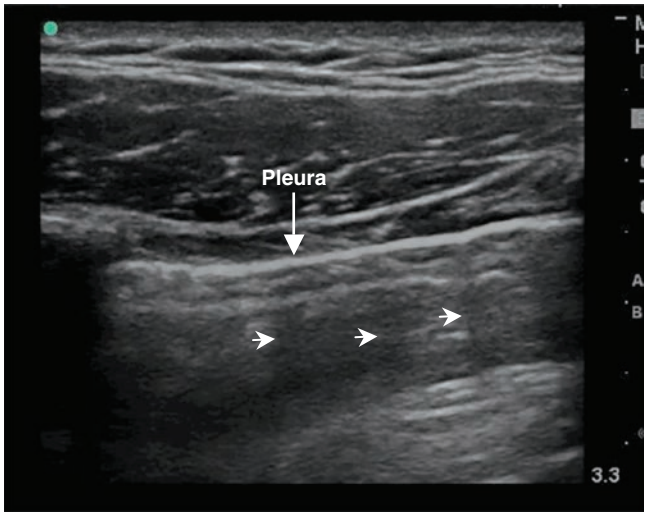

FIGURE 18-12 The "lung sliding" artifact is seen about the pleural line (vertical arrow) in dynamic imaging of the normal lung. Comet tail artifacts (horizontal arrows) can be observed in the normal lung as well.

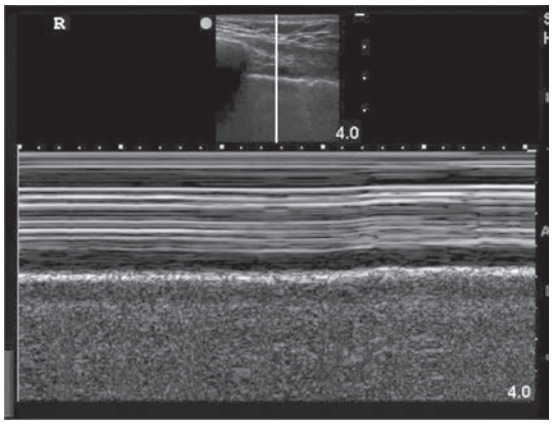
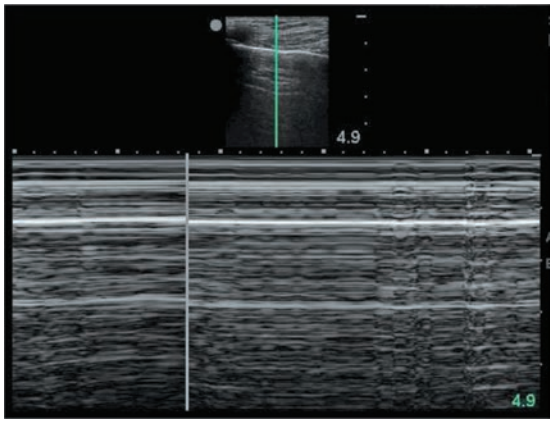


A



B

FIGURE 18-13 M-mode images show a "seashore" sign in the normal lung (**A**) and "barcode sign" in the lung with a pneumothorax (**B**) (see text).

with a pneumothorax, who have air between the parietal and visceral pleurae. If an ultrasound machine with an M-mode (motion mode) function is employed, the cursor is placed perpendicular to the pleural line. While linear and granular patterns are seen above and below the pleural line, respectively, in normal lung ("seashore sign"), a linear pattern both above and below the pleural line, the so-called "barcode sign," is appreciated in patients with a pneumothorax (Fig. 18-13). Finally, an even more specific ultrasonographic sign for a pneumothorax is called the "lung point." The transition zone between normal lung and the pneumothorax is apparent by the seashore (normal) and barcode signs (abnormal) aligning on M-mode or the sliding lung (normal) adjacent to the nonsliding lung (abnormal) in B-mode imaging (Fig. 18-14).

Data in Trauma Patients Using the E-FAST

Application of thoracic ultrasound in the trauma setting has been described since the 1990s.[54,55] In an early series reported by Ma et al,[54] thoracic ultrasound performed by emergency medicine physicians on 240 patients with both blunt and

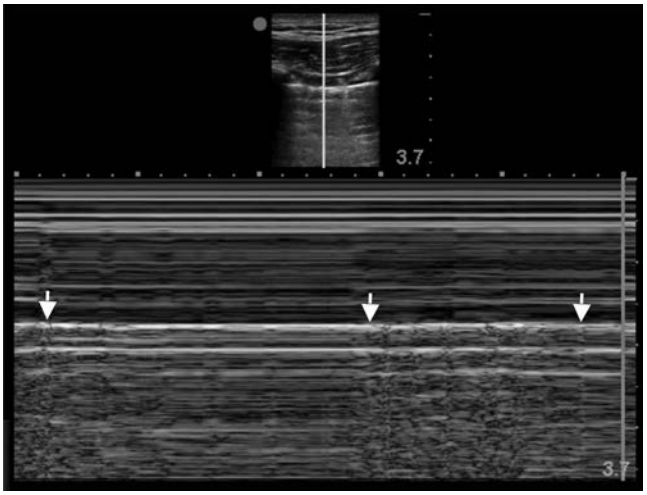


FIGURE 18-14 The lung point is best visualized on M-mode imaging representing the transition between normal lung and a pneumothorax.

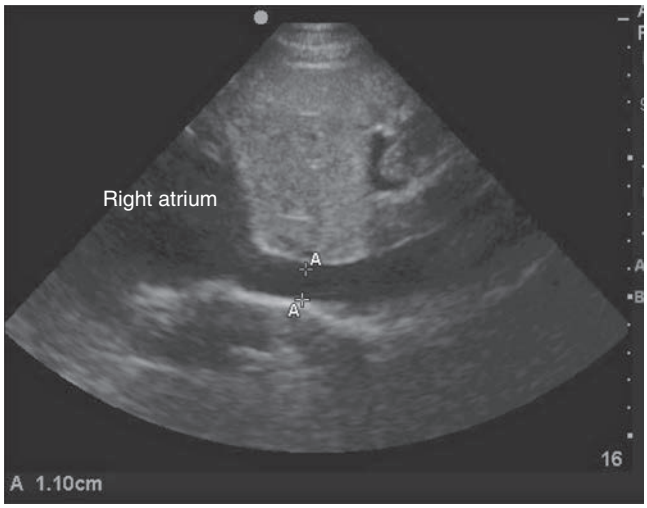

FIGURE 18-15 The inferior vena cava is measured within a few centimeters of entry into the right atrium.

penetrating trauma had a sensitivity of 96.2%, a specificity of 100%, a positive predictive value of 100%, a negative predictive value of 99.5%, and an accuracy of 99.6% to detect a hemothorax confirmed by either tube thoracostomy or CT. Surgeon-performed ultrasound to detect a hemothorax displayed similar results (sensitivity, 97.5%; specificity, 99.7%) to that of the CXR but with a significantly shorter examination time (1.30 ± 0.08 vs 14.18 ± 0.91 minutes, P <.0001).[56] Other early studies that examined the sensitivity and specificity of the ultrasound for a hemothorax also showed promising results comparable to the CXR. The utility of ultrasound to detect a pneumothorax was demonstrated in the 1990s for patients in the ICU.[57] Bedside ultrasound can be helpful to expedite care in patients with unstable vital signs. In trauma patients, Knudtson et al[58] conducted a prospective study to evaluate surgeon-performed ultrasound to detect a pneumothorax. As previously noted, the diagnosis of a pneumothorax was made based on the absence of the lung sliding sign and/or the comet tail artifact. Of note, a low-frequency (2.5–4 MHz) transducer was used in this study. In comparison with the CXR, ultrasound displayed a sensitivity of 92.3%, a specificity of 99.6%, a positive predictive value of 92.3%, a negative predictive value of 99.7%, and an accuracy of 99.3%.

Ultrasound-Guided Resuscitation in the Emergency Department

The resuscitation of severely injured patients should be initiated immediately in the trauma bay. Although damage control resuscitation has been proposed for over a decade, invasive hemodynamic monitoring devices to guide the resuscitation are not always available until the patient is transferred to the ICU. Two components of information that should be obtained using ultrasound are the intravascular volume status (preload) and contractility of the heart. The assessment of intravascular volume status can be estimated by measuring the diameter and collapsibility of the inferior vena cava (IVC) using ultrasound (Fig. 18-15).[59] In one study, noncardiologists successfully visualized the IVC to measure the diameter in 89% of trauma and surgical patients.[60] The assessment of the intravascular volume depletion by a small IVC diameter (<1 cm) with significant collapsibility (>50% with respiration) was comparable to the central venous pressure measured with an intravenous catheter with regard to the examination of cardiac function. Murthi et al[61] compared the cardiac index (CI) obtained by the focused rapid echocardiography evaluation (FREE) to other relevant invasive hemodynamic monitoring methods (pulmonary artery catheter and arterial pressure waveform–based device). Their data suggested that patient management was frequently changed based on the data derived from FREE. Furthermore, there was good agreement between the CIs obtained in FREE and a pulmonary artery catheter. Of interest, the role of point-of-care bedside ultrasound for unstable trauma patients has been evaluated in a randomized control trial.[62] In this study, the limited transthoracic echocardiogram (LTTE) was performed by trained noncardiologists (trauma surgeon, emergency medicine physician, surgical and emergency medicine residents) in the trauma bay. In the LTTE, fluid status, contractility, and pericardial effusion were reported. The use of the LTTE was associated with significantly less volume of intravenous fluid administered, faster time to the operating room, and a higher rate of admission to the ICU. In a subgroup of patients with a traumatic brain injury, a significantly lower mortality rate was also noted in the LTTE group (14.7% vs 39.5%; P = .03).

Ultrasound in Prehospital, Mass Casualty, and Military Settings

With recent advances in technology, ultrasound machines have now become incredibly small and portable. In special environments such as prehospital settings, mass casualty incidents, or military care, a smaller hand-carried ultrasound machine can be used to make rapid diagnoses in injured patients.[63-67]

One of the goals of the ultrasound examination in the out-of-hospital setting is to assist in triaging patients. Although a smaller machine is used, the quality of images should be equivalent to those obtained in the conventional FAST/E-FAST examination within the emergency department. This will facilitate detection of free fluid in the pericardial and intra-abdominal spaces, as well as a hemothorax and/or pneumothorax. In addition, ultrasound has been used for the evaluation of other types of injuries to the eye and extremities.[68,69]

The impact of the prehospital FAST (PFAST) exam on the management of patients with blunt abdominal trauma was evaluated in a multicenter prospective study from Germany.[70] In 95% of patients, the prehospital time was not prolonged because of the PFAST examination (mean time, 2.4 minutes), and good or acceptable quality images could be obtained to establish a diagnosis in 93% of patients. Compared with the FAST examination or CT performed in the emergency department, the PFAST examination displayed a sensitivity of 93%, specificity of 99%, and accuracy of 99%. A mass casualty incident is another unique situation that requires rapid and accurate triage of a large number of trauma victims. The use of ultrasound in a mass casualty incident was initially reported by Sarkisian et al[64] in the early 1990s. Following the Armenian earthquake in 1988, ultrasound examinations identified trauma-related pathology in 51 of 400 patients screened. The average study time was 4 minutes, with no false-positive and four false-negative cases. Zhou et al[67] reported a sensitivity of 91.9%, specificity of 96.9%, and accuracy of 96.6% in detecting any intra-abdominal injury from a more recent experience of surgeon-performed ultrasound in a Chinese earthquake.

There are limited studies that confirm the feasibility of ultrasound for the triage of wounded soldiers and civilians in the combat setting.[71,72] The FAST examination was performed in 281 patients during the 1-month period of the Second Lebanese War.[72] Sensitivity, specificity, and accuracy of the FAST examination to detect intraperitoneal free fluid were 76.5%, 98.4%, and 94.0% in soldiers and 67.6%, 95.2%, and 91.6% in civilians, respectively. As further developments in telemedicine are expected to improve the accuracy of the ultrasound examination in the field, images obtained there can be reviewed by physicians at a support hospital.[73]

The utility of ultrasound in detecting different types of injury has also been studied in weightlessness (eg, the International Space Station [ISS]).[74-76] A preliminary report by Sargsyan et al[74] showed the feasibility of an ISS crew member–performed FAST examination in space. Remote guidance of the examination can be provided by the on-ground ultrasound experts, and images are transmitted via a satellite link for real-time interpretation.

ULTRASOUND IN EMERGENCY GENERAL SURGERY

In addition to a thorough history and physical examination, ultrasound is frequently used in the management of patients with acute abdominal pain. It is particularly helpful when the consulting surgeon personally performs ultrasound imaging to expedite the diagnosis.

TABLE 18-6: Ultrasound Findings of Acute Cholecystitis

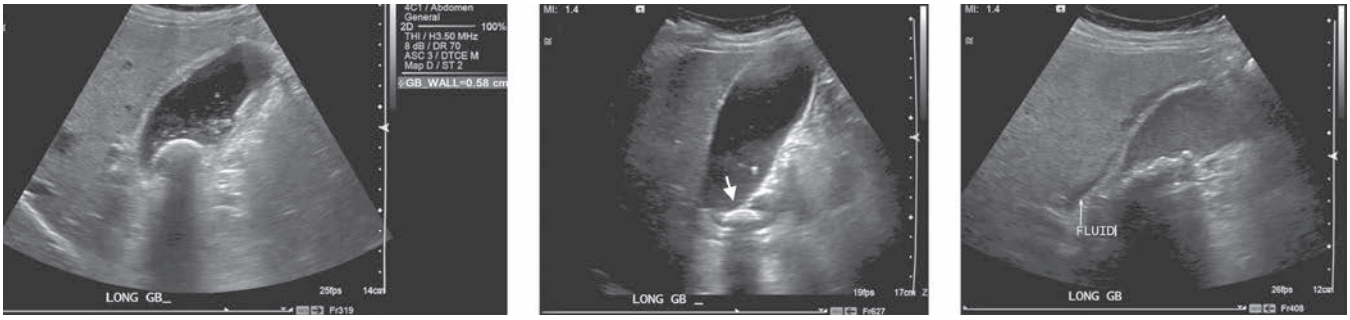
Sonographic Murphy sign (tenderness elicited by compressing the gallbladder with the transducer)
Thickened gallbladder wall (>4 mm)
Noted in patients without chronic liver disease with ascites or right heart failure
Enlarged gallbladder (long axis >8 cm, short axis >4 cm)
Impacted gallstone, debris echo, pericholecystic fluid collection
Sonolucent layer in the gallbladder wall, striated intramural lucencies, and Doppler signals

Acute Biliary Disease

In patients with RUQ abdominal pain, acute biliary disease is always listed within the differential diagnosis. Ultrasound examination of the RUQ area can visualize the majority of biliary structures including the gallbladder and bile duct. Although MDCT is frequently obtained for patients with acute abdominal pain, ultrasound is still considered the imaging modality of choice for patients with suspected acute biliary disorders.[77,78] The diagnostic criteria for acute cholecystitis consist of clinical signs, physical findings, and laboratory results in a guideline based on an international consensus meeting.[79] Ultrasound or other imaging modalities are used to confirm the diagnosis (Table 18-6 and Fig. 18-16). The sensitivity and specificity of ultrasound for acute cholecystitis have been reported previously in multiple studies.[80-82] In 1994, a systematic review by Shea et al[83] documented an 88% sensitivity (95% confidence interval, 0.74–1.00) and 80% specificity (95% confidence interval, 0.62–0.98) in evaluating patients with suspected acute cholecystitis. Nearly two decades later, Kiewiet et al[84] included cholescintigraphy and magnetic resonance imaging to compare the sensitivity and specificity of ultrasound with other imaging modalities. In a head-to-head comparison, the sensitivity of ultrasound (80% vs 94%; P <.001) and the specificity (75% vs 89%; P <.001) were significantly lower than with cholescintigraphy. Nonetheless, because of its availability, low cost, and low risk profile, ultrasound remains the practical diagnostic modality of choice.

Acute Appendicitis

The diagnosis of appendicitis has improved with increased and appropriate use of imaging.[85] Recent data suggest that the negative appendectomy rate has significantly decreased from 23.0% to 1.7%, whereas the preoperative CT rate has increased from 1% to 97.5%.[86] Previous studies comparing ultrasound and MDCT for adult patients with suspected appendicitis showed comparable sensitivities and specificities.[87,88] Limitations of ultrasound examination include the following:



A B C

FIGURE 18-16 Ultrasound findings of acute cholecystitis. (**A**) Gallbladder wall thickness >0.4 cm. (**B**) Enlarged gallbladder and impacted stone (arrow). (**C**) Pericholecystic fluid collection.

(1) operator dependence; (2) decreased accuracy in patients with a thick abdominal wall or overlying bowel gas; and (3) inability to identify other associated pathology. Although MDCT is currently the most commonly obtained study for adult patients with suspected appendicitis, the use of ultrasound is still indicated for pediatric or pregnant patients to avoid radiation exposure or intravenous contrast dye. The sonographic findings to suggest acute appendicitis are listed in Table 18-7 and in Fig. 18-17.[89]

Pyloric Stenosis

Ultrasound is more frequently employed to make a diagnosis of surgical disorders in the pediatric population. Nausea and vomiting in infants can be caused by serious intra-abdominal conditions requiring surgical intervention such as pyloric stenosis. In addition to a history of nonbilious projectile vomiting and a palpable "olive" on a physical examination, ultrasound is considered the dominant imaging test to confirm the diagnosis.[90,91] A target sign is observed in the transverse view, while the length and thickness of the pyloric muscle are measured in a longitudinal view of the upper abdomen (Fig. 18-18). A muscle thickness greater than 3 mm and length greater than 15 mm are considered abnormal, although there are variations in diagnostic criteria.[90] Malcom et al[91] demonstrated the feasibility of the point-of-care ultrasound by nonradiologists to diagnose pyloric stenosis in their case series.

Soft Tissue Infection and Abscess

A superficial soft tissue infection can be easily detected on clinical examination. In contrast, an ultrasound examination can be engaged as an adjunct to visualize a deep space infection, particularly an abscess involving the deep subcutaneous tissue (breast, gluteal area) or muscle (Fig. 18-19). A high-frequency linear transducer is placed over the suspected area. The depth of imaging should be adjusted based on the location (eg, forearm vs thigh), so that a fluid collection (anechoic to hypoechoic area) will not be missed. Furthermore, percutaneous aspiration or incision and drainage can also be guided by ultrasound imaging.[92]

ULTRASOUND IN SURGICAL CRITICAL CARE

As previously noted, the use of ultrasound in the ICU allows surgeons to supplement findings on physical examination to make diagnoses without the need to transport a critically ill patient to another area of the hospital. Furthermore, diagnostic and therapeutic ultrasound examinations are noninvasive, rapid, and readily repeatable. Once a diagnosis has been achieved, ultrasound may allow the surgeon to use invasive techniques under image guidance to provide a lifesaving treatment. Ultrasound guidance and direct visualization during procedures performed by surgeons can lead to decreased complications, shorter hospital length of stay, and decreased cost.[93]

Training programs that teach ultrasound skills in critical care to surgeons should be rigorous and include competence-based testing. Didactic training, hands-on experience, and a partnership with the echocardiography department are essential to develop advanced ultrasound skills. Surgeons should also have a continuing medical education program and formal certification and credentialing process when developing ultrasound skills.[94-97] A certification examination will be administered by the proprietary National Board of Echocardiography beginning in January 2019 and will assess competence in critical care echocardiography and sonography.

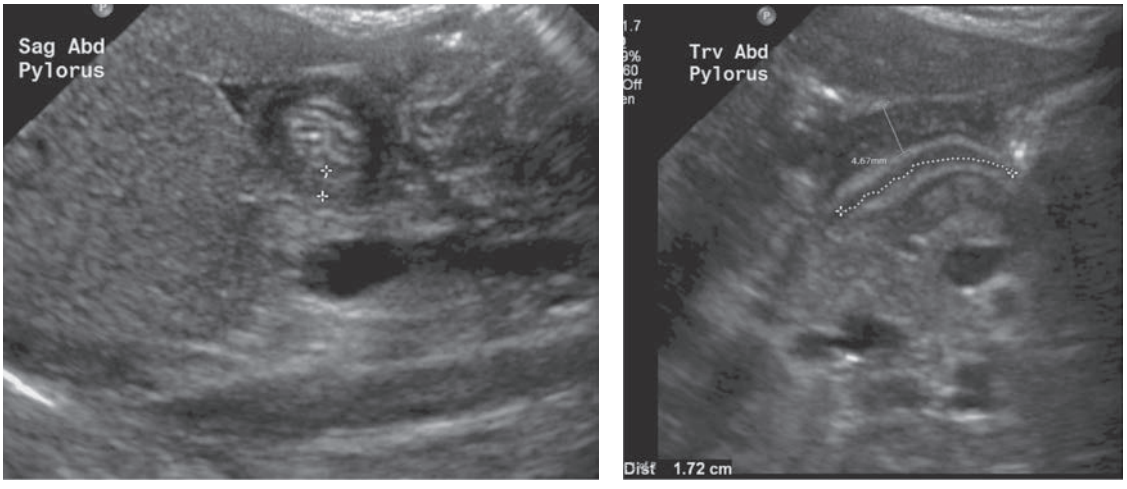
Hemodynamic Monitoring

Focused echocardiography performed by bedside clinicians can be useful for the assessment and management of hemodynamically unstable patients. Training surgeons with previously limited ultrasound skills in focused echocardiography is feasible because this exam is goal directed, problem oriented, limited in scope, and simple compared to traditional echocardiography. In addition, it allows for time-sensitive and repeated assessments. Focused echocardiography can be used to rapidly diagnose causes of hemodynamic instability and/or acute respiratory failure. A surgeon's goal in performing cardiac ultrasound in a hemodynamically unstable patient is to assess global left ventricular (LV) and right ventricular (RV) systolic function, intravascular volume status and preload responsiveness, and the presence of pericardial effusion/tamponade physiology. Additionally, LV diastolic measurements/assessments are possible, unlike with other common monitoring devices (eg, a pulmonary artery flotation catheter). Typically, focused echocardiographic measurements are either qualitative (ie, good vs poor) or semiquantitative based on measuring techniques with substantial extrapolations in computation.

Several variations of the focused echocardiography technique have been described over the years. Their utility has also been examined in critically ill surgical patients.[98] The first, referred to as the focus-assessed transthoracic echocardiography examination, is a two-dimensional and M-mode imaging exam consisting of the most basic cardiac and pleural views. Two derivative examinations have been described in the surgical literature. Gunst et al[59] developed a bedside echocardiography protocol (the bedside echocardiographic assessment in trauma/critical care [BEAT] examination) to be used for the hemodynamic assessment of patients in the surgical ICU. Each letter of BEAT corresponds to a component of the examination (B: beat—CI; E: effusion—pericardial effusion; A: area—subjective cardiac function; T: tank—volume status). In the study, the BEAT examination could be completed rapidly. Of 85 BEAT examinations performed by either surgical trainees or trauma surgeons, the images obtained for the CI calculation were considered of good quality in approximately 60%. In the IVC images for assessment of preload, 97% were



A B

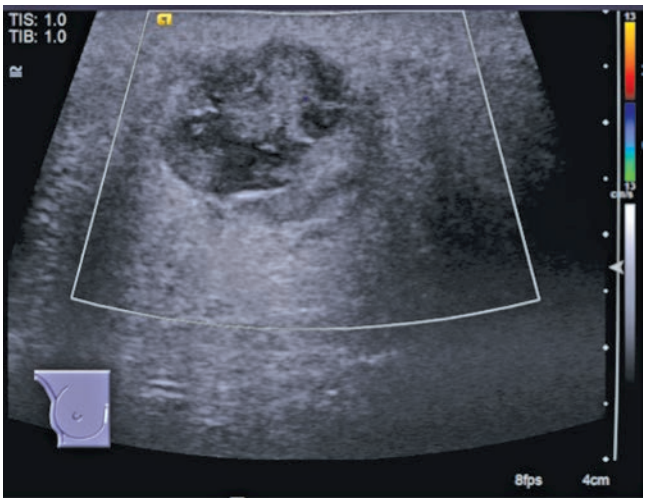

FIGURE 18-19 Abscess cavity is visualized as a hypoechoic lesion (arrow).

of good quality. The CI in the BEAT examination was significantly correlated with that obtained from a pulmonary artery catheter.[16]

Similarly, the focused FREE examination has been used to monitor the hemodynamic status of patients in the surgical ICU. The examiner is able to obtain or calculate information regarding cardiac function, volume status, afterload, and anatomy. Despite the prevalence of thoracoabdominal surgery and mechanical ventilation in their cohort, FREE examiners were successful in completing the study.[61]

TECHNIQUE

Focused echocardiographic examinations are performed using a low-frequency cardiac transducer (small footprint) with the depth set to 14 to 16 cm for adequate visualization of the heart. If available, the cardiac software package and presets should be used as opposed to the abdominal software package that is commonly used in the FAST examination. Cardiac goal-directed ultrasound requires four main views: (1) the subcostal view allows for visualization of IVC size/collapse, RV and LV size, and pericardial effusions; (2) the parasternal long-axis view evaluates LV systolic function and presence of effusions; (3) the parasternal short-axis view allows visualization of LV function at the mid-left ventricle; and (4) the apical four-chamber view can demonstrate a pericardial effusion and RV size and function. In most cases, these four views can be obtained for patients in the supine position. More favorable images can be also be acquired by placing the patient in the left lateral decubitus position as the heart moves more closely to the chest wall. In some patients, only a single view may be possible, but even in these instances, valuable information is available.

The assessment of volume status and preload responsiveness is performed as a part of the cardiac examination. The latter is perhaps the more relevant parameter and represents whether a patient would benefit from volume administration (by increasing stroke volume and cardiac output). Assessment of volume status via echocardiography is typically performed by obtaining a static image of the structure of interest. Determination of preload responsiveness requires the use of dynamic imaging that entails a before and after assessment (relative to administration of fluid or inspiration or another maneuver) of the structure or parameter of interest. The most commonly used structure to determine volume status and preload responsiveness is the IVC. The diameter of the IVC is measured at the end of both the inspiration and expiration phase in the subcostal view. For better representation of the relevant anatomy, a longitudinal view at the junction of the right atrium and the IVC is visualized first. The measurement is taken within a few centimeters of the cavoatrial junction. The volume status and preload responsiveness are estimated based on the static IVC diameter as well as the collapsibility during the respiratory cycle (Table 18-8). Other echocardiographic techniques of preload responsiveness exist and are beyond the scope of this chapter. Nonetheless, it is important to state that static visualization of the IVC is a crude measure of volume status and is most useful at extreme values, (hypo- or hypervolemia) over time or after therapeutic intervention (ie, fluid resuscitation).

Cardiac function can be determined by both qualitative and quantitative means. Qualitative assessment implies visualizing the beating heart and ascribing its function as normal or abnormal (more specifically, as increased, decreased, or normal contractility). This skill is learned quickly and provides information on the cardiac ejection fraction that is not possible with more traditional methods of hemodynamic assessment, including the use of pulmonary artery catheters. Most often, the parasternal short-axis view is employed to acquire qualitative information regarding contractility, morphology, size, and wall motion abnormality of the LV. The LV and RV are visualized simultaneously in the apical four-chamber views for the assessment of the right-sided cardiac function (Fig. 18-20). Normally, the RV size is two-thirds that of the LV. An enlarged RV can be the result of pressure or volume overload. Quantitative and semiqualitative assessment of left-sided heart function provides actual values for either stroke volume (SV), ejection fraction, or both using relatively simple methodologies.[59,61,98] Semiquantitative methods use computational assumptions. Of three popular

TABLE 18-8: Estimated Central Venous Pressure Related to IVC Imaging

IVC diameter	Collapsibility	Estimated central venous pressure (mm H_2O)
<20 mm	>50%	5
<20 mm	<50%	10
>20 mm	<50%	15
>20 mm	Minimal	20

IVC, inferior vena cava.

semi- or fully quantitative methods (fractional shortening, Simpson, and LV outflow tract [LVOT]/velocity time integral [VTI] method) to estimate SV, the fractional shortening method was most significantly correlated with the data obtained from a pulmonary artery catheter in the aforementioned study of patients in the surgical ICU.[99] In the fractional shortening method, a parasternal long-axis view is used for assessment of cardiac function. After an adequate view is obtained in two-dimensional mode, the M-mode cursor is placed to visualize the LV at the level of the distal mitral valve (Fig. 18-21). End-diastolic and end-systolic diameters of the LV are measured in the M-mode image. SV can be calculated by applying these values to a formula stored in the cardiology presets of the ultrasound machine (Table 18-9). Similarly, CI and ejection fraction are calculated. The fully quantitative methodology using a measurement of LVOT and assessment of VTI is thought by others to be the most accurate; however, it requires acquisition of two cardiac views.[100]

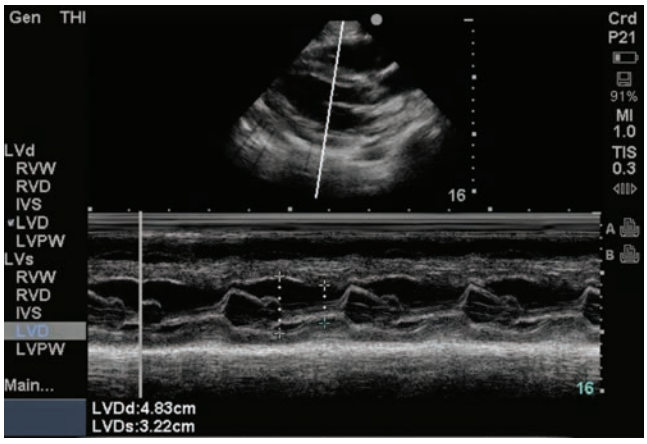

FIGURE 18-21 Parasternal long-axis view is used to calculate the stroke volume in the fractional shortening method.

Pleural Ultrasound

The use of ultrasound for the detection of pleural-based diseases has some advantages over traditional radiographic imaging. Ultrasound eliminates radiation exposure, is easily portable, and provides real-time imaging. Pleural effusions are easily diagnosed and treated by surgeons using bedside ultrasound. As discussed previously in the trauma

TABLE 18-9: Formulas Used in the Fractional Shortening Method

Parameter	Calculation
Left ventricular end-systolic volume	$(7/[2.4 + LVs]) \times LVs^3$
Left ventricular end-diastolic volume	$(7/[2.4 + LVd]) \times LVd^3$
Stroke volume	LVEDV – LVESV
Cardiac output	SV × HR
Cardiac index	CO/BSA
Ejection fraction	SV/LVEDV

BSA, body surface area; CO, cardiac output; HR, heart rate; LVd, left ventricular diastolic diameter; LVEDV, left ventricular end-diastolic volume; LVESV, left ventricular end-systolic volume; LVs, left ventricular systolic diameter; SV, stroke volume.

section, bedside thoracic ultrasound is more sensitive than a plain CXR in detecting the presence of pleural fluid and distinguishing fluid from consolidation of the lung. During bedside thoracentesis to drain a pleural effusion in the ICU, ultrasound guidance increases the likelihood of a successful tap and reduces the risk of a pneumothorax.[93] A pneumothorax may occur in the ICU during mechanical ventilation or after invasive procedures such as a thoracentesis or insertion of a central venous catheter via the internal jugular or subclavian vein. A surgeon can use portable ultrasound to quickly diagnose the pneumothorax in the ICU in the same manner as described in the trauma section.[101,102] In supine and semierect views, an ultrasound is more sensitive than a CXR (91% vs 50%), and both modalities provide similar specificities in the diagnosis of a pneumothorax.[103]

TECHNIQUE

Diagnosis and drainage of pleural effusions can be performed with the patient in the upright position, with the head of the bed elevated to at least a 45° to 60° angle. Patients who cannot tolerate sitting up can be imaged and/or drained in the supine position with the ipsilateral arm positioned across the chest or in lateral decubitus position with the side of the suspected pleural effusion up. A 3.5- to 5.0-MHz convex array transducer is held perpendicular to the skin with the transducer marker pointed cephalad. The transducer is oriented to allow visualization between the ribs to identify pleural fluid. Once the targeted pleural fluid is imaged, a sterile field is prepared and a cover is placed on the ultrasound probe. The pleural space is then entered with a large-gauge needle while aspirating until pleural fluid is obtained. A guidewire is passed through the needle into the pleural cavity using the Seldinger technique. A small skin incision is made around the guidewire, and a pigtail catheter is placed over the wire to allow drainage of the pleural fluid.

Pulmonary Ultrasound

Acute respiratory failure and insufficiency are critical conditions commonly encountered in the ICU. Making a rapid and accurate assessment of the underlying etiology is crucial because patient outcomes can be time dependent. In the past, it was believed that ultrasound was not a useful tool to examine the lung because the air within the normal lung parenchyma prevents transmission of sound waves (Table 18-1). Recently, more data regarding the efficacy of ultrasound in the diagnosis of acute respiratory failure have been published.[104-106]

Lichtenstein and Meziere[106] incorporated several ultrasound findings into a decision tree to identify the cause of acute respiratory failure (bedside lung ultrasound in emergency [BLUE] protocol). Using the algorithm, pulmonary etiologies of acute respiratory failure, including parenchymal (eg, pneumonia, pulmonary embolism) or pleural lesions (eg, pneumothorax), were accurately identified in 90.5% of patients.

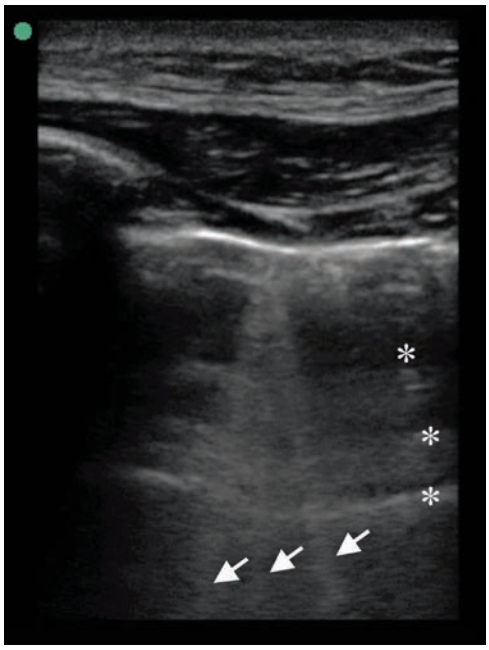

FIGURE 18-22 A lines and B lines on lung ultrasound. A lines (asterisks) are seen as repetitive horizontal lines in normal lung. "Lung rocket" is defined as at least three B lines identified in the intercostal space (arrows).

The BLUE protocol starts with eliciting the aforementioned lung sliding sign (Fig. 18-12), which excludes a pneumothorax. In addition, A lines (repetitive horizontal artifacts) can be identified in normal lung (A profile). A pulmonary embolus should be considered as a cause of acute respiratory failure if venous thrombosis is associated with an A profile. The B line is another artifact characterized as a hyperechoic comet tail arising from the pleural line. Lung rockets are defined as at least three B lines in the intercostal space (Fig. 18-22). The combination of lung sliding and lung rockets (B profile) favors conditions associated with pulmonary edema. Pneumonia can be diagnosed in several patterns of ultrasound findings, including the following: (1) A profile without associated venous thrombosis or positive posterolateral alveolar and pleural syndrome (PLAPS); (2) anterior lung consolidation (C profile); and (3) lung rockets without lung sliding (B profile). An A profile without associated venous thrombosis or PLAPS suggests other pulmonary disorders including chronic obstructive pulmonary disease (COPD) or asthma. The utility of a lung ultrasound protocol has been prospectively evaluated in 189 patients on mechanical ventilation.[105] Sensitivities and specificities of the ultrasound examination for each pulmonary disease were as follows: cardiogenic pulmonary edema, 97% and 95%; COPD or asthma, 89% and 97%; pulmonary embolism, 81% and 99%; pneumothorax, 88% and 100%; and pneumonia, 89% and 94%. Of 253 examinations, patient management was significantly changed in 119 patients (47%). Of note, a majority of these patients (81 of 119) required invasive interventions based on the diagnoses made by the ultrasound of the lung.

Diaphragm Ultrasound

A high incidence of diaphragmatic dysfunction has been reported in critically ill patients, particularly in those receiving prolonged mechanical ventilation (ventilation-induced diaphragmatic dysfunction).[107] Diaphragm dysfunction following mechanical ventilation is significantly associated with extubation failure.[108] Therefore, a bedside ultrasound assessment of diaphragm function can be a useful tool in determining whether the patient can be successfully extubated. Two predictors commonly measured in diaphragmatic ultrasound are the diaphragm excursion and the diaphragm thickening fraction. The diaphragm excursion is the distance that the diaphragm moves during the respiratory cycle. The diaphragm thickening fraction is calculated using a difference in thickness of the diaphragm between end-inspiration and end-expiration. Kim et al[109] defined ultrasonographic diaphragm dysfunction as an excursion of the diaphragm during a spontaneous breathing trial less than 10 mm.[109] In their study, patients with diaphragm dysfunction had a significantly longer total ventilation time, and the rate of weaning failure within 48 hours was significantly higher compared to patients with no diaphragm dysfunction (83% vs 59%, P <.01). The utility of the diaphragm thickening fraction was evaluated in a prospective study by DiNino et al.[110] In patients who were weaned with a spontaneous breathing trial, the positive and negative predictive values of diaphragm thickening fraction of 30% or greater for extubation success were 100% and 67%, respectively, whereas they were 91% and 25%, respectively, with a cutoff of 105 min/L for rapid shallow breathing trial.

TECHNIQUE

The diaphragmatic ultrasound is normally performed while the patient is participating in a spontaneous breathing trial. A low-frequently transducer (3.5–5 MHz) is longitudinally placed in the right midclavicular line below the costal margin or in the right anterior axillary line between the lower ribs to visualize the posterior diaphragm and liver (Fig. 18-23).

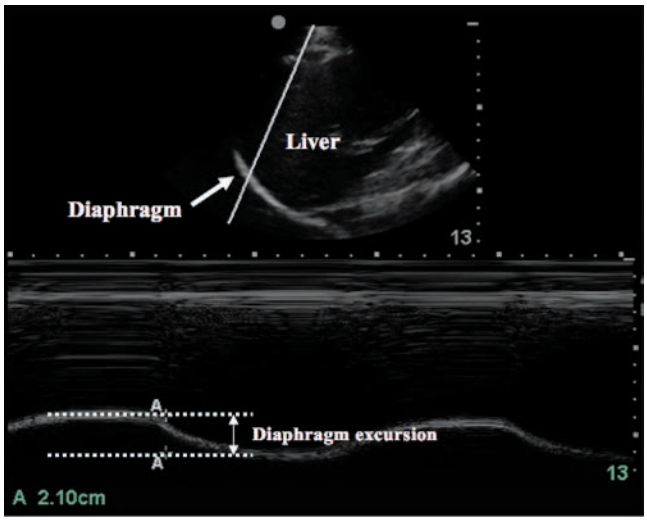

FIGURE 18-23 Measurement of diaphragm excursion.

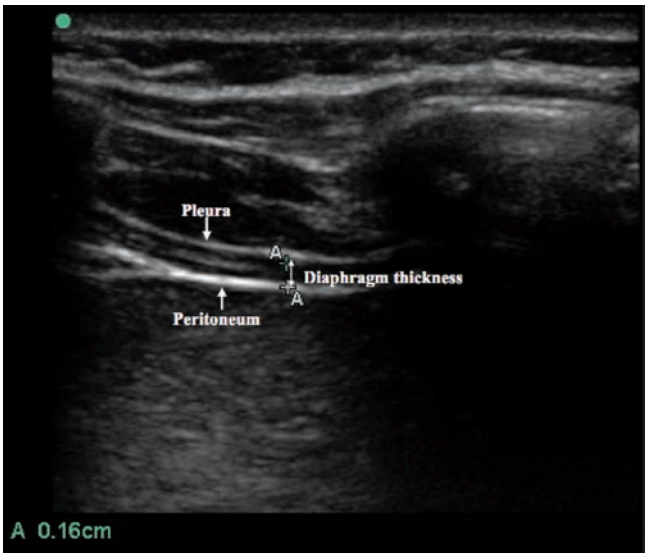

FIGURE 18-24 Measurement of diaphragm thickness.

Then, in the M-mode view, an interrogation line is placed to be perpendicular to the posterior third of the diaphragm. The diaphragm excursion is measured by calculating the depth (centimeters) between the beginning and end of an inspiratory phase. To measure the diaphragm thickening fraction, a high-frequency linear transducer (≥7–10 MHz) is positioned in the midaxillary line between the 8th and 10th intercostal spaces (zone of apposition of the diaphragm to the rib cage). The diaphragm is visualized using the B-mode between the pleura and peritoneum (Fig. 18-24). The M-mode is used to measure diaphragm thickness (millimeters) at end-expiration and end-inspiration. The diaphragm thickening fracture is calculated using the following formula: thickness at end-inspiration – thickness at end-expiration/thickness at end-expiration. Newer measures of diaphragm area (vs. thickness and excursion) have been demonstrated to be more predictive of extubation success in small trials; however, they are beyond the scope of this chapter.

Insertion of a Central Venous Catheter

Insertion of a central venous catheter is performed frequently in critically ill patients. Central venous catheters are required for hemodynamic monitoring, volume resuscitation, administration of blood products, parenteral nutrition and medications, acquisition of lab specimens, and provision of renal replacement therapy.[111] Insertion can be associated with complications such as injury to surrounding vessels causing a hematoma and to the lung resulting in a hemothorax and/or pneumothorax. Ultrasound-guided insertion of a central venous catheter has been clearly shown to decrease the number of attempts at venous cannulation, time required to successful insertion, and the overall complication rate in randomized control studies.[112-114] A meta-analysis including 18 studies concluded that real-time ultrasound-guided cannulation of the internal jugular vein in adult patients was

associated with a lower risk of overall cannulation failure (relative risk [RR], 0.14; 95% confidence interval, 0.06–0.33), fewer complications (RR, 0.43; 95% confidence interval, 0.22–0.87), reduced first attempt failure (RR, 0.59; 95% confidence interval, 0.39–0.88), and reduced first attempt failure rate (1.5 fewer attempts; 95% confidence interval, 0.39–0.88) compared to the landmark technique.[115] Currently, the insertion of a central venous catheter into the internal jugular vein using ultrasound guidance has become considered as best practice and is strongly advised.[114] In contrast, until recently, there were scarce data to support the use of ultrasound to guide cannulation of the subclavian vein.[115] Fragou et al[116] conducted a prospective randomized study that showed significantly improved outcomes associated with real-time ultrasound-guided cannulation compared to the landmark technique. The success rate in the ultrasound group was 100% with a significantly shorter average access time (26.8 vs 44.8 minutes, $P < .05$) and lower complication rates. Because the subclavian vein is located posterior to the clavicle, the penetration of the ultrasound beam is more challenging. In this study, physicians rated the ultrasound-guided subclavian cannulation as a complex task (8 ± 0.2/10). Furthermore, ultrasound-guided cannulation of the subclavian vein is more accurately referred to as an axillary approach.

TECHNIQUE

The internal jugular vein in the cervical and upper thoracic region is imaged with a high-frequency linear transducer. Prior to preparation of the insertion site, the targeted vein should be visualized with ultrasound. The transducer probe is placed transversely on the neck to obtain a cross-sectional image of the internal jugular vein and common carotid artery. The probe is then rotated 90° to obtain a longitudinal image. Patency of the vein should also be assessed by its ability to be easily compressed with the ultrasound transducer. During skin preparation and sterile draping of the insertion site, the ultrasound probe is covered with a telescopically folded sterile sheath. The ultrasound transducer should be held in the nondominant hand perpendicular to the skin. The cannulating needle is positioned in the dominant hand and directed at the target vessel in real time. The tip of needle should be visualized in the image while the needle is being advanced. Once the vein is cannulated by the needle, the remainder of the procedure is completed using the Seldinger technique. The wire should be identified inside the jugular vein before dilating the tract (Fig. 18-25). Typically, the transverse view is used to identify puncture of the vessel, whereas the longitudinal view is beneficial to localize the needle tip and wire.

As the subclavian vein is close to bony structures, it is often challenging to visualize the anatomic relationship to the subclavian artery and pleural line. The axillary vein is the distal continuation of the subclavian vein, and its cannulation under ultrasound guidance can be more easily performed. Similar to imaging of the internal jugular vein, transverse and longitudinal images of the subclavian vein and artery are obtained before draping the area. The subclavian artery is normally located cephalad to the vein. Another key point in cannulation of the subclavian vein is to appreciate the proximity of the pleural line, which can be within a few centimeters below the vein (Fig. 18-26).

Paracentesis

Abdominal paracentesis is a procedure that surgeons use in the ICU for diagnosis and/or therapy. Diagnostic paracentesis consists of obtaining a small amount of peritoneal fluid for culture to rule out infection and to characterize the fluid as a transudate or exudate (or occasionally for lipase/amylase levels to rule out pancreatic ascites). Therapeutic paracentesis is a technique that removes a large volume of ascites (typically in excess of 2 L) to reduce intra-abdominal pressure and treat the resulting abdominal discomfort and dyspnea. Therapeutic paracentesis is a procedure that is commonly performed by surgeons caring for patients with hepatic failure in the ICU setting who are at a high risk of postprocedure bleeding. Ultrasound guidance for paracentesis in patients with ascites results in greater success in acquiring fluid compared to traditional techniques (95% vs 61%).[117] Patients undergoing ultrasound-guided paracentesis also have a decreased risk of bleeding (0.27% vs 1.25% without ultrasound), leading to decreased hospital length of stay and costs.[93]

TECHNIQUE

Paracentesis is typically performed with the patient supine with the needle inserted into the left lower quadrant. The general area of the puncture site is localized 2 to 3 cm medial and 2 to 3 cm cephalad to the anterior iliac spine in the left lower quadrant. A convex ultrasound of 3.5 to 5.0 MHz is then used to locate peritoneal fluid and to visualize the inferior epigastric artery to avoid injury and hemorrhage. Skin preparation and sterile draping of the area and use of the ultrasound probe are performed, followed by insertion of the paracentesis needle. The paracentesis catheter is left in place to achieve removal of the desired diagnostic sample or to reduce intra-abdominal pressure.

SUMMARY

It has been approximately 25 years since surgeons began using ultrasound in the management of trauma patients. Currently, the FAST examination is most useful for patients with blunt trauma who have unstable vital signs. In patients with penetrating trauma to the chest, the pericardial component of the FAST examination is mandatory to rapidly diagnose a cardiac injury.

In recent years, thoracic ultrasound has been more frequently engaged to detect pneumothoraces, hemothoraces/pleural effusions, and lung lesions both in the trauma bay and in the ICU. In the emergency department, focused ultrasound examination is more frequently performed to evaluate patients with suspected intra-abdominal inflammatory processes.

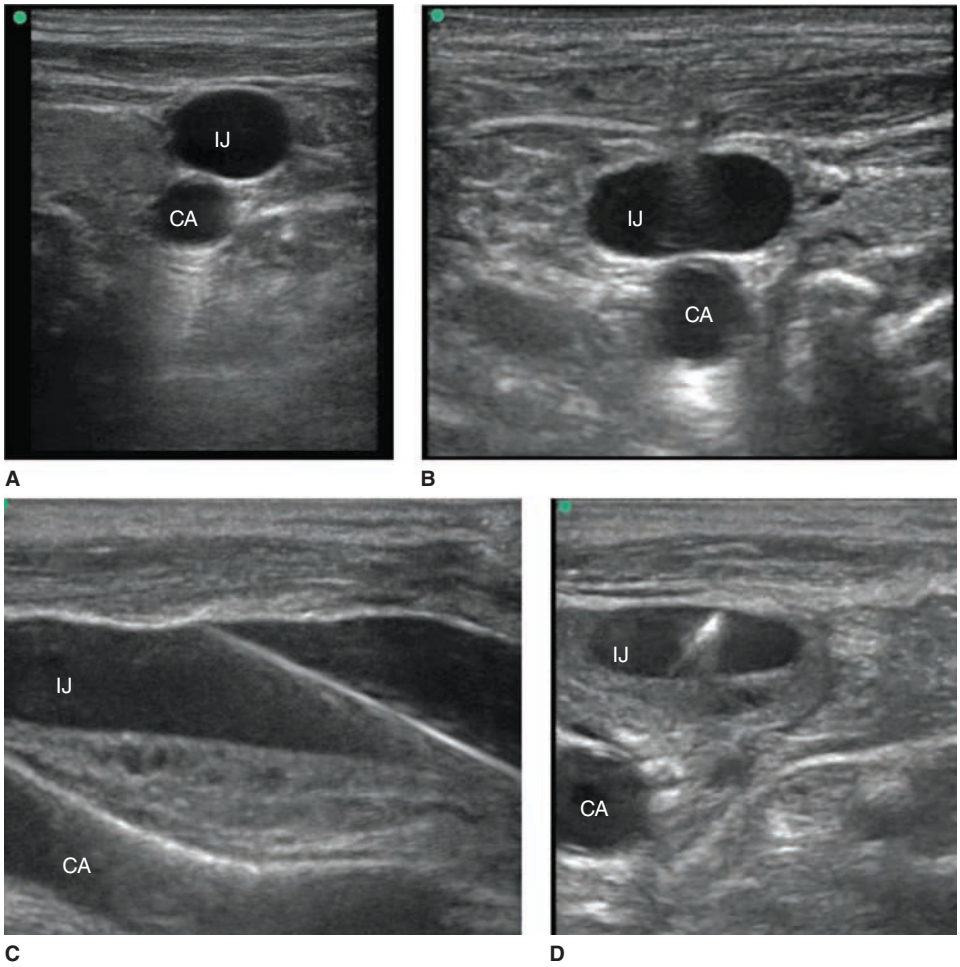

FIGURE 18-25 Ultrasound-guided central venous catheter placement in the internal jugular (IJ) vein. (**A**) Transverse view of right-side neck. (**B**) Tip of needle is visualized on the anterior wall of the IJ. (**C, D**) Guidewire is seen inside the IJ. CA, carotid artery.

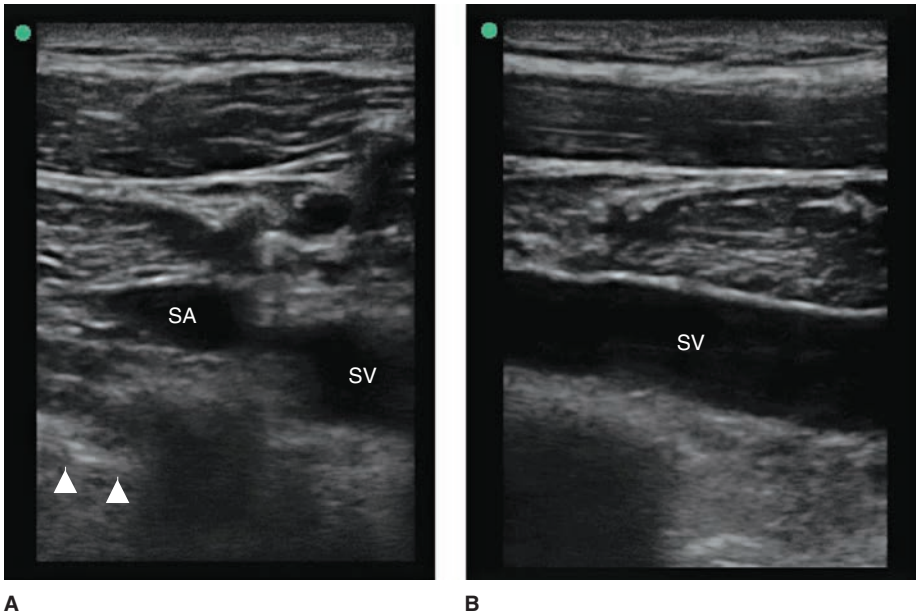

FIGURE 18-26 Transverse (**A**) and longitudinal views (**B**) of subclavian vein (SV). Note that the subclavian artery (SA) is located cephalad to the SV. The pleural line is visualized inferiorly (arrowheads).

Similarly, more advanced ultrasound techniques, including echocardiography, are now guiding the resuscitation of critically ill patients. Of note, these surgeon-performed ultrasound examinations are currently considered the standard care in many clinical settings and hospital systems.

Diagnostic and Interventional Radiology

Scott D. Steenburg

KEY POINTS

- Imaging is a critical adjunct to the comprehensive evaluation of the trauma patient.
- Imaging protocols specific to blunt and penetrating trauma victims should be clearly defined and operationalized to enhance rapid imaging and patient throughput.
- Modern computed tomography (CT) technology and imaging protocols allow for high-resolution imaging of any body part.
- Advanced imaging exams, such as extremity and neck CT angiography, can now be integrated as a part of the initial imaging evaluation of the trauma patient.
- Multiphase CT can provide important information regarding the presence and character of vascular lesions, including active bleeding and solid organ pseudoaneurysms.

INTRODUCTION

Obtaining reliable clinical history and a physical examination may be challenging in the acute trauma patient. Thus imaging can provide timely and helpful information about these patients and identify injuries that otherwise may not be readily recognized. Imaging can be used to assist in injury prioritization and patient triage, as well as guiding the trauma surgeon toward any number of management choices. Despite the advanced imaging technology available in a modern trauma center, it is important to recognize that imaging alone cannot be used to make management decisions in isolation; that is, the surgeon must treat the patient based on an experienced integration of their clinical assessment and diagnostic images.

Practical variables that affect imaging strategies include the proximity of available imaging technology to the resuscitation area, the technical capabilities of the imaging equipment, the experience and availability of radiology technologists performing these imaging procedures, and timely access to expert interpretation and reporting.

Imaging is typically initiated in the trauma bay and integrated as a part of the clinical survey. However, it should reflect the needs of each individual patient. Hemodynamically unstable patients should be resuscitated prior to imaging according to accepted guidelines and recommendations, with some exceptions for image-guided endovascular hemostasis techniques in select scenarios (eg, resuscitative endovascular balloon occlusion of the aorta [REBOA]). To enhance efficiency, imaging should be obtained based on the acute needs for accurate information that can be used to direct treatment of the patient. Close cooperation and open communication between all major stakeholders, including emergency medicine physicians, traumatologists, consultants, nurses, imaging technologists, and radiologists, are essential to optimize any imaging assessment and provide superior patient care.

A single chapter alone cannot reasonably teach interpretation of diagnostic images. Instead, a general overview of trauma imaging strategies is provided. In addition, reflecting current trends in the modern trauma center, an emphasis on advanced computed tomography (CT) technology and capabilities, focusing on select high-yield and common clinical scenarios, is presented.

INITIAL IMAGING FOR THE ASSESSMENT OF BLUNT TRAUMA

Trauma Series

Imaging of the trauma patient is integrated as a part of the secondary clinical survey in the resuscitation suite. The goal of the initial imaging studies is to identify life-threatening, but clinically occult, injuries that require emergent intervention prior to any further imaging, such as an unstable pelvic fracture, hemopneumothorax, or malpositioned/misplaced

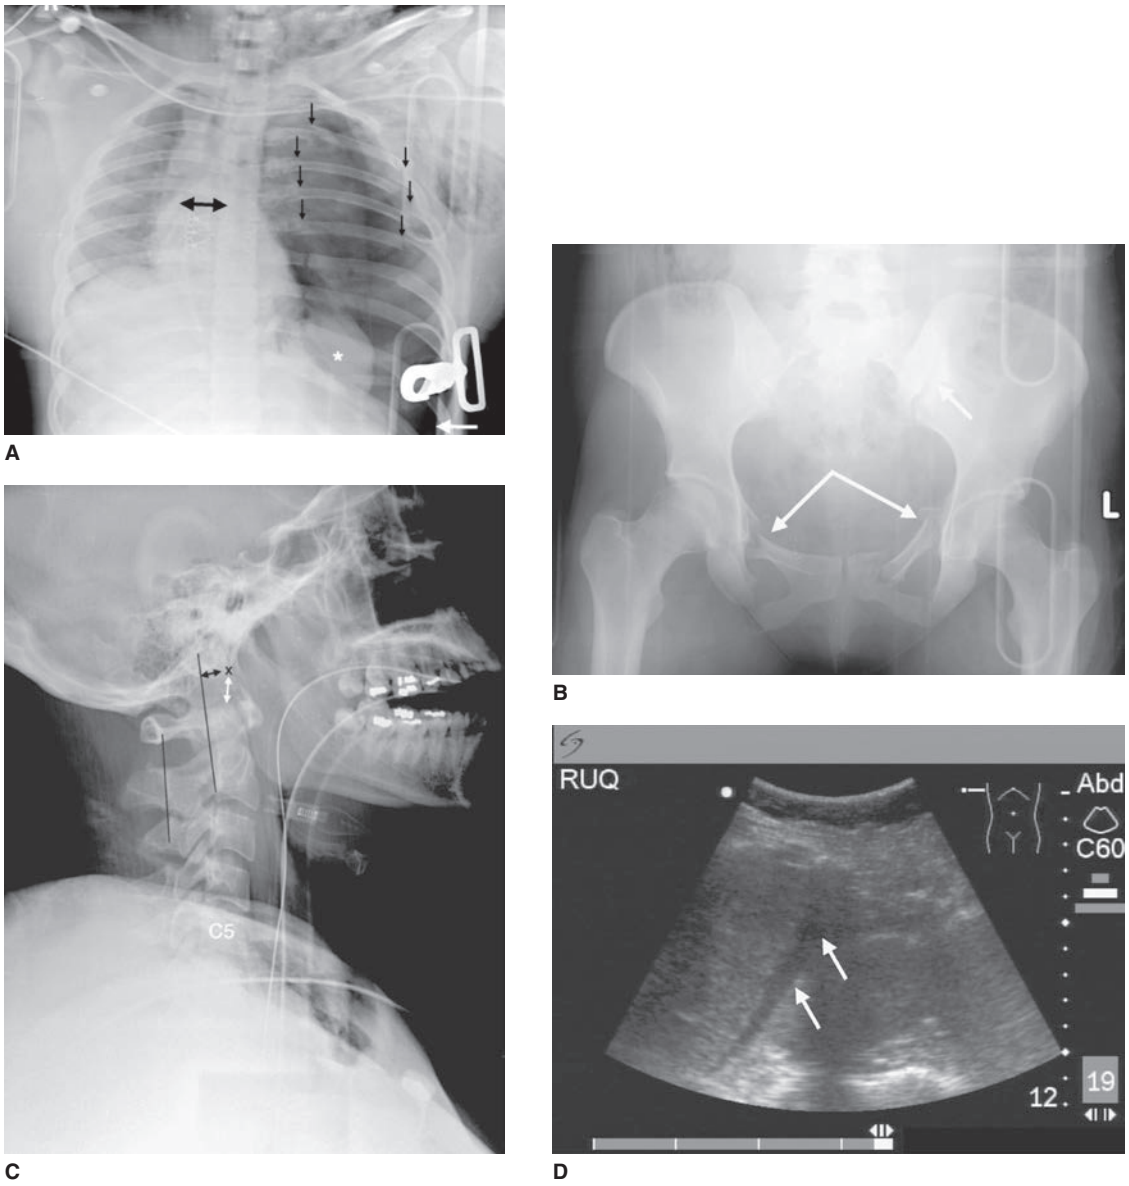

FIGURE 19-1 Trauma series. This 27-year-old unrestrained left rear seat passenger sustained multiple injuries in a high-speed side-impact crash. (**A**) Anteroposterior (AP) recumbent chest radiograph shows hyperexpanded and hyperlucent left hemithorax with deep sulcus sign (short white arrow) and rightward mediastinal shift (double-ended arrow) due to left tension pneumothorax. Short black arrows show multiple displaced rib fractures. Asterisk shows irregularity of left hemidiaphragm, which strongly suggests herniation of abdominal contents through left diaphragmatic laceration. (**B**) AP pelvis radiograph shows lateral-compression–type pelvic ring disruption consisting of bilateral iliopubic and ischiopubic ramus and left sacral fractures (long arrows) with sacroiliac joint disruptions (short arrow). (**C**) Cross-table lateral cervical spine radiograph is grossly normal to C5. Therefore, this constitutes a nondiagnostic study. Craniocervical alignment should be assessed and may be easily overlooked. Dens–basion distance (white double-ended arrow) is normally no greater than 12 mm. Posterior axial line represents cephalad extension of posterior cortex of C2 body (and is normally no more than 12 mm posterior or 4 mm anterior to basion) (black double-ended arrow). Anterior atlantodens interval is normally no greater than 3 mm in adults and 5 mm in children (8 years and younger). Laminar point of C2 (laminar points are most anterior extent of neural canal margin of lamina) should be within 1.5 mm of line connecting laminar points of C1 and C3. (**D**) Coronal image of right upper quadrant (RUQ) from focused abdominal sonography for trauma (FAST) shows free intraperitoneal fluid in anterior subhepatic (Morison's) space (arrows), compatible with hemoperitoneum.

support lines and tubes.[1] Anteroposterior (AP) supine chest and AP supine pelvis radiographs are typically performed as a part of this initial assessment, if clinical evaluation alone is deemed insufficient (Fig. 19-1). A single-view, cross-table, horizontal beam cervical spine radiograph can be obtained to evaluate for gross cervical malalignment but should not be used to exclude all fractures of the cervical spine (see later section).

The trauma resuscitation ABCD strategy may be extended to this trauma series. Verification of the integrity of the

airway (and other tubes and lines) should occur on the chest radiograph. Radiographic pulmonary opacities associated with hypoxemia include pulmonary contusions, aspiration pneumonitis, and atelectasis (including collapse due to aspirated dental or foreign debris). Tension pneumothorax and hemothorax are typically detected on clinical examination, whereas clinically occult pneumothoraces or hemothoraces are commonly shown by chest x-rays as a deep sulcus sign and generalized hemithoracic opacification, respectively. Other injuries, such as rupture of the hemidiaphragm, flail chest, pneumopericardium, and pneumomediastinum and hemomediastinum, may be diagnosed or at least suggested by initial x-ray findings. Hemodynamic instability may arise from any number of causes, including extraperitoneal hemorrhage from pelvic ring disruption or hemoperitoneum from solid organ injuries. Biomechanically unstable disruptions of the pelvic ring are almost always shown on AP radiographs and may be associated with injuries to the bladder and urethra. In addition, pelvic x-rays may show hip dislocations and fractures of the acetabulum and proximal femur.

Although used less commonly, a technically adequate (C1–T1) lateral x-ray of the cervical spine is a limited examination but may provide helpful information in the setting of a cervical spine fracture/dislocation or other gross malalignment and may confirm that spinal shock from a vertebral fracture is the cause of unexplained hypotension.

Focused Assessment with Sonography in Trauma

Focused assessment with sonography in trauma (FAST) is performed as part of the secondary survey in victims of torso trauma to identify fluid accumulations in the chest and abdomen. These abnormal fluid collections serve as a proxy for significant internal injury. The ultrasound probe is used to search for fluid in the pericardial sac, both upper abdominal quadrants, and the intraperitoneal recesses in the pelvis adjacent to the bladder. Scanning is optimally performed in two orthogonal planes (eg, longitudinal and transverse) and may also be used to detect a hemothorax or a pneumothorax immediately superior to the perihepatic and perisplenic views. In patients who have severe hemodynamic compromise or obvious hemorrhagic shock, FAST can establish the abdomen as a source of hemorrhage within a few seconds. It is important to recognize that FAST is a limited anatomic examination and, as such, the identification of intraparenchymal and retroperitoneal injuries is not a goal, but certainly occurs. FAST is widely available, inexpensive, and noninvasive; uses no ionizing radiation; is portable; and can be repeated serially with little additional time and effort. Commercially available handheld real-time imaging devices are technically adequate to perform FAST.

FAST is uniformly accurate for the detection of intraperitoneal fluid with moderately large volumes greater than 400 cm^3 (at smaller volumes, accuracy varies with user experience).[2-4] Unfortunately, isolated hepatosplenic injuries with minimal or no hemoperitoneum represent as many as one-third of solid organ injuries.[5,6] Fortunately, small isolated intraparenchymal lesions with less than 250 mL of intraperitoneal blood often do not require endovascular or surgical intervention (liver <1%, spleen <5%).[7] False-positive interpretation of FAST images can result from improper machine settings (gain), sonolucent perinephric fat (which is rarely sonolucent in both axial and coronal scanning planes), fluid-filled bowel and bladder, various types of fluid-filled intra-abdominal cysts, physiologic fluid (especially in females), or preexisting nontraumatic free fluid (ascites). A final false-negative scenario outlines a negative pericardial window despite the underlying presence of a cardiac injury secondary to ejection of the blood out of the pericardial sac via an adjacent rent in the pleura or diaphragm.

The FAST does, however, require operator training and experience for reliable performance and interpretation, which may limit its value. In addition, FAST lacks value in patients with preexisting nontraumatic ascites, bowel and mesenteric injuries, injuries to the retroperitoneum, subcutaneous emphysema, and hemoperitoneum due to pelvic fractures. Although a systematic review of the literature would not support the use of FAST as a replacement for diagnostic peritoneal lavage (DPL) and CT in blunt abdominal trauma, many trained surgeon-sonographers use it on a daily basis with great accuracy.[8]

Hemodynamically stable patients who have suffered trauma with a clinical presentation suspicious for injuries, even in the setting of a positive FAST scan, are candidates for intravenous contrast-enhanced CT of the abdomen and pelvis to identify or exclude internal injuries.

COMPREHENSIVE IMAGING FOR BLUNT POLYTRAUMA

Blunt polytrauma victims are triaged based on the physical examination, initial imaging assessment, and hemodynamic status to the operating room, intensive care unit, or angiography suite for ongoing resuscitation. Some remain in the trauma center for completion of secondary and tertiary clinical surveys and advanced targeted imaging. Typically, this consists of CT for clinically appropriate imaging (eg, head, neck, chest, abdomen, pelvis, and lower extremities) for hemodynamically stable patients. Subsequently, conventional x-rays of the extremities may be obtained. Less severely injured individuals may take a slightly different route with conventional x-rays preceding CT and directed at abnormalities found by clinical examination or prior imaging.

There has been recent increased utilization of the "pan scan" or other variations of whole-body CT imaging techniques as a method of screening patients for clinically unsuspected injuries or to further define injuries identified or suspected on physical examination and initial imaging. This paradigm advocates rapid acquisition of high-resolution thin collimation images to include CT of any or all body parts, including the extremities in some instances. Some literature suggests that integrating whole-body CT as a part of the comprehensive evaluation of the trauma patient decreases

morbidity and mortality.[9,10] Employing this strategy provides excellent anatomic coverage with high accuracy for the detection and exclusion of injuries and is most frequently used in high-volume facilities with considerable imaging resources and expertise.

Multidetector Computed Tomography

The widespread availability of multidetector CT (MDCT) scanners has revolutionized the way that trauma patients are imaged.[11-13] Modern MDCT scanners, particularly those with 16 or more detector rows, acquire imaging data at submillimeter slice thickness. Because of this isotropic spatial resolution, two-dimensional (multiplanar) images in any arbitrary plane can be reconstructed with the same resolution as the axial images. Three-dimensional images with surface shading and cinematic rendering approximate that of anatomic specimens. Some of the newest software packages can reconstruct CT raw data sets to generate "virtual" radiographs (Fig. 19-2).

This, coupled with rapid intravenous contrast injection and increased table speed, allows for even shorter scan times as well as imaging large portions of the body during multiple phases of vascular and organ enhancement. As a result, patients can be scanned from the cranial vertex to feet in only a few seconds.[14,15] Reconstructions of any scanned body part, including the face, thoracolumbar spine, pelvis, and extremities, can be generated in multiple planes, thus reducing unnecessary repeat scanning. The previous practice of focused, specialized imaging of the face and spine can be abandoned. As such, individual repeat thin-section imaging of parts of the body in addition to the CT survey is superfluous, increases ionizing radiation unnecessarily, and increases time away from the resuscitation area.

Instead of sending all of the submillimeter thin-section data to a picture archiving and communication system (PACS) for review (which can be quite time consuming, despite improved image transfer time), the thinner slices are stacked together so that maximum useful information can be extracted without overwhelming the reviewer with high image volume. It is typical for images though the chest, abdomen, and pelvis to be reconstructed at 2- to 5-mm slice thickness in axial, sagittal, and coronal planes, although any slice thickness can be prescribed and tailored to local preferences. It is common practice for the axial images to be reconstructed using thicker slices (eg, 3–5 mm), with sagittal and coronal images reconstructed using thinner slices (eg, 1.5–3 mm) to provide finer spatial resolution of the pelvis and spine. Specific soft tissue and/or bone reconstruction algorithms can be applied to the CT raw data, again supplanting redundant focused imaging. Open communication with the radiology team is strongly encouraged so that optimal image quality and the imaging needs of the trauma surgeon and patient can be achieved. Consistency and familiarity with the scanning process and the image reconstructions can help improve patient throughput once a standard trauma CT survey is agreed upon, thus decreasing patient time away from the trauma care area.

In the era of "as low as reasonably achievable" (ALARA), there is concern regarding the radiation doses that trauma patients receive given the younger demographic of trauma patients, as well as the need for additional or repeat imaging for monitoring. Although dose reduction in CT is achievable, multiple studies have demonstrated cutoffs for minimum dose and noise levels for maintaining image and diagnostic quality in a variety of clinical settings. In the setting of trauma, it is essential to balance dose reduction with diagnostic quality given the potential for significant morbidity and mortality resulting from missed diagnoses in this patient population.

There are a number of radiation dose reduction techniques available. Aside from only scanning what is deemed necessary, there have been many technologic advances that have resulted in substantial radiation dose reduction delivery to the patient while maintaining diagnostic image quality. Inherently high-contrast structures, such as the bones and lungs, lend themselves well to dose reduction. Z-axis dose modulation can be employed to automatically reduce delivered dose through less dense parts of the body (eg, through the lungs), thus only using the dose necessary to maintain diagnostic image quality. Back-end computational methods for image reconstruction from the raw data can be used to reduce image noise, thus providing the potential to reduce radiation dose while maintaining desired image quality.

Computed Tomography of the Head

Axial noncontrast CT scanning remains the reference standard in patients with acute craniocerebral trauma, guiding initial decisions regarding clinical management.[16,17] Indications for CT of the head include the following: (1) objective evidence of closed injury to the brain, including decreased level of consciousness; (2) cranial or facial deformity; (3) hemotympanum; or (4) evidence for leakage of cerebrospinal fluid (Figs. 19-3 to 19-5). Clinical criteria reliably predict significant intracranial injury and help determine which patients will require CT scanning of the head. In children, significant intracranial injury is extremely unlikely in any child who does not exhibit at least one of the following high-risk criteria: (1) evidence of significant skull fracture; (2) altered level of alertness; (3) neurologic deficit; (4) persisting vomiting; (5) scalp hematoma; (6) abnormal behavior; or (7) coagulopathy.[18] More generically, minor trauma to the head may lead to surgically important injuries to the brain, and liberal utilization of CT is appropriate among individuals who have sustained "high-risk" mechanisms. These clinical criteria are not as reliable in the elderly patient.[19]

Head CT images are traditionally acquired using a conventional "step and shoot" axial technique. Most modern MDCT scanners, however, have the capability of scanning the head using helical acquisition, as used for other body parts, and can thus reconstruct head CT images in both sagittal and coronal planes. Traditionally, axial images are reconstructed at 5-mm slice thickness using both bone and soft tissue algorithms and are viewed using bone windows and at least two different soft tissue windows (including "brain" and "blood" window settings).

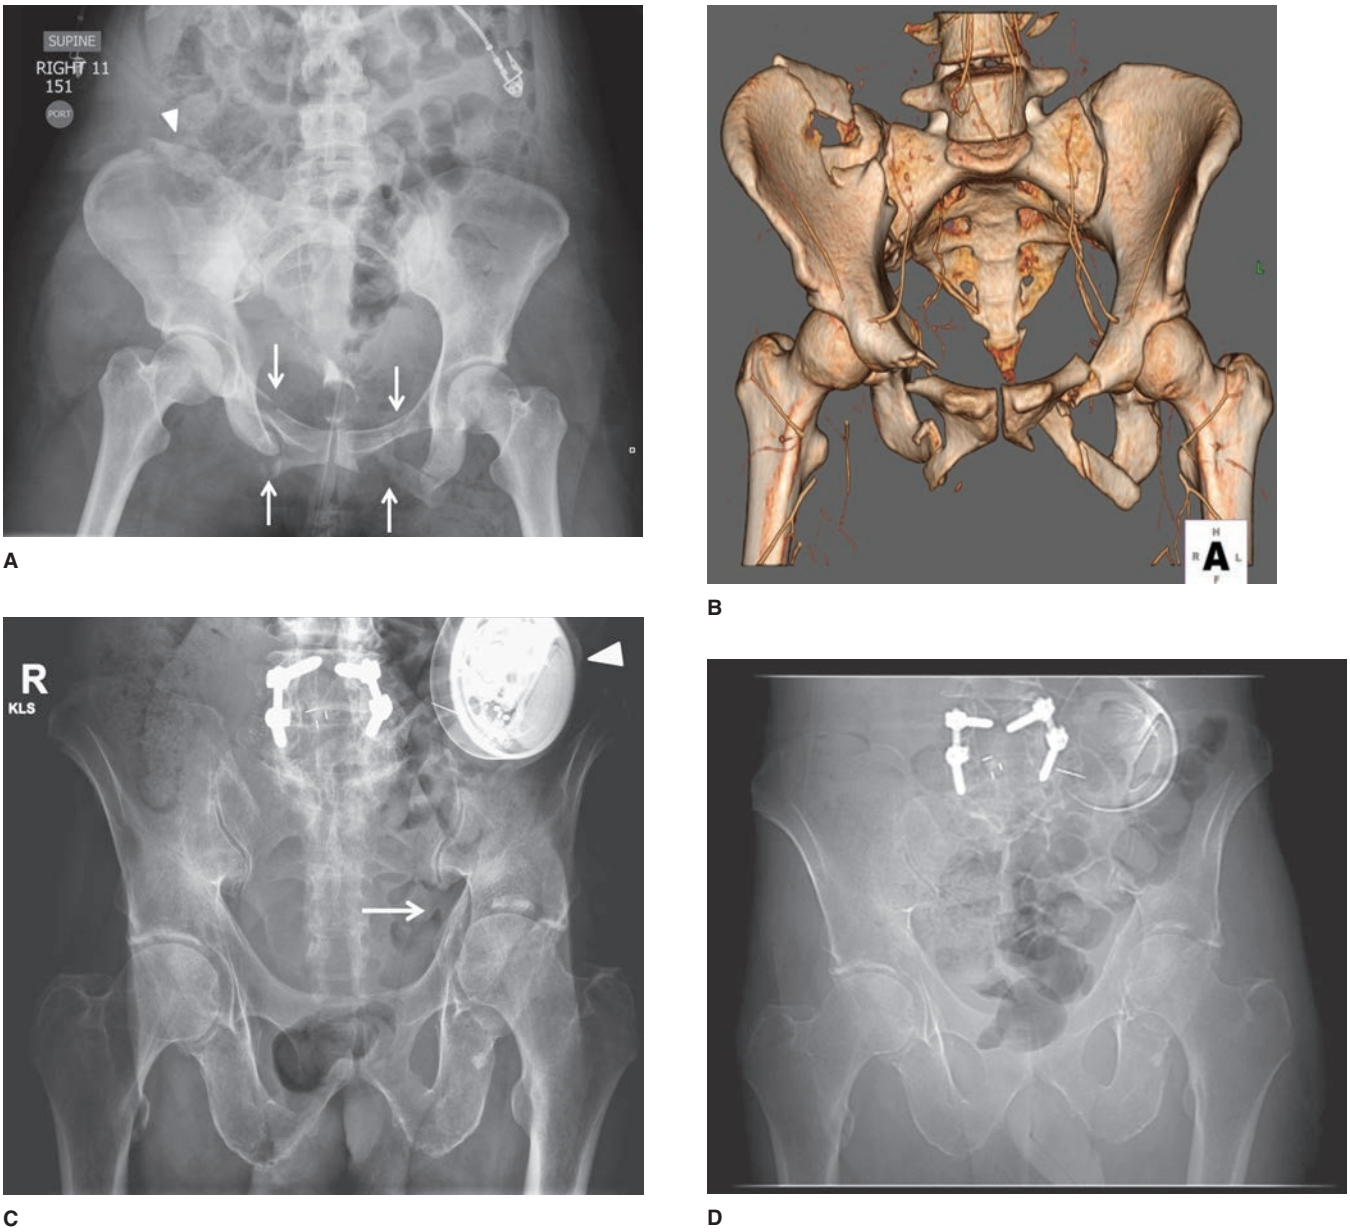

FIGURE 19-2 Advanced computed tomography (CT) imaging depicting pelvic and acetabular fractures. (**A**) Anteroposterior (AP) frontal radiograph of a 34-year-old female following a motorcycle crash. There is a highly disorganized pelvic ring disruption with fractures of the superior and inferior pubic rami (arrows) indicating a lateral compression force vector. There is also a comminuted fracture of the right iliac crest (arrow head). Notice the vertical height difference indicating a vertical shear mechanism of injury in addition to lateral compression. (**B**) Three-dimensional image with surface detail from the same patient nicely displays the bony fractures and their relationships to one another, with overlying soft tissue, bowel gas, and stool no longer a limiting factor. (**C**) AP frontal radiograph of a 74-year-old male with a left acetabular fracture (arrow) following a fall from standing height. The patient has L4–L5 posterior fixation hardware as well as a pain pump reservoir (arrowhead) overlying the left ilium. (**D**) A "virtual" pelvic radiograph on the same patient as in **C**, generated using the raw data from a subsequently performed pelvic CT. Notice that the pain pump reservoir has been partially removed from the image.

CT scanning is highly sensitive and specific for the detection of extra- and intra-axial hemorrhage, mass effect and midline shift, soft tissue injuries to the scalp and globes, and fractures to the calvarium, skull base, bony orbits, and paranasal sinuses. In patients with diffuse axonal injury, however, CT may even be normal and discordant between the severity of the clinical brain injury and radiographic findings (Fig. 19-4). On a cautionary note, skull fractures that are aligned in the plane of scanning may easily elude detection, and review of multiplanar reconstruction (MPR) images or the scout views used to plan the CT study of the head may alert the clinician to such fractures. Except for medicolegal imaging of pediatric nonaccidental trauma (child abuse), conventional x-rays of the skull are usually not necessary.[20]

FIGURE 19-3 Epidural hematoma. (**A**) Axial computed tomography (CT) using brain windows shows epidural hematoma (arrows), associated midline shift (white line), and leftward deviation of the left lateral ventricle (arrowhead). (**B**) Axial CT at level of the suprasellar cistern and brain windows shows epidural hematoma (arrow) and obliteration of the basal cisterns due to uncal herniation (arrowhead).

Computed Tomography of the Maxillofacial Skeleton

Indications for specific facial CT scans include the following: (1) deformity or instability of the maxillofacial structures found by physical examination; (2) deformity, opacification, or fracture of the periorbital or paranasal sinus shown on head CT; and (3) clinical evidence for leakage of cerebrospinal fluid (Fig. 19-6). The mnemonic LIPS-N (lip lacerations, intraoral lacerations, periorbital contusions, subconjunctival hemorrhage, or nasal lacerations) provides a helpful tool during clinical examination of trauma patients given the high association between LIPS-N lesions and facial fractures.[21] Fortunately, physical examination is highly sensitive for selecting which patients need maxillofacial CT imaging.[22] Absence of paranasal or periorbital sinus fluid on CT (the "clean sinus" sign) generally excludes surgically important injury to the maxillofacial skeleton, with only very rare exceptions.[23]

Images of the face are acquired using helical scanning technique and are reconstructed in the axial, sagittal, and coronal planes at 1- to 2-mm slice thickness, typically using both soft tissue and bone reconstruction algorithms. Helical acquisition with MDCT technology can be used to generate three-dimensional (3D) surface-rendered images of the bones, which can be quite helpful in determining the type of facial fracture patterns, particularly for patients with highly comminuted and disorganized high-energy midface smash fracture patterns. This technique provides valuable information on spatial relationships and is particularly useful in planning operative treatment.[24,25] However, axial and two-dimensional reformations best portray defects in soft tissue, interposition of osseous fragments, and herniations of soft tissue (eg, orbital floor blowout fractures) and are best for quantifying size of fractures.[26,27] It is important to recognize that some institutions do not routinely include the mandible as a part of the maxillofacial CT scan protocol; thus, open communication with the radiology team is important in order to include the relevant anatomy for evaluation.

Radiation reduction techniques for CT continue to evolve; however, maxillofacial CT can still deliver significant radiation to the orbits and to the soft tissues of the neck (eg, thyroid), which is an important consideration when imaging children in particular.[28]

Imaging for Soft Tissue Injuries of the Neck

Clinical findings for blunt injury to the aerodigestive tract are nonspecific but include subcutaneous crepitus, hemoptysis, hoarseness, neck pain, and abrasions or hematomas (eg, from the shoulder harness of a three-point restraint; Figs. 19-7 and 19-8). X-ray findings include parapharyngeal or precervical

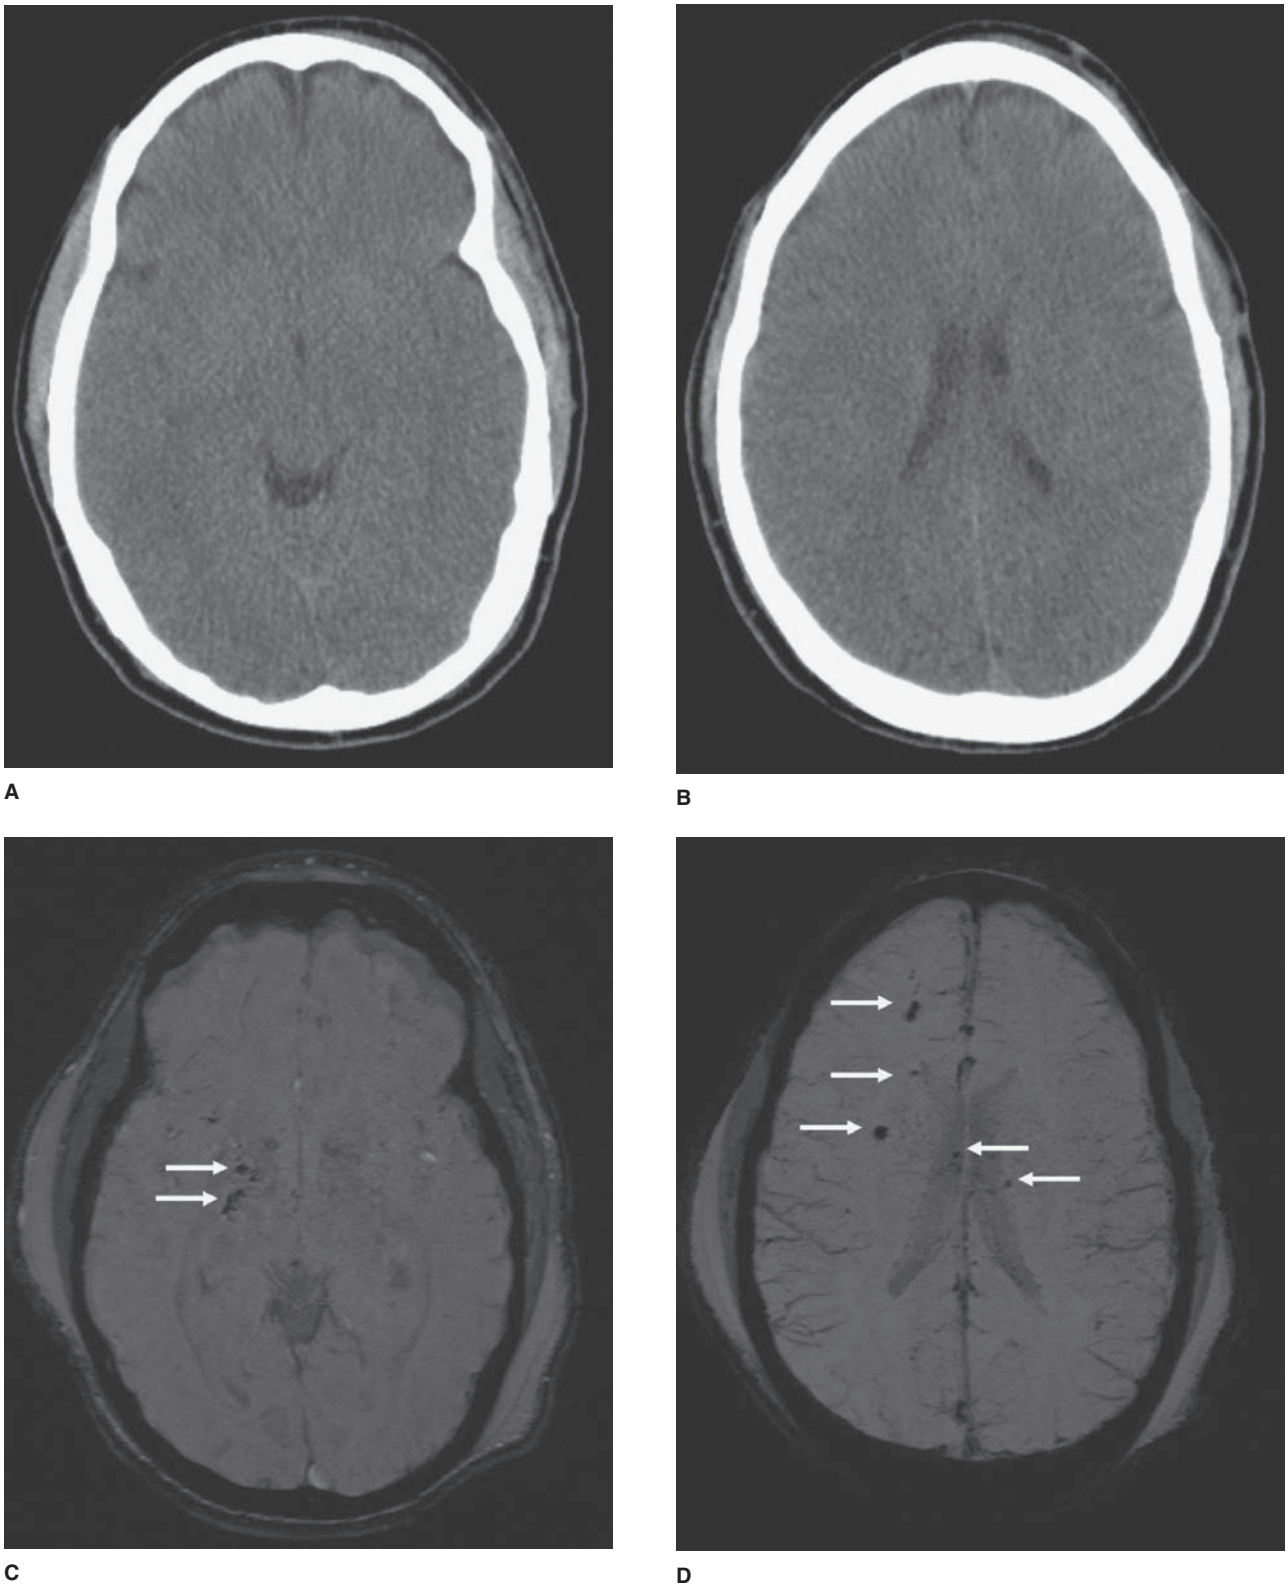

FIGURE 19-4 Blunt head injury: axonal shear injury. A 24-year-old helmeted male following a high-speed motorcycle collision. Admission axial noncontrast computed tomography (CT) at level of the third ventricle (**A**) and lateral ventricles (**B**) demonstrates no significant abnormality. The patient's neurologic status did not improve; therefore, brain magnetic resonance imaging (MRI) was performed 25 hours after admission (**C, D**). Axial MRIs at the same levels as **A** and **B** using gradient echo (GRE) sequences (which are highly sensitive for blood products) demonstrated numerous hemorrhagic foci throughout the brain, concentrated in the right basal ganglia (**C**) and the gray-white junction (**D**) (arrows).

FIGURE 19-5 Patterns of herniation. (**A**) Axial computed tomography (CT) at level of suprasellar cistern shows extensive subarachnoid hemorrhage extending from lateral aspect of suprasellar cistern (1), into the Sylvian fissure (2), circumferentially about brainstem and perimesencephalic cistern (3), along tentorium (4), and interpeduncular cistern (5). Entrapment of lateral ventricles is shown as dilatation of temporal horns (white arrows). Brainstem appears relatively lucent and heart shaped, with pointed inferior portion of heart due to "beaking" of mesencephalon due to upward herniation. (**B**) Subfalcine shift. Axial CT of another patient at level of lateral ventricles shows marked leftward subfalcine shift (white double arrow), quantified as distance from midline (vertical white line) connecting the anterior and posterior portions of the sagittal sinus (which tend not to shift due to their fixed relation to calvarium) to the interventricular septum. Note a right-sided holohemispheric subdural hematoma with hematocrit level (white arrow). (**C**) Uncal herniation. Axial CT of the same patient as in **B** at the level of middle cranial fossa again shows right-sided subdural hematoma (white arrow) with associated right uncal herniation (arrowhead). Enlargement of the left temporal horn (notched white arrow) is compatible with obstruction of the cisternal system.

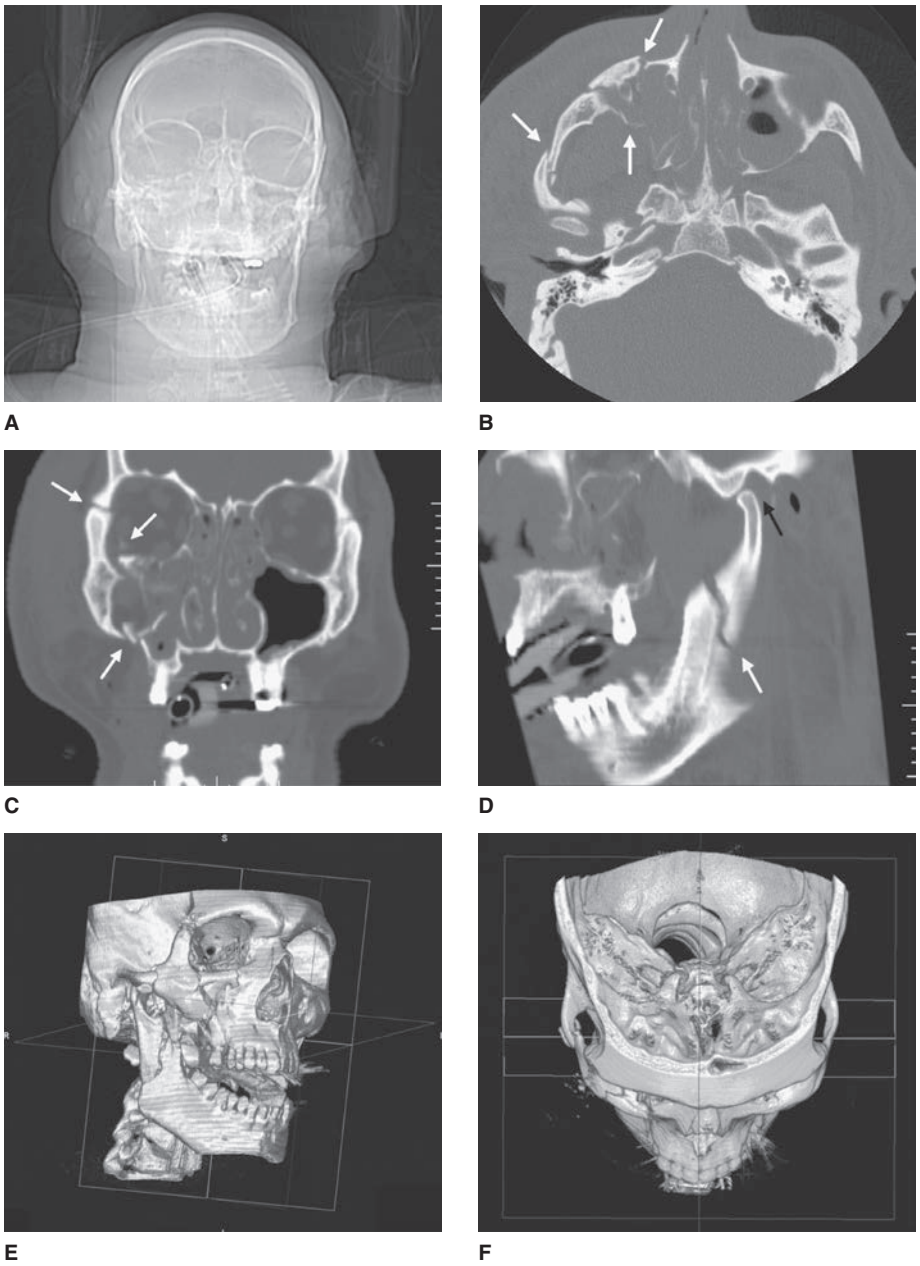

FIGURE 19-6 Facial fracture: zygomaticomaxillary complex (ZMC) fracture with associated naso-orbito-ethmoid (NOE) complex fracture. This 54-year-old male sustained a blow to the face in a motorcycle crash. (**A**) Anteroposterior (AP) scanogram shows loss of symmetry to orbital volumes, with elliptoid enlargement of right orbit. Associated indistinctness of orbital floor and lateral maxillary sinus walls is also present. Opacification of right maxillary sinus is shown. (**B**) Axial computed tomography (CT) image at the level of zygomatic arches shows depression and overriding apposition of impacted zygomatic arch fracture (lateral white arrow), posterolateral maxillary sinus wall disruption (posterior arrow), and segmental comminuted fracture of anterior maxillary wall (anterior arrow). Medial to this anterior arrow is the base of the nasofrontal process of the maxilla with a fractured nasolacrimal duct just posterior to it. Internal rotation of the nasofrontal process of the maxilla and associated fracture of the nasolacrimal duct are not portions of ZMC fracture and represent an associated NOE complex fracture. (**C**) Coronal CT reformation shows separation of right frontozygomatic suture (lateral and superior arrow), disruption of orbital floor (white arrow projected over orbit), and lateral maxillary wall (inferior white arrow). (**D**) Sagittal CT reformation shows associated vertical fracture of right ascending ramus of mandible, with anterior subluxation at temporomandibular joint (white and black arrows, respectively). (**E**) Three-dimensional CT reformation gives an overview of complex fracture of zygomaticomaxillary region and right mandibular fracture. It is important to note that spatial resolution is lost with three-dimensional reformations, although spatial comprehension is often improved. (**F**) Three-dimensional CT reformation shows depression of right zygomatic arch and loss of projection of the right zygoma (flat cheek).

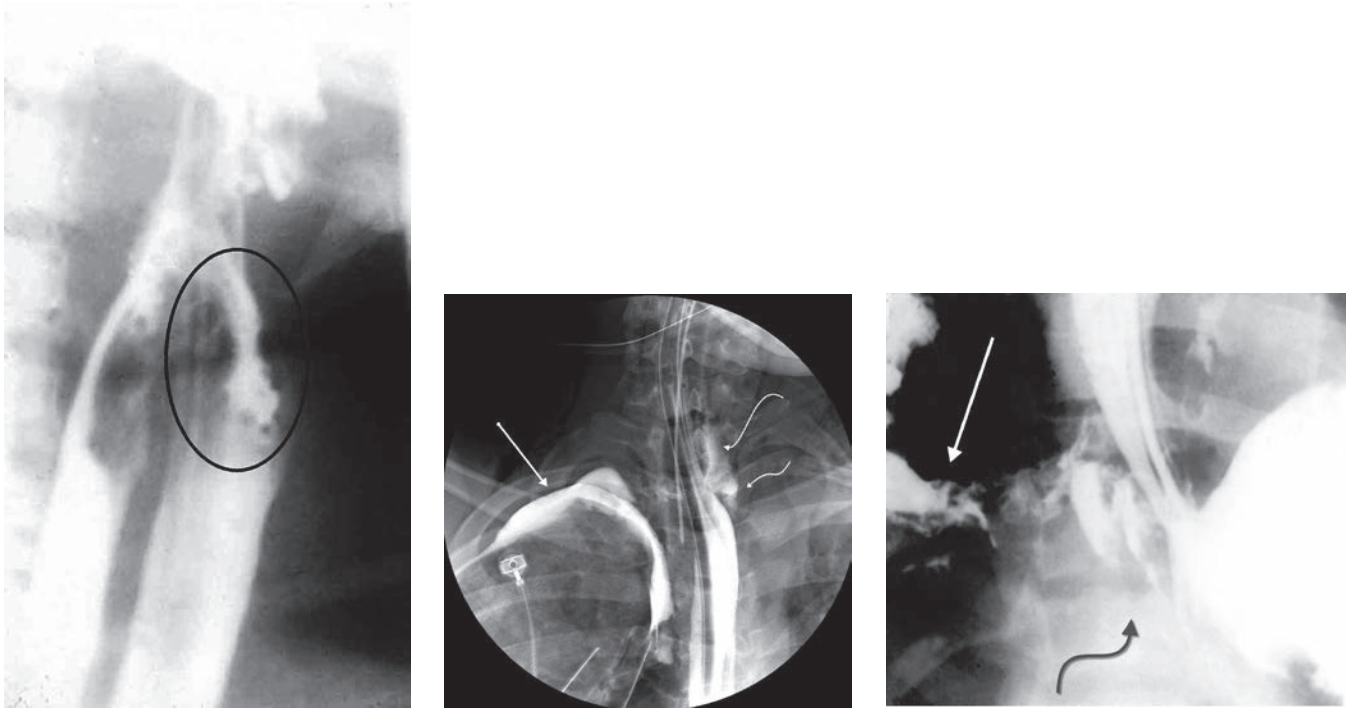
FIGURE 19-7 (*Continued*) (**E**) Axial CT from a 36-year-old male who was hit in the neck with a hockey puck reveals a fracture of the midline (triangle) and right side (arrow) of the thyroid cartilage. The patient was intubated due to immediate voice changes and to protect the airway.



A B C

FIGURE 19-8 Esophageal injuries. (**A**) Gunshot wound in zone II of the neck of a teenager. Barium extravasation directly enters the airway from a high laryngoesophageal fistula (circled). (**B**) Gunshot wound traversing zone I into the right chest. Barium swallow shows leak on both the left side of the cervical esophagus (curved arrows) and the right thoracic esophagus (straight arrow). (**C**) A 27-year-old male sustained a low transverse mediastinal gunshot wound entering left and exiting right. Gastrografin esophagram shows leak into the right chest (straight right arrow) and into the peritoneal cavity (curved black arrow).

emphysema, soft tissue swelling, or fracture of the larynx or hyoid bone on the lateral image of the cervical spine. Soft tissue injuries are inadequately evaluated using radiography; hence CT is the accepted imaging standard for imaging this area.

MDCT of the neck with intravenous contrast can not only be used to evaluate for upper aerodigestive tract injuries, but can also be used to simultaneously evaluate the cervical vasculature and spine (see later). Images are routinely reconstructed in three planes using both soft tissue and bone algorithms.

CT is often most helpful in the evaluation of laryngotracheal injuries when physical examination and endoscopy are technically difficult (Fig. 19-7E).[29] A careful search for direct signs of a laryngotracheal injury, manifested by focal defects, guides the need for intervention for debridement and mucosal closure. Soft tissue gas may be focal adjacent to the site of injury, but larger defects, particularly if the patient is under positive-pressure ventilation, can result in massive soft tissue emphysema extending into the skull base and head superiorly or into the mediastinum and beyond inferiorly.[30] CT can assist in the grading of laryngotracheal injuries but tends to understage injuries compared to endoscopy or open exploration. The most common injuries are those to the thyroid cartilage, which typically occur within 2 to 3 mm of the anterior crest of the two lateral laminae. Comminuted fractures of the laminae generally result from higher energy and direct impact injuries to the larynx and are more commonly associated with thyrocricoid dislocation. In addition, CT can demonstrate subluxations and dislocations of the arytenoid cartilage. Most tracheal disruptions are in the membranous portion of the trachea and can heal with conservative therapy. Soft tissue emphysema immediately adjacent to the trachea suggests an injury in this location but, again, could be massive in volume and anatomic distribution. A search for a fracture of a tracheal ring is often fruitless unless the fracture is displaced. Coronal reformations through the trachea may show separation (vertical diastasis between tracheal rings) of the trachea compatible with more serious grades of injury.

Blunt esophageal injuries are very uncommon, but when they do occur, they are most often observed in the proximal third of the esophagus. However, a penetrating injury to the esophagus is more common and may involve any portion of the esophagus. Any focal gas adjacent to the esophagus, without an obvious airway source, should raise the possibility of an injury, particularly if a wound tract extends up to or through the region of the esophagus.

If there is a concern for an esophageal injury, contrast esophagography, endoscopy, or both should be performed. Both tests have a sensitivity of 80% to 90%, but this increases to approximately 95% when both examinations are performed.[31,32] As a result, clinicians must use their level of suspicion to determine which of these tests (or both) to employ. Iso-osmolar water-soluble contrast material is the preferred *initial* contrast agent of choice for suspected esophageal injuries because it is less toxic to the lungs if aspirated and is better tolerated if leaked into the mediastinum or peritoneum. Unfortunately, iso-osmolar contrast material is less dense on fluoroscopy, with the potential to miss subtle injuries. Barium sulfate is easier to see but can be irritating to the soft tissues if an esophageal injury is present and should be used after initial water-soluble esophagography is negative. Gastrografin should be avoided because of its hyperosmolarity and because it can cause life-threatening pulmonary edema if aspirated.

Esophagography performed on patients who are awake and able to cooperate with the examination is performed as any other esophagram, but with the contrast agent modifications as described earlier. Performing esophagography in intubated and/or sedated patients is technically challenging and often limited despite maximal efforts on the part of the radiology team. A nasogastric tube is necessary to perform this examination on obtunded, intubated, and/or sedated patients. The patient is placed in reverse Trendelenburg position (10–20° as tolerated) with the fluoroscopy table floor board in place. The radiologist manipulates the nasogastric tube to the distal esophagus and, under real-time fluoroscopic surveillance, injects the contrast agent in an attempt to achieve full distention of the esophagus. The contrast is then immediately aspirated, and the nasogastric tube is repositioned more proximally. This process is repeated to evaluate all segments of the esophagus. Care should be taken to avoid overdistention of the proximal esophagus, which can result in reflux and aspiration, even in intubated patients. Rapid imaging is necessary, with fluoroscopic cineradiographs obtained at 2 to 3 frames per second.

IMAGING OF CERVICAL VASCULAR INJURIES

Neck CT angiography (CTA) with MDCT has a sensitivity of 90% to 100% for blunt cervical vascular injuries and is, therefore, the imaging test of choice in patients without indications for immediate surgery or catheter angiography. Neck CTA can be performed as its own stand-alone examination (as in the setting of penetrating neck injuries), added on to the standard trauma CT protocol, or integrated as a part of a single-pass whole-body CT trauma protocol.[33-37] Neck CTA protocols vary widely based on local preferences and mechanism of injury (ie, blunt vs penetrating). Positioning of the patient's arms is an important consideration when integrating neck CTA into the imaging evaluation of these patients, as increased image noise and decreased image quality will result when the arms are included in the scanned region.[37] Optimal cervical arterial opacification can be obtained following either a timing bolus or using a fixed scan delay. These images are reconstructed at 1- to 3-mm slice thickness from the aortic arch to the skull base (or to the cranial vertex if needed), with MPR reconstructed in axial, sagittal, and coronal planes. Coronal maximum-intensity projections (MIPs) are particularly helpful for visualizing the cervical vasculature but should not be relied upon for evaluation of the vertebral arteries due to volume averaging effects and the potential for a missed injury. Liberal use of a dedicated 3D volume viewing station

for manipulation of the data set is strongly encouraged, as it is often the case that a cervical vascular injury may be best visualized and displayed using nontraditional planes.

Catheter angiography is indicated emergently in patients with an expanding cervical hematoma; active extravasation from the nose, mouth, or ears; or a cervical bruit in individuals younger than 50 years old.[38] Angiography is not only a diagnostic test in symptomatic blunt carotid and vertebral artery injuries, but is also a therapeutic tool as it allows for rapid utilization of endovascular therapy for bleeding and identifies patients at risk for embolic stroke.[39,40] The sensitivity of duplex Doppler US is inadequately low (38.5%) for directly depicting vascular injuries in the neck and is, therefore, not a primary tool for evaluation of the cervical vasculature.[41] Existing literature for the use of magnetic resonance angiography (MRA) demonstrates limited sensitivity for cervical vascular injuries compared to CTA and catheter angiography.[42] This, in addition to the technical and practical limitations of MRI in the setting of trauma, limits the utility of magnetic resonance imaging (MRI)/MRA in the acute setting.

BLUNT CERVICAL VASCULAR INJURIES

Blunt carotid and vertebral injuries (Fig. 19-9A–C) are now known to be much more common than previously appreciated, occurring in 1% to 3% of screened asymptomatic patients.[35] Vascular imaging of the neck is warranted in injury patterns associated with a high risk of blunt injury to the carotid and vertebral arteries, including the following: fracture of the cervical spine (especially involving C1–C3, involving the transverse foramina, or extension into the foramen magnum), neurologic deficits not explained by findings at brain imaging, new-onset Horner syndrome, high-energy facial fractures (Le Fort II or III), fracture of the skull base involving the foramen lacerum, or soft tissue injury in the neck (neck belt sign and "hangings" sufficient to cause central anoxia).[39,43] It should be noted, however, that approximately one-fifth of patients with blunt cervical vascular injuries do not have these classically described risk factors and thus may elude detection if selective screening is employed.[44]

PENETRATING NECK INJURIES

Penetrating injuries to the neck are associated with high morbidity and mortality, primarily due to injuries of the cervical vasculature, upper aerodigestive tract, and spine. As such, any patient with "hard" signs of a cervical vascular injury (eg, expanding pulsatile hematoma, active bleeding from the wound, hemorrhagic shock) or compromise or injury of the upper aerodigestive tract or airway (eg, stridor, hoarseness) requires urgent intervention by individuals with experience managing such injuries. Neck CTA has proven highly useful in identifying and excluding injuries that require intervention and can significantly reduce the rate of nontherapeutic cervical explorations for patients without indications for immediate surgery or intervention[45-48] (Fig. 19-9D–E). In addition, it can be used to determine trajectory and identify direct signs of vascular injury. When patients are stable or asymptomatic, immediate CTA has great value in excluding injury, in detecting vascular injuries that can be treated nonoperatively by embolization or insertion of a stent or stent graft, and in facilitating surgical exploration.

There has been a shift away from mandatory evaluation of the neck with surgery and other invasive tests based on the zonal wound location toward a "no zone" selective approach with CTA evaluation of the neck.[49] Many factors must be considered when approaching the patient with a penetrating wound to the neck, including the mechanism of injury (high vs low energy), the number and location of surface wounds, hemodynamic and neurologic status, and the likelihood of injury. Gunshot wounds can result in significant soft tissue cavitation that may result in direct or indirect vascular injuries. In addition, fragments of bone and metal frequently cause artifacts in the area, which make interpreting a CT difficult. Catheter angiography (particularly digital subtraction angiography) is extremely useful for the evaluation of the carotid and vertebral arteries when they are partially obscured by beam hardening artifact from metallic bullet fragments.

Neck zonal anatomy is an important consideration for patients with "hard" clinical signs of significant internal injury; however, it should be noted that clinically significant internal injuries may be present in a zone differing from that of the physical examination and that penetrating wound tracts may extend beyond the neck into the skull base, cranial vault, mediastinum, or upper thorax. Zone III, above the angle of the mandible extending to the skull base, is difficult to assess clinically and to explore operatively. There are numerous vessels at risk, including the internal carotid artery, the external carotid artery and branches, the vertebral artery, and the accompanying veins. Thus, imaging plays a vital role in these patients. Neck CTA can be used to evaluate these vessels, but a low threshold for catheter angiography should be maintained for patients with possible injuries in zone III. Selective internal and external carotid arteriography, vertebral arteriography, and four-vessel intracranial arteriography all play important roles in detecting and evaluating zone III vascular injuries. Indeed, arteriography is so valuable for the evaluation and treatment of bleeding in this zone that aggressive steps to resuscitate the unstable patient and control bleeding by packing are warranted to allow angiography to proceed. Most vascular injuries in zone III are best managed by an experienced interventional radiology service.

Zone II, between the inferior margin of the angle of the mandible and cricoid cartilage, is more easily and reliably evaluated by physical examination. If the common carotid artery or the internal jugular vein requires repair, operative exposure is relatively simple and unobstructed. Thus, little imaging is necessary after penetration when "hard" signs of a vascular injury are present. The detection and treatment of vascular injuries in asymptomatic patients are more controversial.

D

FIGURE 19-9 Cervical vascular injuries. (**A**) A 24-year-old female involved in a high-speed motor vehicle collision. Admission axial computed tomography (CT) image demonstrates an intimal flap in the distal internal carotid artery (arrow) that is actually a pseudoaneurysm seen best on the sagittal image (**B**). The patient was treated conservatively. (**C**) Repeat neck CT angiography 20 days after injury reveals an enlarging pseudoaneurysm (arrow). (**D**) A 24-year-old male with common carotid artery and tracheal injuries following a dog attack. The right common carotid artery is not opacified (arrow) due to injury and subsequent thrombosis. A tracheal defect (arrowhead) is present, along with extensive cervical emphysema. (**E**) The extent of the cervical emphysema (arrows) is best seen on the scout image with gas extending inferiorly into the mediastinum (arrowheads).

Zone I is the area between the cricoid cartilage and the sternal notch. Structures here include the brachiocephalic vessels, trachea, and esophagus. Vascular injuries in this zone may result in rapid exsanguination, and as a result, symptomatic patients may undergo urgent exploration without imaging.

IMAGING OF THE SPINE

Imaging of spinal trauma often begins with simple radiography to evaluate for biomechanically unstable injuries, such as burst fractures and dislocations. It is critical to note that adequate radiographs of the spine may be technically difficult to obtain, may have limited quality in obtunded or immobilized patients, and may not detect all fractures. A meta-analysis of the sensitivity of radiography for cervical spine fractures by Holmes and Akkinepalli[50] documented a pooled sensitivity of 52%, compared to 98% for cervical spine CT. Thus, the decision to image with radiography or CT must be made based on the mechanism of injury and the likelihood of a spinal fracture and must be balanced with the possibility of other more life-threatening injuries. If an abnormality is identified on conventional x-rays, CT and/or MRI can be used to further characterize the injury for planning of treatment and provide information on the patient's prognosis.

Conventional Radiographs of the Spine

Validated clinical prediction rules (ie, National Emergency X-Radiography Utilization Study Group [NEXUS] and the Canadian Cervical Spine Rule) for adults and older children (≥10 years old) can reliably identify trauma victims who need imaging of the cervical spine.[51,52] In essence, oriented asymptomatic individuals without findings on a physical examination following trauma do not require subsequent imaging. Imaging of the thoracic and lumbar spine following blunt trauma is indicated when patients present with one or more of the following: (1) signs or symptoms of local injury (pain, tenderness, interspinous step-off); (2) depressed level of consciousness, including intoxication; (3) acute myelopathy or radiculopathy referable to the thoracolumbar spine; and (4) major distracting injury, including concomitant injuries to the cervical spine.[53,54]

A cross-table lateral cervical spine radiograph is often obtained in the setting of acute trauma, although its use is declining due to the easy availability of MDCT and relative lack of sensitivity compared to CT. Single-view lateral cervical spine films may not reveal a significant percentage of fractures. In fact, a study by Brohi et al[55] in 2005 reported a sensitivity of 39.3% and a sensitivity of 51.7% for single lateral view radiography evaluating unstable cervical injuries. This same study reported the sensitivity, specificity, and negative predictive value of CT to be 98.1%, 98.8%, and 99.7%, respectively.[55] The standard three-view cervical spine series includes an AP open-mouth odontoid view (an AP image of the craniocervical junction), an AP view of the subdental cervical spine, and a lateral view of the cervical spine that extends down to the C7–T1 interspace. To supplement these three views, a swimmer's lateral image (one arm elevated above the head and the other arm in caudal traction) is often obtained to better visualize the cervicothoracic junction, and bilateral oblique views are obtained to evaluate the facet joints. The addition of these supplemental images adds time and radiation exposure and may still be technically limited, despite maximum effort on the part of the x-ray technologist and the patient.

Given the differences in the incidence of injury to the cervical spine in children and the differences in their distribution (far more common in the upper cervical spine) relative to adults, an examination limited to frontal and lateral views is generally acceptable.[56] In infants 0 to 4 years of age and in children 5 to 9 years of age, AP, lateral, and open-mouth views are satisfactory. All patients age 10 and over require a minimum of three views to as many as five or six views to adequately survey the cervical spine. Clinical decision rules developed for adults cannot be reliably applied to children.

Films of the thoracic and lumbar spine are usually obtained as separate sets of frontal and lateral projections. The upper thoracic spine may require the addition of a swimmer's lateral view, if one has not been previously obtained as part of a cervical spine series. In general, if pathology is identified, then further evaluation with CT is indicated to further define the fracture pattern and to identify potential adjacent spinal injuries.

Technically inadequate examinations of the cervical or thoracic spine may be due to lack of visualization of the cervicothoracic junction or overlying arms due to upper extremity injuries. It is necessary to see the top of T1 on the cervical spine and the bottom of C7 on radiographs of the thoracic spine. A careful count of the vertebral bodies on the frontal examination to establish the correct levels is recommended to avoid wrong level surgery and is based on the number of rib-bearing (thoracic) and non–rib-bearing (lumbar) vertebrae. On the lateral images, it is important to look at the corners of the vertebral bodies, especially the anterior superior corner, which is affected in approximately 90% of all vertebral body fractures. On the frontal images, it is most important to evaluate the adjacent end plates for continuity, the lateral margins of the vertebrae, the posterior elements for pathologic interspinous and interpedicular widening, and horizontal lucencies that would suggest horizontal soft tissue and/or osseous disruption of a flexion-distraction–type injury.

One of the common errors made in evaluating the cervical spine is mistaking developmental variations for pathology. Common variations at the craniocervical junction include the following: (1) fusion of C1 to the occiput (which may be partial or complete); (2) failure of fusion or development of the posterior elements of C1; (3) pseudospreading of C1 relative to C2, which may mimic Jefferson burst fractures (most common in the 0- to 4-year age range, but may be seen up through puberty); (4) pseudosubluxation of C2 on C3 in pediatric patients, which can be recognized as normal by a normal C1–C3 spinolaminar line; and (5) os odontoideum

(an anomalous bone that replaces all or part of the dens but is not attached to the C2 body).

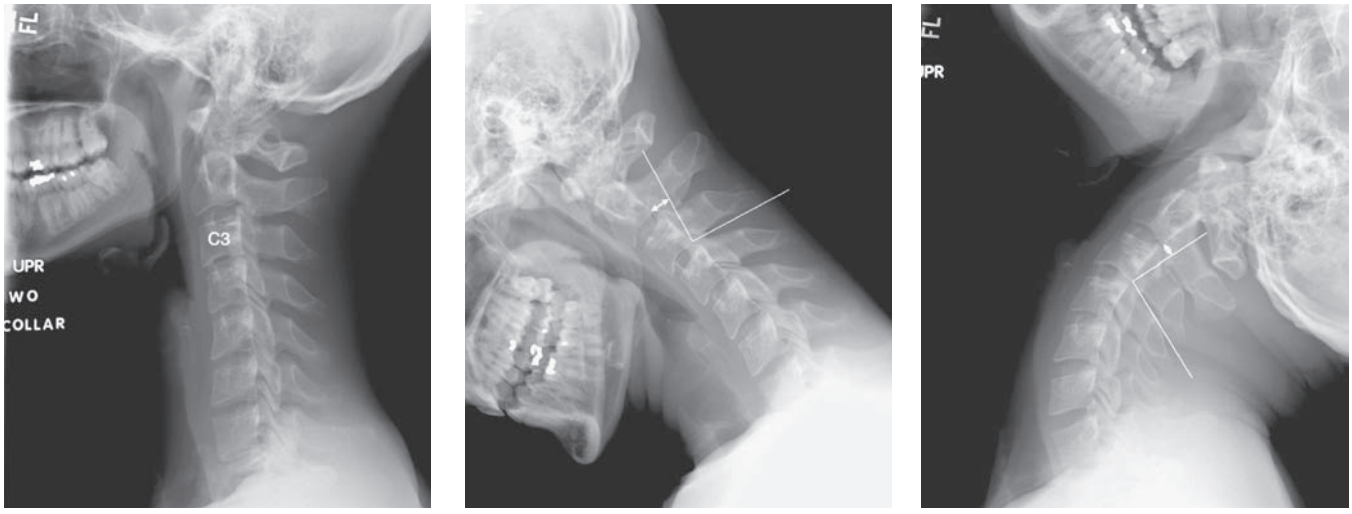
Flexion and Extension Cervical Spine Radiographs

Flexion and extension radiographs may be used to assess for potential ligamentous instability in patients who are completely alert and who have normal x-rays but exhibit posterior midline tenderness (Fig. 19-10). Some centers have recommended the use of passive (guided by the physician) flexion and extension studies using fluoroscopy, and although this may be appropriate in very limited circumstances in the hands of physicians with considerable experience, the published data are not sufficiently strong to warrant generalization.

A qualified physician should be in attendance if the examination is performed shortly after injury (hours to days), and the patient needs to be completely alert and able to assume an upright posture and precisely follow commands. An initial lateral radiograph is obtained with the patient upright and with the cervical spine in a neutral position. This image is reviewed by the physician overseeing the examination, and if normal, the patient is asked to actively extend the neck. An additional lateral image in maximum extension is obtained. The patient's cervical spine is then returned to a neutral position. This extension x-ray is evaluated in a manner similar to that taken with the cervical spine in a neutral position. If normal, the examination is repeated with maximum effort at flexion, and an x-ray is obtained. Standards for an adequate examination vary from a range of motion of 30° to 90°. The test is intended to study the capacity of the spine to resist physiologic stresses, however, and the mean normal range of motion in adults is approximately 90°. If the flexion-extension x-rays are abnormal in the acute or subacute setting, MRI is pursued. If the examination does not show an adequate range of motion, the patient's spine is immobilized, and the examination is repeated in 2 weeks if the patient remains symptomatic. It should be noted that approximately one-third of flexion-extension x-rays exhibit suboptimal flexion and/or extension, thus limiting its utility.[57] As a result, some centers with available resources omit flexion-extension series and move straight to MRI.

Computed Tomography of the Cervical Spine

Blackmore et al[58] developed a clinical prediction rule to determine preimaging risk of fracture in select patients about to undergo a helical CT to survey the cervical spine for fracture and soft tissue injuries (Figs. 19-11 and 19-12). For the application of this rule, it is assumed that the patient will already be undergoing CT of the cranium. Any one of three mechanisms of injury or any one of three clinical findings puts the patient at a pretest risk of greater than 5% of harboring an injury in the cervical spine. High-risk mechanisms of injury include a high-speed motor vehicle crash greater than 35 mph (or greater than 50 km/h), combined impact, motor vehicle crash with a death at the scene, or a fall from a height



A B C

FIGURE 19-10 Flexion-extension radiograph: cervical spine showing subtle instability at C2–C3. This 24-year-old male bicyclist was struck by a car from behind, and posterior midline tenderness of upper cervical spine was palpated. (**A**) Upright lateral out-of-collar radiograph shows loss of usual cervical lordosis without focal kyphosis or translation. Precervical soft tissues are normal. (**B**) Upright lateral flexion radiograph of cervical spine shows no gross interspinous widening or loss of parallelism of facet joint. Reference lines are drawn from posteroinferior corner of C3 to most inferior aspect of C3 spinous process. Perpendicular to that line from posteroinferior corner, a line is used as a reference for translation of C2 relative of C3, as demonstrated by double-arrowed line. (**C**) Upright lateral extension radiograph of cervical spine again shows no gross widening of anterior disk space. Using same reference for translation of C2 on C3, 2.5 mm of difference at C2–C3 disk space is demonstrated between flexion and extension, compatible with partial, dynamic instability.

(**G**) Axial diffusion-weighted magnetic resonance image demonstrates restricted diffusion (arrow) in the left cerebellar hemisphere compatible with acute cerebellar infarction.

of greater than 10 ft or greater than 3 m. Clinical parameters suggesting an increased risk for injury to the cervical spine that are associated with a high-risk mechanism include a significant closed injury to the brain (or intracranial hemorrhage shown on head CT), acute neurologic deficits referable to the cervical spine (acute myelopathy or radiculopathy), or either pelvic fracture or multiple extremity fractures. Hanson et al[59] validated the clinical prediction rule prospectively and showed its application by separating victims of blunt trauma into a high-risk group (12% prevalence of acute cervical spine injury) and a low-risk group (0.2% prevalence of cervical spine injury). No validated clinical decision rules exist for infants (<1 year old) and younger children (<9 years old). In general, patients with greater severities of injury (Injury Severity Score >25) have an elevated risk of injury to the cervical spine. For patients age 9 years or younger, conventional x-rays will depict essentially all clinically important fractures and dislocations. CT is generally not indicated in younger children and infants to screen the cervical spine or to search for other occult injuries causing neurologic deficits.[60] CT should be reserved as a staging/treatment planning procedure among patients with a known bony abnormality.

Modern helical MDCT scanners allow for high-resolution imaging of the cervical spine, with the quality of sagittal and coronal images equating to that of the axial images. Axial slices of the cervical spine are obtained at 1.0- to 3.0-mm slice thickness from the skull base through the upper thoracic spine (T2–T4 vertebral body level). Coronal and sagittal reformations are typically 1.0- to 3.0-mm-thick images and reconstructed using bone and soft tissue algorithms. Generally, the information gathered from these reformations is sufficient and makes plain x-rays unnecessary. PACS workstations can facilitate the rapid review of these large image sets, and the use of cross-referencing tools assists with identification of specific vertebral levels.

Careful review of the entire cervical spine in all three planes is necessary for comprehensive evaluation. Some of the more common fracture patterns (eg, type II fractures of the base of the odontoid process or horizontally oriented fractures of the spinous process) have "in plane" axial fracture lines and thus may be difficult to identify when reviewing the axial images alone. The coronal reformations may be viewed using the same approach as standard AP x-rays, whereas viewing of the sagittal reformations can be performed with guidelines used for the lateral cervical spine. Nonetheless, careful attention to axial images is necessary to detect fractures involving the craniocervical junction, transverse processes (which increase the likelihood of a vertebral artery injury), margins of vertebral bodies, pedicles, lateral mass, or lamina and spinous processes.

The sensitivity and specificity of cervical spine CT for acute bony injuries are routinely in excess of 95%. Although CT does not directly show soft tissue injuries to the spine, focal kyphosis, focal lordosis, and widening of the disk space can be used as with conventional x-rays to suggest associated injuries to soft tissue. Occasionally, acute disk herniations can be identified on axial or sagittal soft tissue images. Some authors feel that clinically important injuries to soft tissue causing biomechanical instability are almost always evident on technically adequate CTs of the cervical spine (especially on the sagittal and parasagittal reformations).[61]

Computed Tomography of the Thoracolumbar Spine

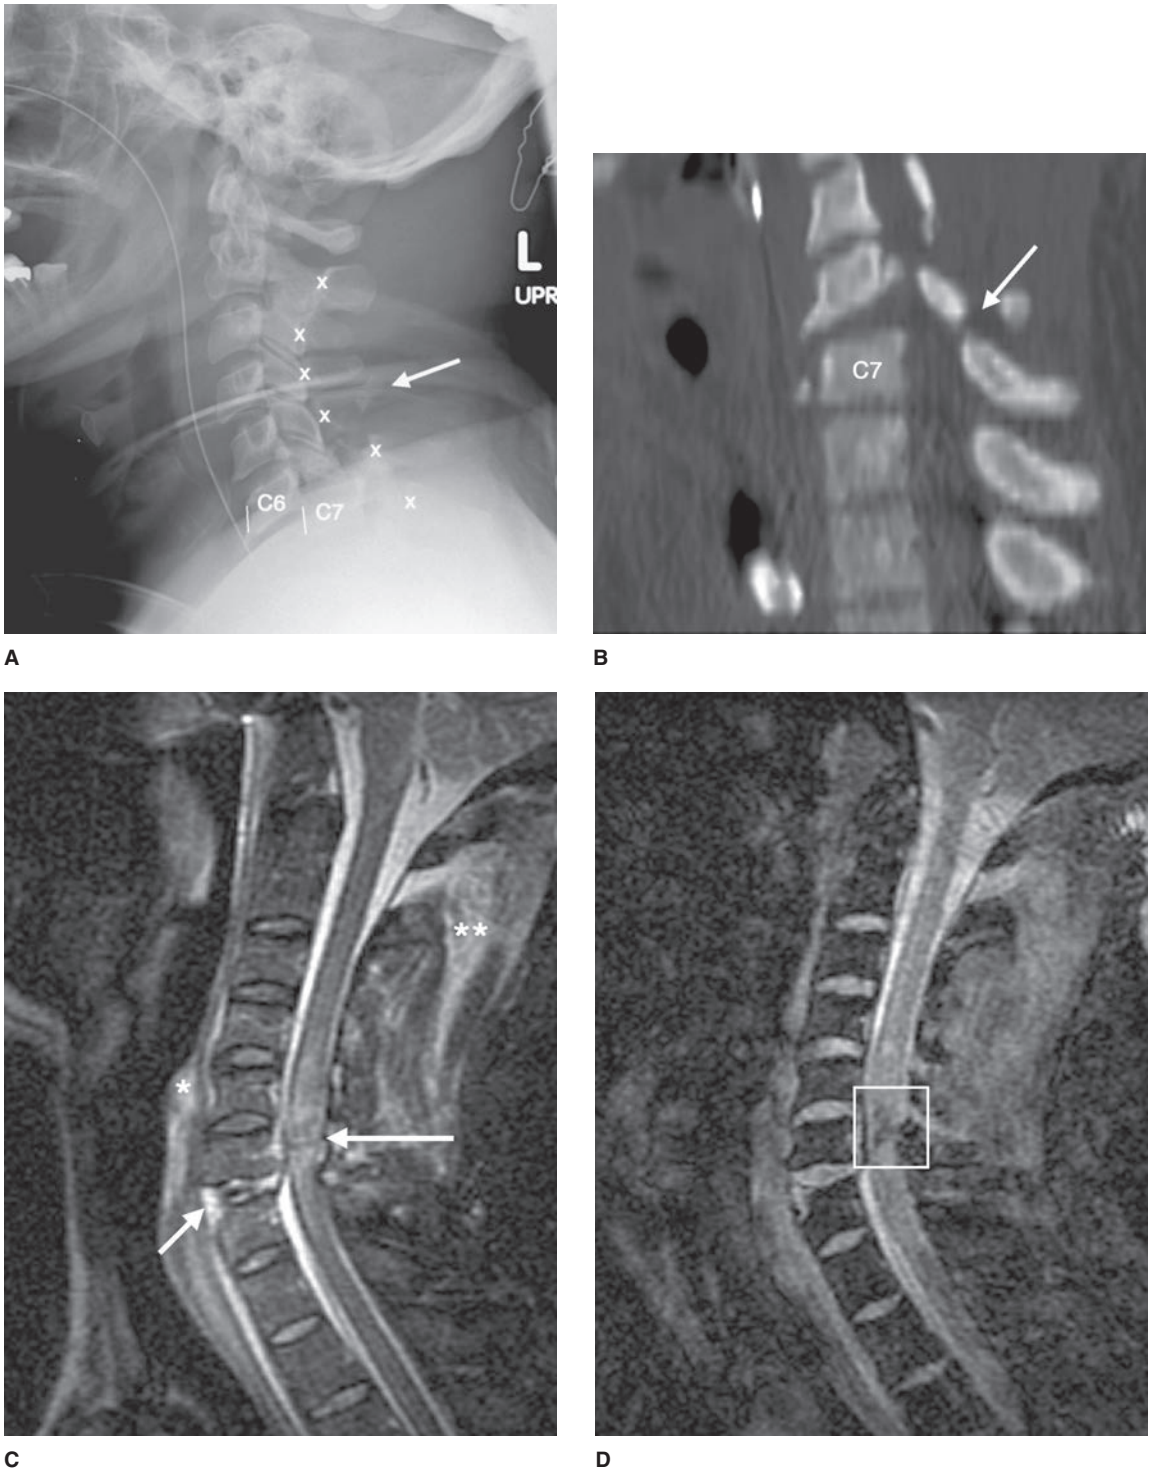
A low threshold should be maintained for the use of CT to further evaluate vertebral body deformities identified on conventional x-rays. In addition, patients with high-risk mechanisms and impressive signs or symptoms without abnormal x-rays should undergo a thoracolumbar CT to detect occult minimal burst fractures or Chance or flexion-distraction–type injuries. Dedicated radiographs of the thoracolumbar spine can be omitted if a CT of the chest and/or abdomen is obtained. The CT raw data of the chest and/or abdomen can be used to generate dedicated coned down images of the thoracolumbar spine, reconstructed in axial, sagittal, and coronal planes using a bone algorithm, without the need to reimage the patient. Limited imaging of specific vertebral body levels based on radiographic findings is being replaced by more comprehensive spinal imaging.

Typically, 2.0- to 3.0-mm-thick axial slices are acquired and are reconstructed using both bone and soft tissue algorithms. Imaging of the entire thoracic or lumbar spine is advised as it allows more accurate determination of the location of injury. Sagittal reformations are made in both algorithms and viewed at bone and soft tissue windows, respectively. Careful attention to the paraspinal structures, such as the ribs, mediastinum, and retroperitoneum, is strongly recommended if a flexion-distraction or Chance fracture is detected on dedicated thoracolumbar CT imaging. This diagnostic pitfall is becoming less of a factor due to the increased use of contrast-enhanced whole-body CT imaging in trauma.

Magnetic Resonance Imaging of the Spine

The principle indications for MRI are to characterize soft tissue injuries and potential spinal cord injuries in patients with associated fractures and/or malalignment of vertebrae (Fig. 19-13). An MRI is indicated in individuals who have no conventional x-rays or CT abnormality but who have an acute myelopathy or radiculopathy (spinal cord injury without radiographic abnormality [SCIWORA]). The use of MRI is frequently controversial in the setting of dislocation of bilateral or unilateral facets. Some advocate initial reduction followed by MRI, but this is a practice that varies from institution to institution. In general, urgent MRI is appropriate when there is an evolving neurologic deficit or neurologic deficits without explanation.

Edema of the spinal cord has a much better prognosis than cord hemorrhage. MRI is helpful in making this distinction, as well as detecting epidural hematomas that may require decompression. Evaluations of the disk spaces, ligaments of



A B C D

FIGURE 19-13 Multimodality correlations: cervical spine. A patient with C6–C7 fracture dislocation underwent prereduction lateral conventional radiograph (**A**), postreduction sagittal reformation (**B**) from axial computed tomography (CT), and magnetic resonance imaging (MRI) of the spine and cord (**C**) and (**D**). (**A**) White Xs mark laminar points, and connecting them shows disruption of spinolaminar line at C6–C7. Arrow points to fractures of inferior articular process of C6. Sagittal CT reformation (**B**) shows improved alignment of vertebral bodies but persistent encroachment of neural canal from bony fragments from body and posterior elements (arrow). (**C, D**) Sagittal MRI performed using short tau inversion recovery (STIR) and gradient recalled echo (GRE) sequences following reduction of C6–C7 fracture dislocation. Single asterisk shows precervical edema, and double asterisk shows edema in posterior spinal musculature. Long white arrow shows a region of cord swelling with heterogeneous signal, suggesting cord transection at C6 level. Short arrow shows abnormal signal within C6–C7 disk space. GRE sequences (**D**) show decreased signal at C6 level within the center of the cord that is compatible with hemorrhage (white square), which portends poorer neurologic prognosis than edema alone.

the spinal column and facet joints, and the craniocervical junction are best made with MRI.

Spine MRI imaging protocols in trauma vary among institutions, but sagittal and axial T1-weighted and fluid-sensitive sequences (eg, T2-weighted short tau inversion recovery [STIR]) are standard. Gradient echo (GRE) sequences are useful in detecting magnetic susceptibility artifact due to blood products. When assessing the transverse atlantal ligament, images should be obtained in the axial plane parallel to Ranawat's line (a line from the anteriormost portion of the anterior tubercle of C1 to the most posterior aspect of the posterior arch of C1).

MRIs have been used to "clear" the cervical spine in obtunded or unexaminable patients with otherwise normal imaging (CT or high-quality conventional radiographs).[62,63] The absence of abnormal high signal intensity in ligaments and disks effectively excludes biomechanically significant injuries; however, an abnormal signal does not necessarily confirm instability.

Computed Tomography of the Chest

Chest CT has high sensitivity, specificity, and negative predictive value in the setting of trauma and can provide significant information about the lungs, pleural cavities, thoracic vasculature, and chest wall.[64] Chest CT is generally performed to evaluate adult victims of high-energy blunt trauma (especially those with chest pain, deformity, or hypoxia), with particular attention to the mediastinal structures (Figs. 19-14 to 19-18). Children presenting with hypotension, elevated respiratory rate, abnormal physical examination, depressed consciousness, and femur fractures after blunt trauma are at a substantially increased risk for an intrathoracic injury.[65]

Chest CT is performed with intravenous contrast, preferably with the patient's arms abducted above the head, from the thoracic inlet to the mid abdomen to include the entire thoracic cavity. Continuing the scan through the abdomen and pelvis can be easily performed. Images are acquired during the systemic arterial phase to maximize aortic enhancement and are reconstructed in the axial, sagittal, and coronal planes at 2.0- to 4.0-mm slice thickness. MPRs are used to evaluate not only the thoracic aorta and mediastinum, but also the thoracic spine (see earlier discussion). Tailored MPRs, such as sagittal oblique ("candy cane" view of the aorta), may be helpful in visualization of an aortic injury. Noncontrast chest imaging has limited utility in the setting of trauma, although mediastinal blood, hemopneumothoraces, and fractures to the spine and ribs may be detected on noncontrast imaging. In patients unable to receive contrast due to a known severe allergy, noncontrast CT can be effective in detecting a mediastinal hematoma and guiding the patient to evaluations such as transesophageal echocardiography and MRA. In patients with renal insufficiency, the risk of contrast-induced nephropathy or worsening renal function should be weighed against the risk of missing a major thoracic injury.

Chest CT is believed to be most cost-effective when patients: (1) are already undergoing another CT examination (eg, CT of the head, abdomen, and pelvis); (2) are at risk for injury to the thoracic aorta because of high-energy mechanism, associated injuries, or age (>50 years old); or (3) have a previously abnormal chest radiograph. A clinical decision rule was proposed by Blackmore et al,[66] in which individuals with two or more of the following are at high risk for aortic injury: age greater than 50, unrestrained occupant in motor vehicle crash, hypotension, thoracic injury (rib fracture, pneumothorax, pulmonary contusion, or laceration), abdominopelvic injury (fracture of lumbar spine or pelvic ring, injury requiring laparotomy), fractures of appendicular skeleton, or injury to the brain.

The role of MDCT in the diagnosis of acute traumatic aortic injury has undergone significant evolution over the past 25 years, with sensitivity and negative predictive value of contrast-enhanced chest CT routinely in excess of 98% for modern scanners. In fact, patients who have direct signs of a thoracic aortic injury on MDCT no longer require catheter angiography confirmation, as was often the case in the past, and a normal thoracic aorta on chest CTA reliably excludes a traumatic aortic injury.[67] CT imaging features of a traumatic aortic injury can be divided into direct and indirect findings. Direct findings of traumatic aortic injuries include pseudoaneurysms, intimal flaps, pseudocoarctation (due to subadventitial dissection), and active bleeding. A mediastinal hematoma, however, is an indirect finding and can be present in the absence of an aortic injury. To suggest an aortic injury, a mediastinal hematoma should be contiguous with the aortic wall and should not be separated from the aorta by a rim of fat (Fig. 19-17D). Determination of whether or not a mediastinal hematoma has obliterated juxta-aortic fat can be difficult in thin patients or in patients with extensive soft tissue edema. Complex atheromatous disease can make interpretation of the examination difficult, particularly for subtler injuries. An emerging form of an acute aortic injury, called the "minimal" or "minor" aortic injury, is an injury pattern thought to be secondary to advancing imaging technology (Fig. 19-19).[68,69]

There is significant debate regarding what lesion is defined as a "minimal" aortic injury. More specifically, they may include an intimal injury with thrombus, intimal flap less than 1 cm in length, and pseudoaneurysm less than 1 cm in diameter. There is often very little or no mediastinal hemorrhage with this type of injury.[68,69] There are no universally accepted imaging follow-up recommendations for patients with minimal aortic injuries, although serial short interval follow-up to resolution has been advocated.[69] Finally, aortic pulsation artifact (particularly involving the aortic root and ascending aorta) and beam hardening artifact due to dense contrast in adjacent venous structures may make interpretation difficult. Further evaluation with catheter angiography can be performed in equivocal or suboptimal examinations but is of low diagnostic value in the setting of a high-quality diagnostic chest CT angiogram. Multiplanar and 3D reformations of the injured thoracic aorta are particularly helpful for planning treatment. It is important to delineate the anatomy of interest to the trauma surgeon, such as the distance

FIGURE 19-17 Mediastinal hematoma caused by nonaortic injury. (**A**) Anteroposterior (AP) chest radiograph performed on 19-year-old unrestrained driver in head-on motor vehicle crash shows multiple injuries, including T6 and left shoulder fractures. Widening of right paratracheal stripe (H), obscuration of aortic arch (black arrow), and abnormal right paraspinal line (white arrows) suggest mediastinal hematoma. In absence of osteophytes, right paratracheal stripes are not typically seen in young adults, and their presence locally should direct search for underlying pathology. Left paraspinal line is typically seen due to descending aorta and should not be seen as continuous line between the lower chest and the apex of lung. Continuous left paraspinal line from apex to diaphragm is pathognomonic for mediastinal collection, such as hematoma in setting of trauma. (**B**) Same patient as in **A**; axial computed tomography (CT) following intravenous contrast shows extensive posterior mediastinal hematoma (asterisks). (**C–E**) This is a 56-year-old male involved in a motor vehicle collision. (**C**) AP supine chest radiograph demonstrates a widened mediastinum with abnormal and ill-defined aortic contours, concerning for a mediastinal hematoma. (**D**) Axial postcontrast CT through the upper mediastinum demonstrates retrosternal hematoma (arrow) with a clean fat plane between the hematoma and aorta (asterisk) and no periaortic hemorrhage. (**E**) Axial postcontrast CT through the mid chest demonstrates a fracture of the sternal body (arrowhead) as a source of the mediastinal hematoma (arrow). The aorta was not injured.

C

FIGURE 19-18 Pulmonary contusions and lacerations due to blunt-force injury. (**A**) Anteroposterior (AP) supine chest radiograph of a patient involved in a T-bone motor vehicle collision shows extensive right perihilar distribution airspace opacities (arrows). The left lung is clear. (**B**) Axial postcontrast computed tomography (CT) image reveals a right pneumothorax (asterisk, which was radiographically occult) and multiple pulmonary parenchymal lacerations (arrows) of various sizes, the larger of which demonstrates a layering blood fluid level. Ground glass opacities surrounding these lacerations are due to pulmonary contusions (arrowheads). There are patchy peripheral ground glass opacities in the left upper lobe compatible with pulmonary contusions (bracket), which are better appreciated on CT. Pulmonary contusions are typically present by the time the patient presents to the hospital and may evolve for 48 to 72 hours. Progression thereafter should be considered a complication, such as pneumonia or adult respiratory distress syndrome. Typically, pulmonary contusions resolve within 1 week. This example nicely illustrates that a supine chest radiograph often underestimates the severity of a chest injury. (**C**) Axial CT through the upper chest shows an aortic injury (arrow) and pulmonary contusions/lacerations (triangle) not as well seen on this soft tissue image.

from the most proximal point of injury to the origin of the left subclavian artery or any anomalous branches. These capabilities have significantly altered the role of catheter angiography from its traditional role of diagnosis, staging, and pretreatment planning, to one more often used for resolving diagnostic conundrums raised by CT or transesophageal echocardiography or as part of treatment using an endovascular stent graft.

CT is the most sensitive diagnostic method for detection of acute blood in the pericardium.[70] It is also among the most sensitive methods for detection of injuries to the chest wall, pleural cavities, and lungs.[64] Older CT technology exhibited relatively low sensitivity for the detection of injuries to the hemidiaphragm (sensitivity of 65%–70%) but has vastly improved with helical MDCT technology, now with sensitivities of 71% to 90% and specificities of 98% to 100%.[71] For suspected diaphragmatic injuries, especially herniations through a diaphragmatic tear, coronal and sagittal multiplanar reformations are useful because they better display characteristic findings (Fig. 19-20). Direct CT signs of diaphragmatic rupture include focal diaphragmatic defect, the "dangling" diaphragm sign (from a free-floating diaphragm flap), and

FIGURE 19-20 A 60-year-old-male with a left diaphragm rupture following a high-speed motor vehicle collision. (**A**) Portable chest film on admission demonstrates superior displacement of the stomach (asterisk). There is a left upper lobe opacity (arrow) due to pulmonary contusion. (**B**) Axial computed tomography (CT) image through the lower chest demonstrates the stomach (asterisk) above the diaphragm next to the heart. There is herniation of abdominal fat and colon (arrow) into the left thoracic cavity. Notice that the stomach and abdominal fat are displaced posteriorly and are layering dependently against the posterior chest wall, referred to as the "dependent viscera sign," a specific sign of a diaphragm rupture. (**C**) Coronal CT image demonstrates the stomach (asterisk) herniated into the left thoracic cavity. There is a nasogastric tube in place (arrow).

herniation of abdominal contents through a diaphragmatic defect. A normal contour of the diaphragm and no pleural collections or adjacent airspace disease effectively exclude diaphragmatic injury.

CT is helpful for diagnosing injuries to the tracheobronchial tree and has a sensitivity of 85% for tracheal rupture.[30] Nearly all patients with tracheobronchial injuries exhibit a massive pneumomediastinum or soft tissue emphysema (Fig. 19-7A and B; Fig. 19-9D and E).

Computed Tomography of Abdomen and Pelvis

Abdominopelvic CT is one of many adjunctive tests to assist the trauma surgeon in the evaluation of hemodynamically stable patients with suspected occult intra-abdominal injuries or to aid in more definitive characterization of injuries previously detected by other diagnostic tests (eg, DPL or FAST; Figs. 19-21 to 19-27). Usual indications include abdominal signs (eg, lap belt sign) or symptoms (eg, pain and tenderness) following high-energy blunt trauma. The combination of pleuritic chest pain at the left costal margin and left lower rib fractures is an independent predictor of splenic injury and warrants diagnostic evaluation.[72] Abdominopelvic CT is extremely helpful in guiding management and has been shown to significantly decrease the number of negative or nontherapeutic laparotomies. There has been a recent increase in the utilization of "triple-contrast" abdominopelvic CT in the setting of penetrating trauma, in the absence of indications for immediate laparotomy (eg, peritonitis or hemodynamic instability).[73] This is particularly true for back and flank penetrating wounds.

It is estimated that clinical signs and symptoms of intra-abdominal injuries may be misleading in 20% to 50% of patients, that physical examination has a 55% to 65% sensitivity for the detection of internal injuries, and that up to 19% of patients with blunt abdominal trauma have unsuspected injuries.[9,74,75] This, coupled with a negative predictive value of greater than 97% for abdominopelvic CT, has resulted in overall increased utilization of CT in the setting of blunt abdominal trauma. In addition, abdominopelvic CT is the principle means of both detection and characterization of renal injuries among adults with gross hematuria, children with microscopic hematuria (>50 red blood cells per high-power field), or microscopic hematuria among adults who have had one or more episodes of systolic hypotension.

CT of the abdomen and pelvis acquired during the portal venous phase (60- to 75-second scan delay) has been shown to have a high sensitivity, specificity, and negative predictive value for the diagnosis, grading, and exclusion of solid organ injuries. The addition of an arterial phase aids not only in the detection of arterial injuries, but also in the detection of pseudoaneurysms in solid organs, which may not be visible on portal venous phase images (Fig. 19-26).[76,77]

Portal venous or delayed phase imaging can also assist in the detection of active bleeding from the organs or pelvis. CT is accurate in the detection of urinary leaks from the upper genitourinary tract, and delayed excretory phase (>5 minutes) imaging is recommended in the setting of renal lacerations to evaluate for urinary leaks (Fig. 19-25). Isolated fluid around the ureters on initial scanning should raise the possibility of an injury, and 5-minute delayed scanning is indicated (Fig. 19-27).

Portal venous or delayed phase scanning through the pelvis is helpful for the detection of pelvic active bleeding. Images of all acquired phases should be reconstructed at 2- to 5-mm slice thickness in the axial, sagittal, and coronal planes.

The arterial-weighted phase images are particularly useful for the detection of brisk arterial bleeding and may detect an intraparenchymal pseudoaneurysm in a solid organ or an arteriovenous fistula, which may otherwise go undetected if portal venous phase imaging alone is acquired (Fig. 19-26). Recent literature suggests that a comprehensive evaluation to assess for the presence of a splenic injury requires both arterial and portal venous phases. The arterial phase performs better for the detection of splenic pseudoaneurysms, and portal venous phase has improved detection for parenchymal lacerations and active bleeding over arterial phase alone.[76] Extravasation of venous contrast is observed in 5% to 10% of victims of high-energy blunt trauma and may be difficult to differentiate from slow arterial bleeding on CT. The spleen is the most common region of isolated active extravasation of contrast; however, fractures of the pelvic ring are most commonly associated with multiple sites of extravasation.[78] The amount of hematoma associated with disruptions of the pelvic ring directly correlates with the likelihood of an angiographically demonstrable arterial injury (200 cm^3, 5% arterial injury; >500 cm^3, approximately 50% arterial injury).[79] Nonetheless, otherwise unexplained continued hemodynamic instability in patients with blunt pelvic fractures warrants angiographic evaluation, even in the absence of a pelvic hematoma or active pelvic bleeding on the initial CT (Fig. 19-28).[80]

Active bleeding identified on a CT is an independent predictor for the failure of nonoperative management, particularly when bleeding is arising from the spleen, liver, mesentery, or pelvis. Active bleeding from the spleen or liver is a stronger indicator for the need for intervention than the organ injury grade alone (Fig. 19-21). The detection of lacerations that extend to the hepatic veins is of particular importance in the liver, as these have a strong predictive value for failure of nonoperative management when associated with large (>10 cm) hypoperfused regions.[81] Adrenal hemorrhage is relatively common, particularly on the right, and is not of clinical importance unless bilateral. Even then, posttraumatic hypoadrenalism is rare. It should be noted that CT grading scales for the solid organs do exist, and although there is significant overlap with the American Association for the Surgery of Trauma (AAST) solid organ grading scales, they are not identical. Thus, open communication with the interpreting radiologist is recommended to avoid any miscommunication. Evaluation of the lower genitourinary tract can be performed with urethrography or cystography (Figs. 19-29 and 19-30). CT cystography typically is performed after the

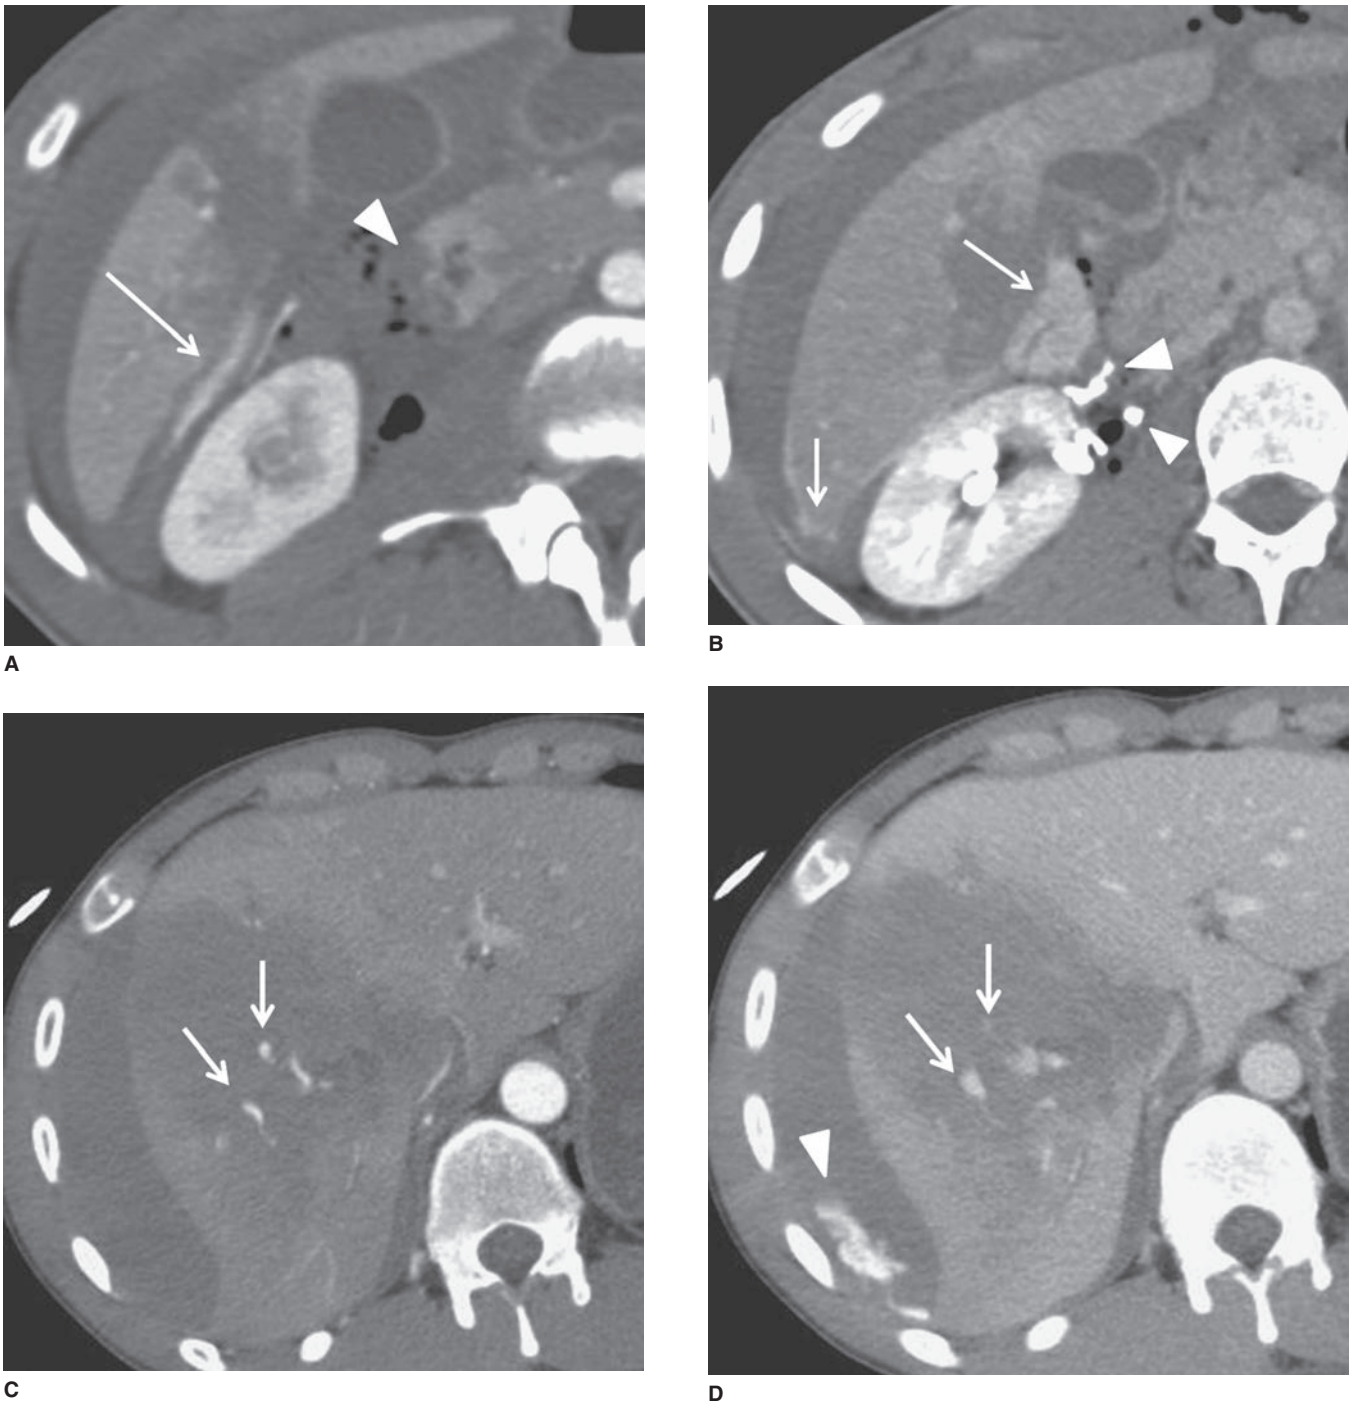

FIGURE 19-21 Examples of contrast extravasation in the abdomen. (**A, B**) Laceration of the right hepatic lobe following a gunshot wound. There is active contrast extravasation seen on arterial phase (**A**, arrow), which enlarges on 5-minute delayed phase (**B**, arrows) compatible with active bleeding. There is retroperitoneal gas due to a full-thickness duodenal injury (**A**, arrowhead). Five-minute delayed scan (**B**) also reveals extravasated urinary contrast from a renal pelvis laceration (**B**, arrowhead). (**C–E**) Active bleeding from a large liver laceration. Axial arterial phase (**C**), axial portal venous (PV) phase (**D**), and coronal maximum-intensity projection PV phase.

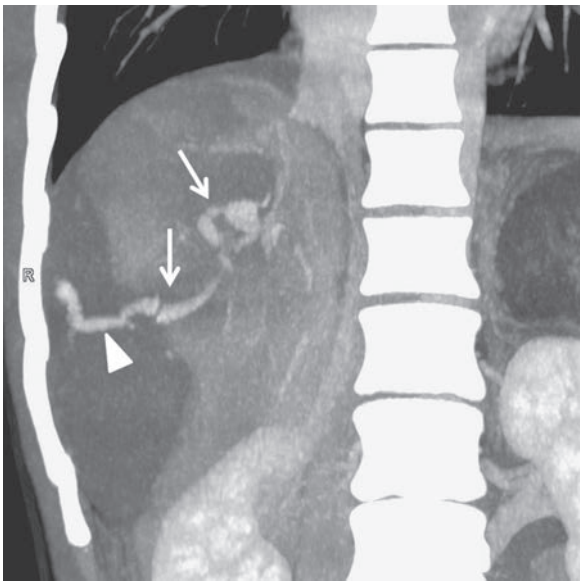
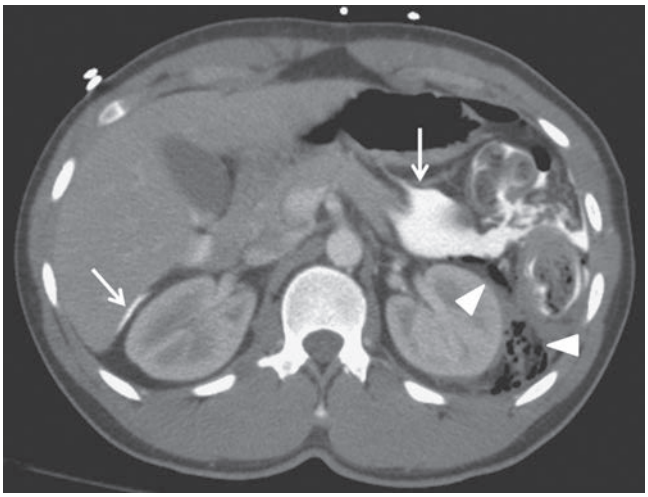
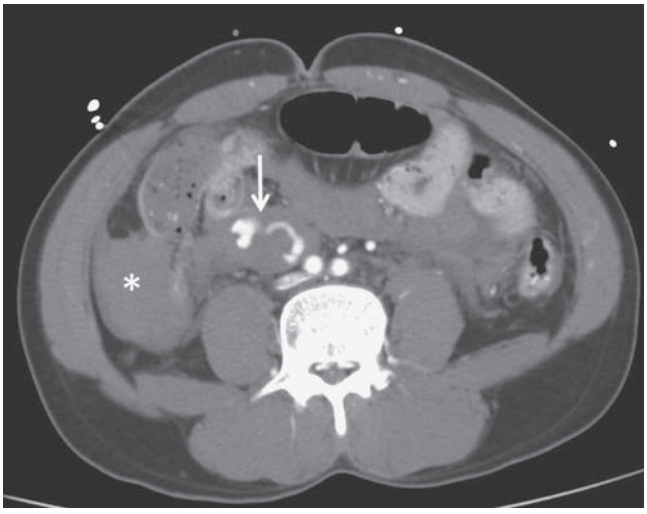


E



F



G

FIGURE 19-21 (*Continued*) (**E**) Image demonstrates active bleeding (arrows), which enlarges on the PV phase, accumulating in a large subcapsular hematoma (arrowhead). (**F**) Bowel contrast leak. A 23-year-old male following a left flank gunshot wound demonstrates leakage of a large amount of rectally administered contrast (arrows) from a full-thickness colon injury. Bubbles of extraluminal gas are seen in the left retroperitoneum (arrowheads). (**G**) Active contrast extravasation (arrow) from small bowel mesenteric root in a 28-year-old male following a motor vehicle collision. A large amount of free fluid and hemoperitoneum (asterisk) are also present. Active bleeding from the mesentery and an associated small bowel perforation were identified at surgery.

administration of intravenous contrast, as a large amount of leaked extraperitoneal contrast may obscure active arterial extravasation in the pelvis. CT cystography can be easily included in the initial evaluation of the trauma patient after the traditional trauma CT survey and is highly accurate for the diagnosis, exclusion, and comprehensive characterization of bladder injuries.[82] Passive physiologic filling of the bladder (eg, a 10-minute delay with a clamped Foley catheter) may detect injuries to the bladder but has been shown to be insufficient for the reliable exclusion of all injuries and should not be relied on as the sole examination for suspected bladder trauma (Fig. 19-30).[82,83]

To perform CT cystography, the bladder is first emptied of unopacified urine to diminish the effects of contrast dilution. Scanning through the pelvis is then performed. Administration of dilute water-soluble contrast via low gravity drip can proceed only after the positioning of the Foley catheter within the bladder is confirmed. It is not uncommon for a Foley catheter to be inserted through a laceration of the bladder dome in a patient with an intraperitoneal bladder

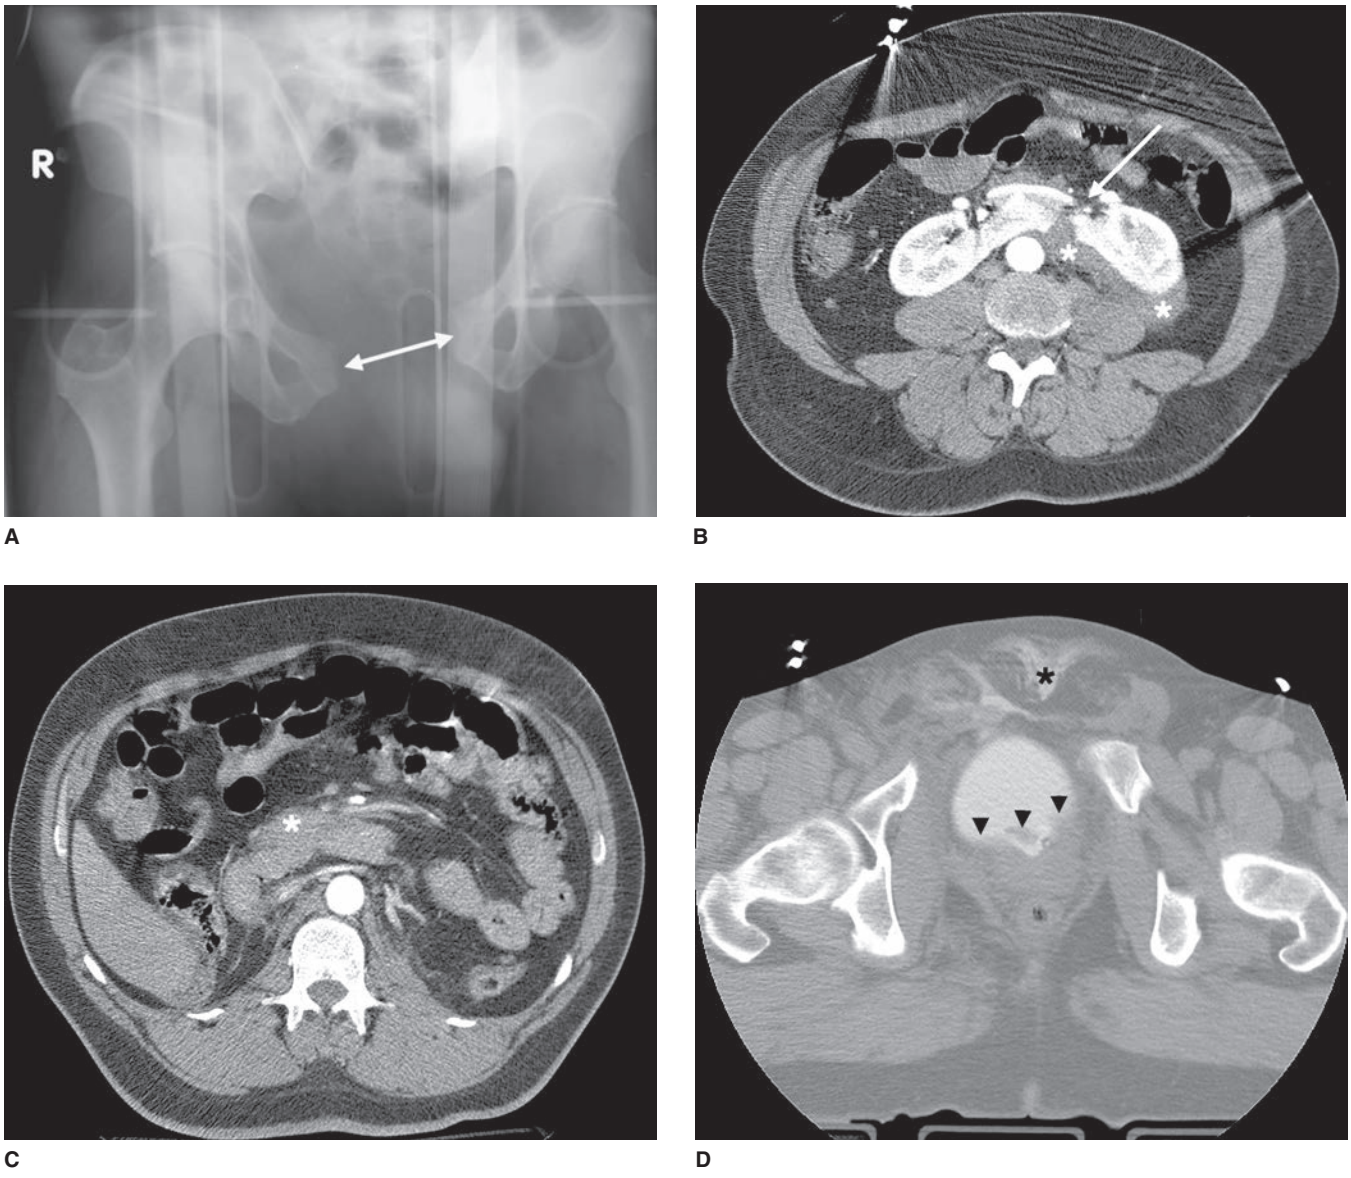


FIGURE 19-22 Patterns of injury: "the central package." This 54-year-old male motorcyclist sustained multiple injuries, including laceration of horseshoe kidney, duodenal contusion, bladder rupture, and anteroposterior (AP) compression fracture of pelvic ring. (**A**) AP radiograph of pelvis. Greater than 2.5-cm diastasis of pubic symphysis is compatible with disruption of sacrospinous, sacrotuberous, and anterior capsular ligaments of sacroiliac joints. Appearance supports AP compression mechanism and is associated with increased risk for intra-abdominal, intrathoracic, and head injuries. (**B**) Axial computed tomography (CT) of abdomen at L3–L4 level in the arterial phase. White arrow shows median fracture of horseshoe kidney with posterior perinephric hematoma (asterisks). This is an arterial phase image because there is dense opacification of aorta directly posterior to neck of horseshoe kidney without opacification of the inferior vena cava immediately to its right. Arterial phase images best demonstrate active extravasation and pseudoaneurysms. (**C**) Axial CT at level of third portion of duodenum shows paraduodenal hematoma (asterisk), suggestive of duodenal injury. (**D**) Axial CT at level of right acetabulum shows widening of symphysis and extraperitoneal bladder laceration as contrast in anterior abdominal wall (asterisk). Posterior wall of bladder is irregular with double densities within urine contrast compatible with hematoma (arrowheads).

rupture. The bladder should then be filled with at least 250 to 300 mL of contrast, or until the patient can no longer tolerate the degree of bladder distention or until the contrast stops passively flowing into the bladder. It should be noted that contrast may continue to freely flow in patients with intraperitoneal bladder injuries, and infusing over 350 to 400 mL without scanning is not advised. Scanning through the pelvis with maximum bladder distention is then performed. All scan series are reconstructed in axial, sagittal, and coronal planes at 1- to 3-mm slice thickness. Review of the images using "bone" windows may make the identification of the source of urinary leak more apparent, depending on the density of the contrast material in the bladder. Postvoid scanning may identify small bladder leaks, but this is rare.

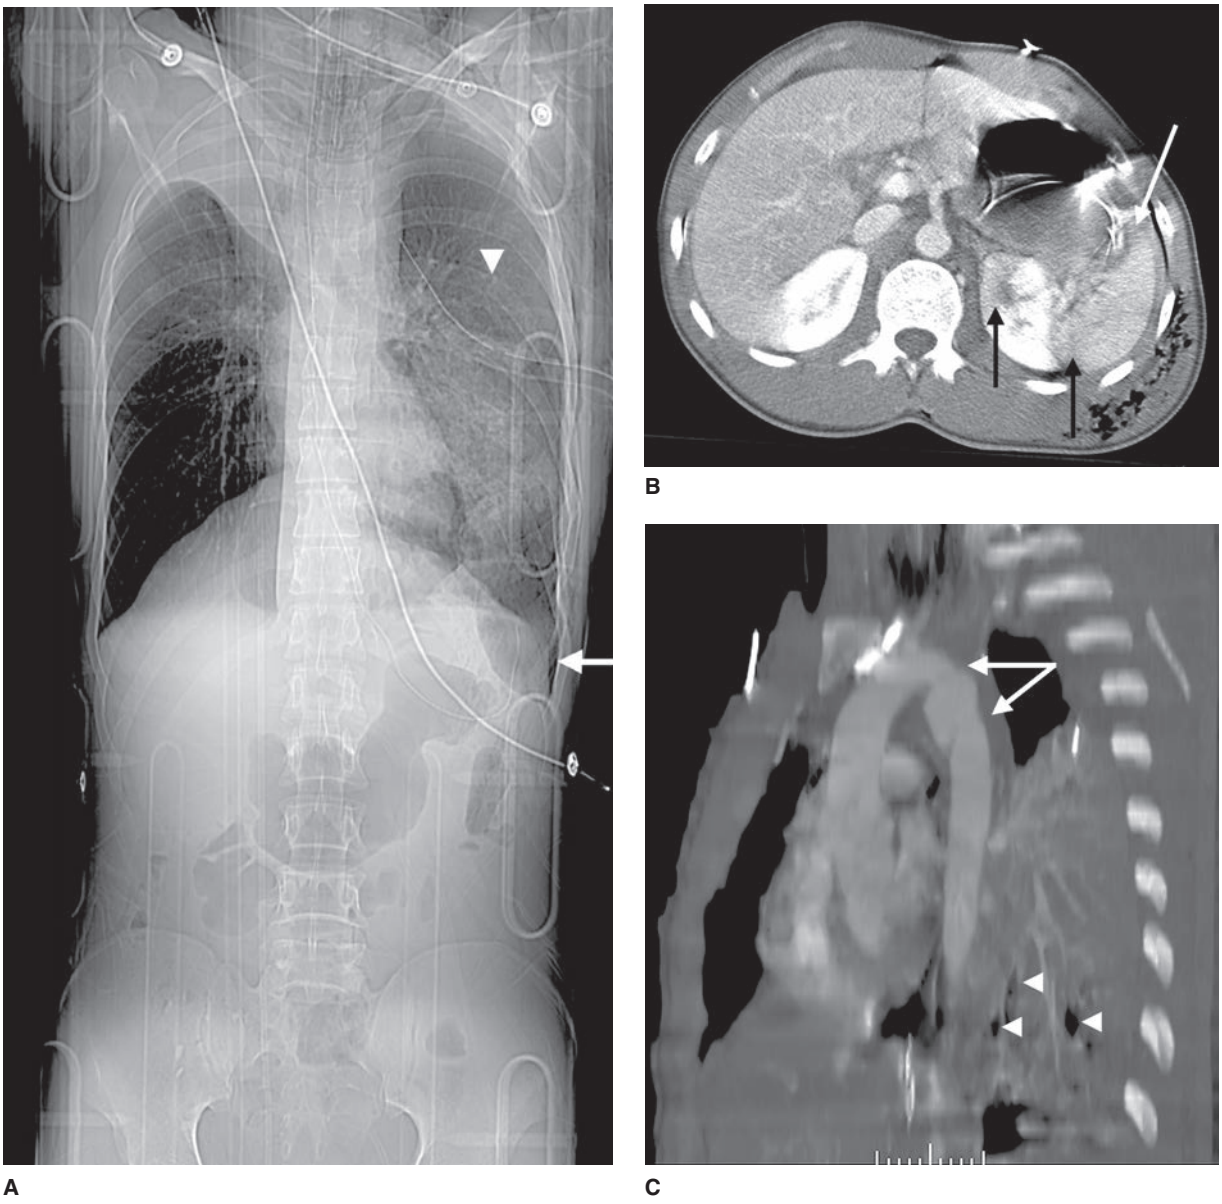

FIGURE 19-23 Patterns of injury: "the left package." This 22-year-old male driver was injured in a side-impact crash with substantial intrusion to driver's side of car. Multiple injuries were sustained. (**A**) Anteroposterior (AP) scanogram from computed tomography (CT) of chest, abdomen, and pelvis shows extensive opacity of left mid and lower lung fields compatible with contusion, a deep sulcus (arrow) at left costophrenic angle compatible with left pneumothorax, and multiple left-sided rib fractures (arrowhead). Patient is intubated, and there is right upper lobe collapse. (**B**) Axial CT of upper abdomen during parenchymal phase shows injury of the anterior portion of left kidney (medial arrow) and splenic laceration with sentinel clot (black and white arrows, respectively). Although rib fractures are not shown on current image, subcutaneous emphysema in left chest wall and distal extent of small pneumothorax are shown. (**C**) Oblique sagittal reformation from CT aortography shows complex segmental intimal injury to proximal descending aorta in the typical location (arrows) and pseudoaneurysm formation due to acute traumatic aortic injury. Air-fluid levels (arrowheads) are compatible with pulmonary lacerations.

Indications for CT cystography include hematuria and fracture of either the pelvic ring or acetabulum or hematuria and free intraperitoneal fluid in the absence of a clearly identifiable source. Cystography is low yield in the absence of hematuria and pelvic fractures.

Injuries to the bowel and mesentery are thought to occur in 1% to 5% of patients with blunt trauma but, when present, are associated with increased morbidity and mortality primarily due to a delayed diagnosis.[84,85] The physical examination alone lacks sensitivity and specificity, particularly in patients with an unreliable physical examination.[85] The sensitivity and specificity of CT for bowel injuries are modest, ranging from 69% to 95% and 94% to 100%, respectively.[85] Specific CT findings of bowel injuries include thickened bowel

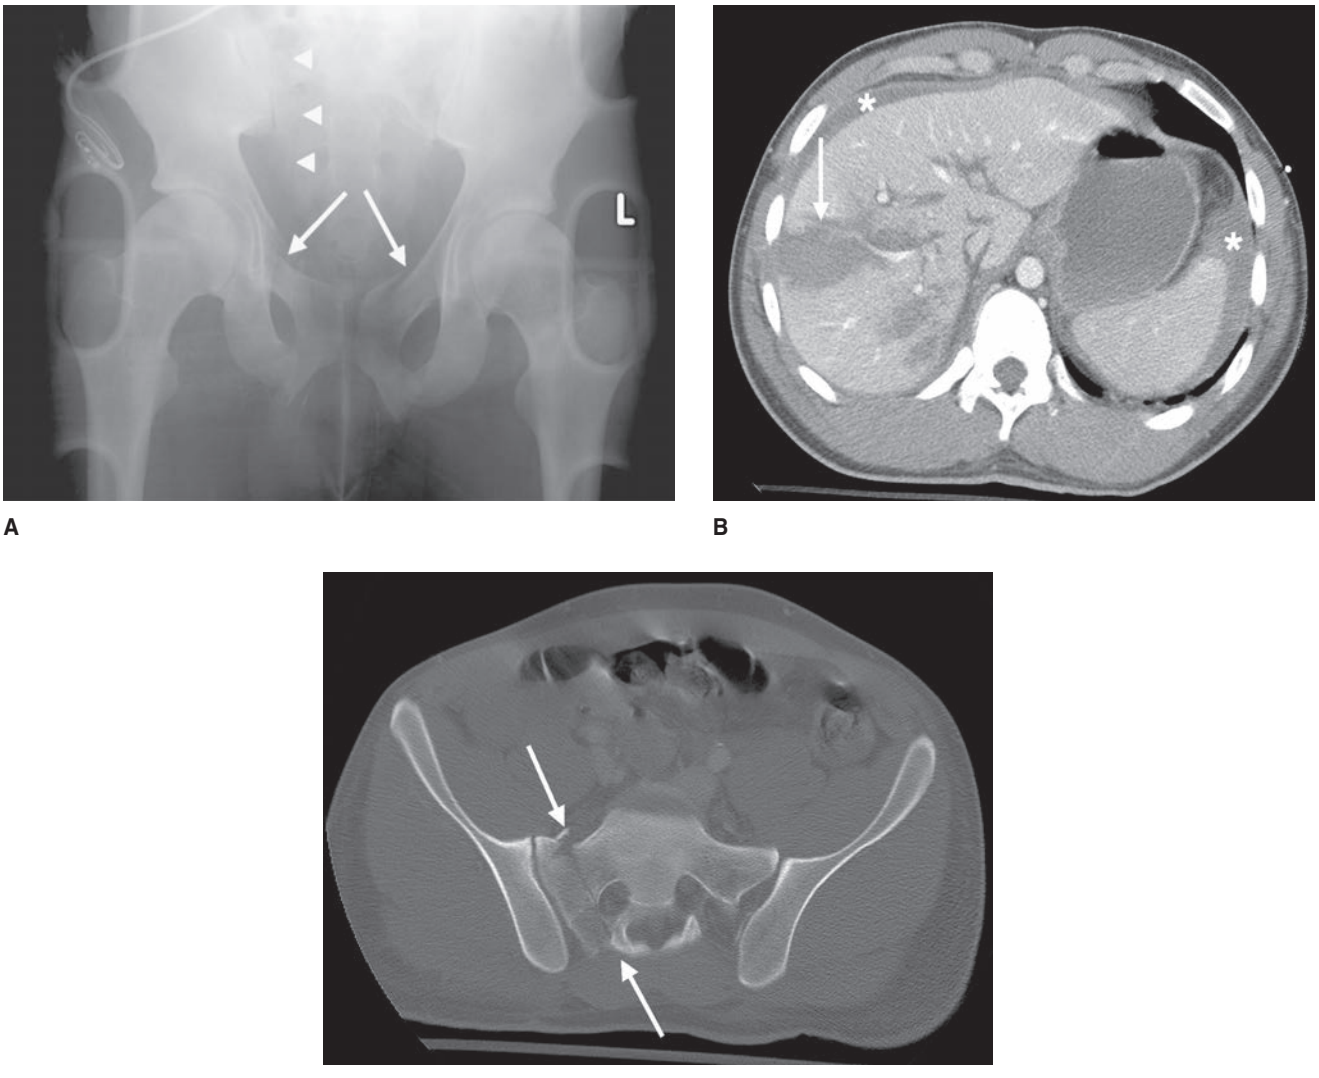

FIGURE 19-24 Patterns of injury: "the right package." This 22-year-old unrestrained passenger was ejected from a car in side-impact high-speed crash. (**A**) Anteroposterior (AP) view of pelvis shows bilateral iliopubic and ischiopubic ramus fractures (white arrows) and disruption of right sacral arcuate lines (arrowheads); findings are compatible with lateral compression fracture due to right lateral impact. (**B**) Axial contrast-enhanced abdominal computed tomography (CT) shows free intraperitoneal fluid (asterisks) due to complex collection of liver lacerations (arrow) extending to the intrahepatic inferior vena cava. The relatively uniform enhancement of hepatic parenchyma suggests that the hepatic veins are not occluded. (**C**) Axial CT through S1, bone windows, shows through-and-through fracture of S1 ala, which traverses S1 neuroforamina (white arrows). Such through-and-through fractures are typically associated with biomechanical instability.

wall, asymmetric mural enhancement, pneumoperitoneum, leak of oral contrast, focal defect in the bowel wall, and free fluid not explained by other injuries (Fig. 19-31). Unfortunately, the specific signs of a bowel perforation are relatively uncommon and are not sensitive.[85,86] Active bleeding from the bowel mesentery, as with active bleeding elsewhere in the body, is an indication for intervention and is associated with a high likelihood of injury to the bowel or delayed necrosis of the bowel.[87] Fluid present in the mesentery or between loops of bowel is very suspicious for a transmural injury to the bowel, even in the presence of injury to a solid organ and even immediately following DPL (Fig. 19-31). One note of caution regarding free intraperitoneal fluid is that women of childbearing age may have small amounts of fluid (±50 mL) in their pelvis. Recent observations also suggest that a small volume of isolated free fluid in the pelvis in male patients with blunt abdominal trauma, which can be seen in up to 4.9%, is unlikely to be due to a bowel injury.[88] Patients who have been vigorously resuscitated (especially if they are >24 hours from their injury) may have ascites and interloop fluid present due to a capillary leak syndrome (Fig. 19-32). Acute and subacute hemorrhage typically measures 40 to 70 Hounsfield units (HU), whereas urine, bowel contents, and ascites measure closer to water (eg, 0 +/–20 HU). If a patient

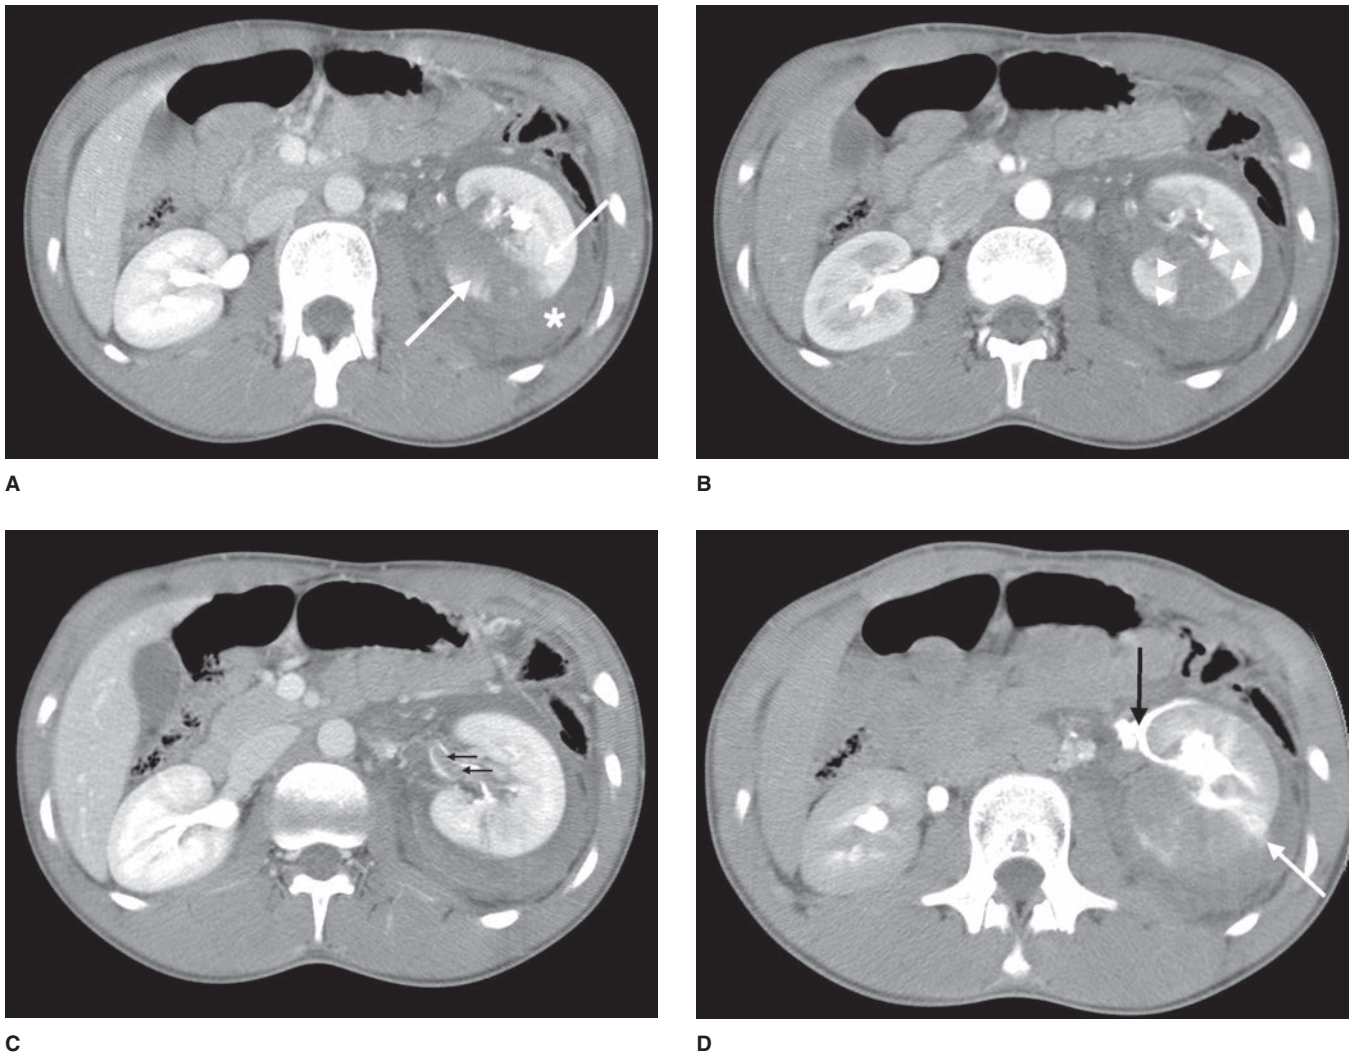

FIGURE 19-25 Grade IV renal laceration. This 14-year-old sustained an injury in a fall from a dirt bicycle while jumping. (**A**) Contrast-enhanced axial computed tomography (CT) scan, soft tissue windows, performed in parenchymal phase shows perinephric hematoma on left (asterisk) adjacent to laceration that extends into renal hilum (arrows). Right kidney shows normal pyelographic phase. Free intra-abdominal fluid is due to grade III splenic laceration (not shown). (**B**) Contrast-enhanced axial CT obtained in arterial phase shows wedge-shaped defect in left kidney (arrowheads) compatible with laceration and infarct extending to capsule secondary to segmental arterial occlusion. (**C**) Contrast-enhanced axial CT at level of kidneys shows thrombus within collecting system (black arrows), perinephric hematoma, and contusion of posterior aspect of kidney, just below laceration seen on image **A**. Perinephric hematoma surrounds kidney. (**D**) In such complicated cases, delayed images (10 minutes) are highly valuable in assessing associated urinary leakage. Ten-minute delayed images show a type III extravasation of contrast-enhanced urine from anterior and medial pole of kidney into the perinephric space (black arrow). Striated nephrogram is present posteriorly (white arrow), compatible with contusion adjacent to laceration.

with blunt trauma has free fluid in the peritoneal cavity of uncertain source and lacks signs of peritonitis on physical examination, a repeat short-interval abdominopelvic CT in 4 to 6 hours may be warranted.[89]

CT performs well in the diagnosis of peritoneal violation and intra-abdominal injuries in the setting of penetrating abdominal trauma.[73] The diagnosis of injuries to the bowel following penetrating trauma is aided by the use of the triple-contrast protocol using intravenous, oral, and rectal contrast material. Leakage of enteric contrast is highly specific for bowel injury (Fig. 19-21F). A wound tract that extends to the bowel surface is the most sensitive sign of an associated bowel injury, in the absence of other definitive findings.

Computed Tomography of the Pelvis and Acetabulum

CT is extremely valuable in the evaluation of the pelvic girdle, including the pelvic bones, acetabulum, and sacrum, following both blunt and penetrating trauma. There are several indications for pelvic CT, including the following: (1) to evaluate

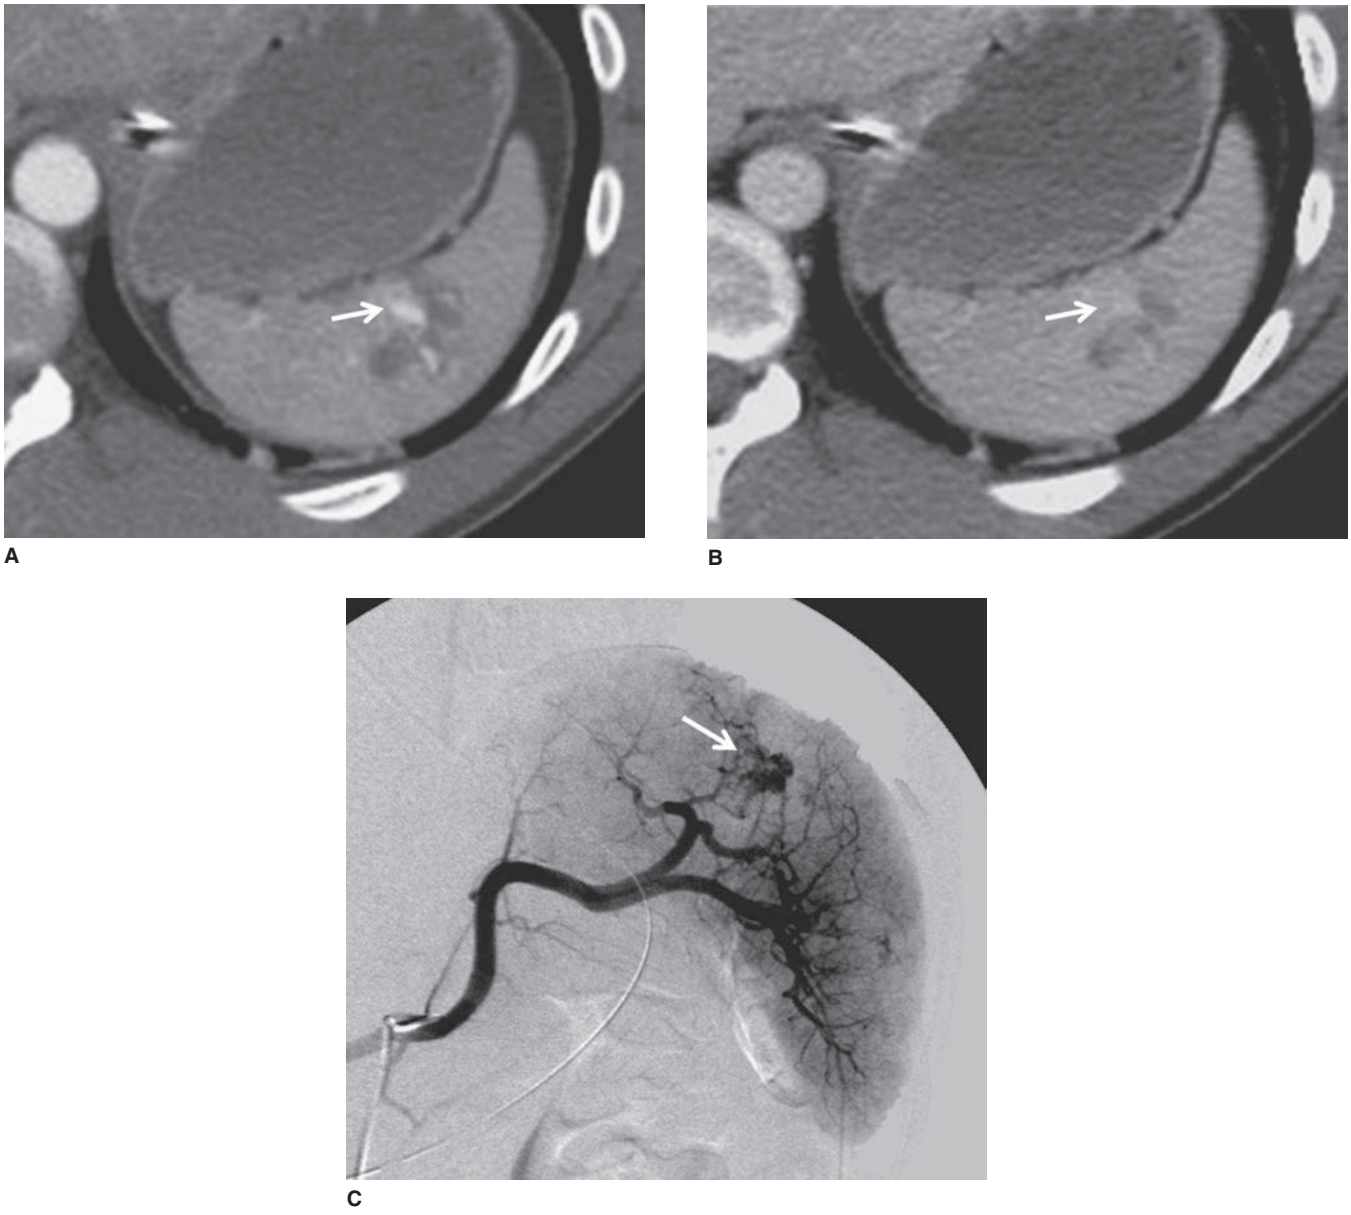

FIGURE 19-26 Spleen laceration with associated pseudoaneurysm. Axial postcontrast computed tomography during arterial (**A**) and portal venous (**B**) phases demonstrate a laceration of the splenic hilum. There is a focal hyperdensity within the laceration on arterial phase (**A**, arrow), which becomes isodense to adjacent parenchyma on portal venous phase (**B**, arrow) consistent with a traumatic pseudoaneurysm. (**C**) Splenic angiogram confirms the presence of a splenic pseudoaneurysm (arrow).

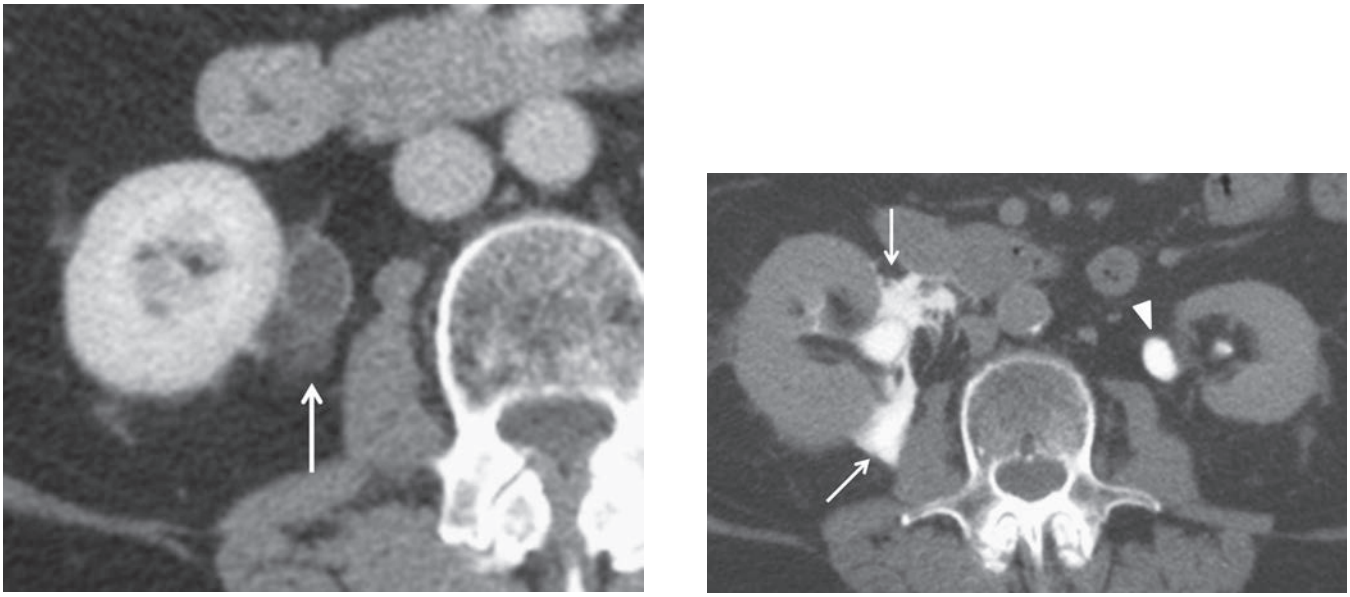
unstable fractures of the pelvic ring as determined by physical examination or appearances on conventional x-rays; (2) to evaluate for radiographically occult fractures in the setting of high clinical suspicion; (3) to detect entrapped intra-articular debris/bone fragments following hip dislocation; and (4) for preoperative surgical planning (Figs. 19-33 to 19-37). Pelvic CT can be performed on its own or be reconstructed from the raw CT data of the abdomen and pelvis performed as a part of a whole-body trauma CT series. Three-dimensional volume-rendered images can be generated from the CT data set, and dedicated evaluation of acetabular fractures can be performed with femoral head subtraction. In fact, some of the most recent CT scanner software packages can generate "virtual pelvis" images from the CT raw data that approximate images of conventional pelvic radiographs (Fig. 19-2D).

The primary goal of CT evaluation of disruption of the pelvic ring and acetabular fractures is to aid in surgical planning.[90] CT scans of acetabular fractures are performed for the following: (1) assessment of fracture types; (2) secondary congruence of the hip (eg, are the fracture fragments symmetrically oriented about the intact femoral head?); (3) evidence for marginal impaction (eg, subarticular bone depressed or



A B

FIGURE 19-27 Renal pelvis laceration following blunt abdominal trauma. (**A**) Admission portal venous phase image reveals a small amount of fluid (arrow) surrounding the right renal pelvis. No other injuries or other abnormalities were seen. (**B**) Delayed excretory phase image reveals a large amount of extravasated urinary contrast (arrows) in the retroperitoneal space compatible with a renal pelvis laceration. The contralateral normal renal pelvis (arrowhead) is included for comparison.

impacted and not showing secondary congruence); (4) detection of a fracture of the femoral head; and (5) detection of intra-articular debris. There is approximately a 15% concurrent rate for fractures of the pelvic ring and acetabulum, so any fracture of the pelvis or acetabulum should initiate a search for other fractures in the pelvic girdle.

CT of the pelvis and acetabulum typically uses a slice thickness of 1 to 3 mm in the axial plane, and images are reconstructed using a bone algorithm. Sagittal and coronal reformatted images can be helpful in fully characterizing a fracture of the pelvic ring or acetabulum.

A systematic approach should be employed when reviewing pelvic CT images, with special attention paid to the fractures that one would expect to see in the setting of AP compression, lateral compression, and vertical shear force. Correlation with at least an AP pelvic radiograph is recommended to provide an overview of the type of pelvic ring disruption. Fractures of the iliopubic and ischiopubic rami, as well as the sacral wings, are typical of a lateral compression-type injury. The anterior surface of the sacrum is carefully evaluated for "buckle" fractures due to internal rotation of the hemipelvis due to a lateral impact. Fractures of the iliopubic and ischiopubic rami are assessed for their orientation (lateral compression fractures typically show orientation in the axial plane or coronal plane, whereas AP compression and vertical shear fractures will show orientation in the sagittal plane). Diastasis of the pubic symphysis and sacroiliac joints (eg, "open book" pelvis) is typical of an AP-type injury. The normal pubic symphysis should not be more than 1 cm in width in normal subjects, regardless of age. When the pubic symphysis is traumatically wider than 2.5 cm, both sacrospinous and sacrotuberous ligaments are presumed to be injured. In the posterior ilium, it is important to look for avulsion fractures of the posterior superior iliac spine, so-called crescent fractures, as these are strongly associated with biomechanically unstable fractures in the presence of disruption of the anterior pelvic ring. The axial images give good evaluation of the amount of internal or external rotation but underestimate the amount of flexion or extension of a hemipelvis relative to the intact pelvis. Furthermore, evaluation of the amount of pelvic hematoma may be helpful in determining the need for angiography for embolization. Localization of these hematomas is a good predictor of associated pelvic vascular injuries. Indeed, as discussed earlier, a search for active bleeding in the pelvis should be conducted if the patient undergoes the contrast-enhanced trauma CT series.

It should be noted that CT is not a dynamic examination and provides information for a single snapshot in time. As such, the assessment of potential biomechanical instability of the pelvis may be difficult. Certainly, the combination of a crescent fracture from the posterior superior iliac spine and displaced anterior pelvic ring fractures will be unstable under anesthesia. The stability of other patterns, however, is not so predictable, even though CT images provide a great deal of information about the injury pattern. Therefore, conventional x-rays are necessary as guides to intraoperative reduction even for the most experienced pelvic orthopedic surgeon.

If an acetabular fracture is present, the goal is to determine what remains attached to the intact hemipelvis and to describe and characterize the major fracture fragments and

FIGURE 19-28 Pelvic ring disruption and active bleeding in a young female following a motorcycle collision. (**A**) Anteroposterior radiograph demonstrates marked diastasis of the pubic symphysis (double arrow). Axial arterial phase (**B**) and delayed phase (**C**) computed tomography images at the level of the widened pubic symphysis reveal active bleeding (**B**, arrow), which increases in size (**C**, notched arrow) and diffuses into the existing blood pool. (**D**) Right posterior oblique pelvic digital subtraction angiogram shows the focus of active bleeding (arrow) next to the right pubic root.

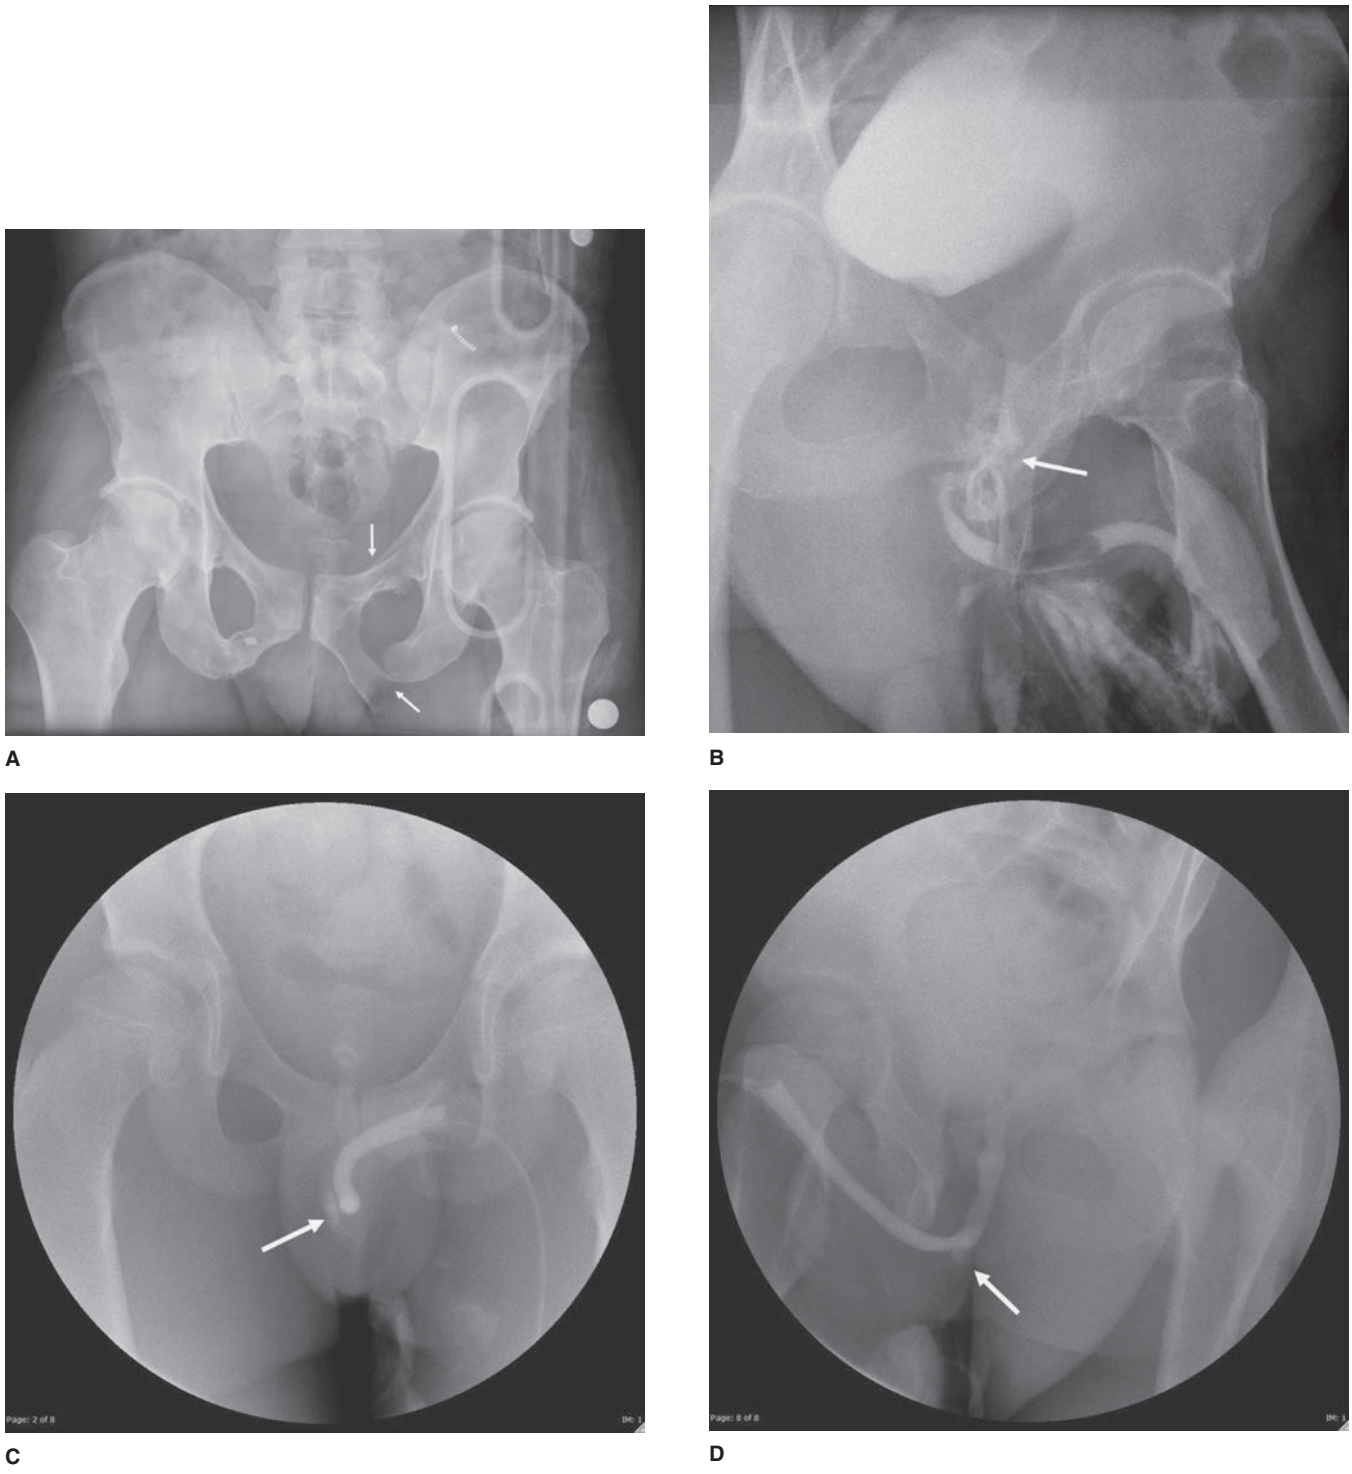

FIGURE 19-29 Urethral injuries. (**A, B**) Young male status post blunt pelvic trauma. (**A**) Anteroposterior (AP) pelvic radiograph demonstrates fractures of the left superior and inferior pubic rami (arrows). The patient was unable to void, and there was blood at the penile meatus. (**B**) Left posterior oblique image from a retrograde urethrogram (RUG) demonstrates leak of contrast from the membranous portion of the urethra (arrow), with contrast extending inferior to the urogenital diaphragm. (**C, D**) An 11-year-old male with a straddle injury and blood at the meatus. AP (**C**) and right posterior oblique (RPO) (**D**) RUG images demonstrate focal contrast outpouching along the right inferior aspect of the bulbous anterior urethra (arrows) indicating a urethral injury. (**E, F**) A 27-year-old male status post transpelvic gunshot wound.

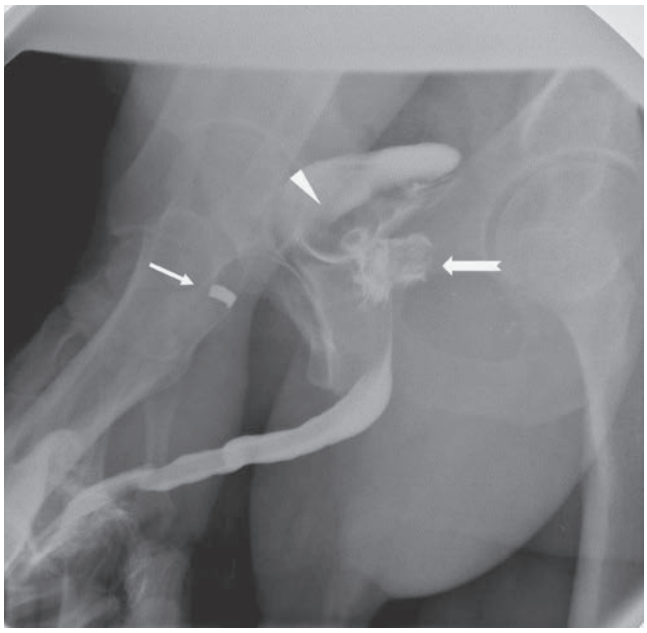
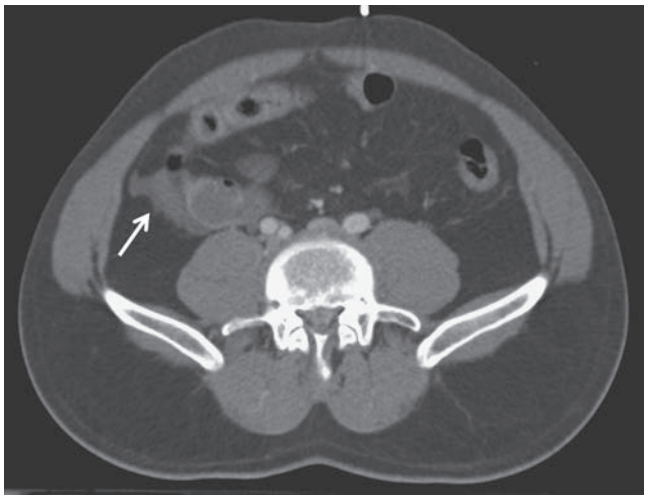
E

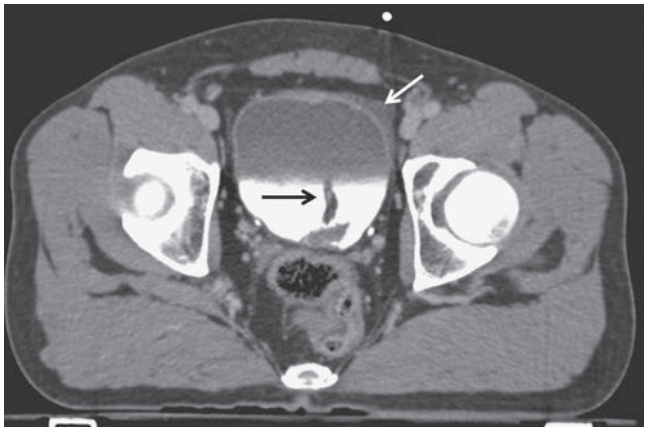


F

FIGURE 19-29 (*Continued*) (**E**) Axial computed tomography image through the lower pelvis shows the bullet trajectory extending through the region of the urethra. The wound tract extends from the left lateral gluteal region (asterisk), through the left ischiopubic ramus (notched arrow), with bullet resting just medial to the right proximal femur (arrow). A Foley catheter (triangle) was able to be passed in the trauma bay without incident. (**F**) RPO RUG image, performed by inserting a small-bore pediatric feeding tube adjacent to the existing Foley catheter, shows leak of contrast from the prostatic portion of the urethra (notched arrow). The Foley balloon is appropriately positioned in the bladder (arrowhead). Bullet fragment (arrow) is again seen adjacent to the right proximal femur.

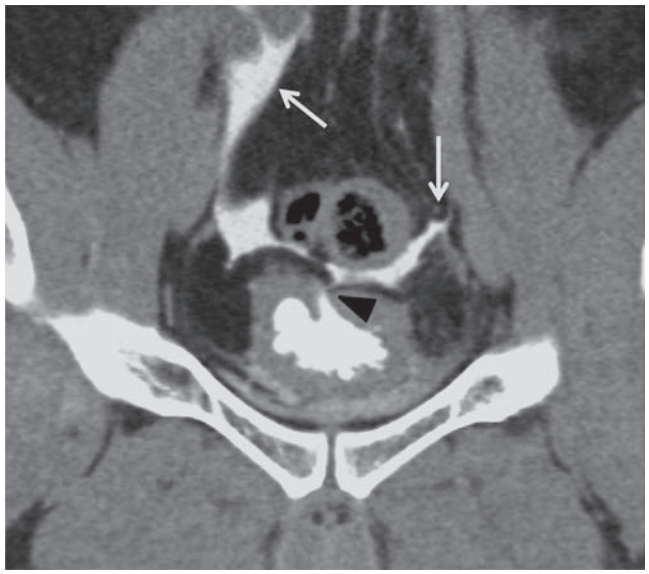


A



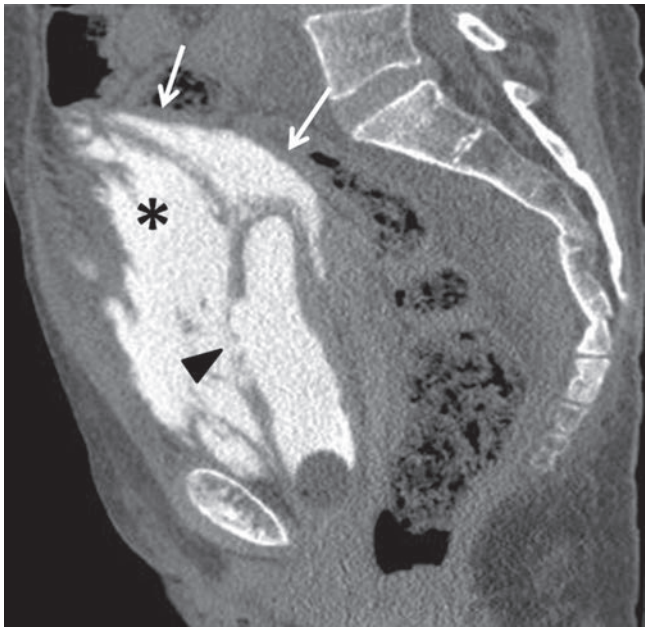
B

FIGURE 19-30 Blunt traumatic bladder rupture. (**A–C**) Intraperitoneal bladder rupture in a patient following blunt trauma. (**A**) There is free fluid in the right paracolic gutter (arrow) without other computed tomography (CT) signs of solid organ injury or bowel perforation. (**B**) Five-minute delayed excretory phase image through the pelvis demonstrates filling defects (black arrow), due to blood clot, in a partially opacified bladder. There is no leak of urinary contrast via passive physiologic filling of the bladder. There is trace free fluid adjacent to the bladder (white arrow).

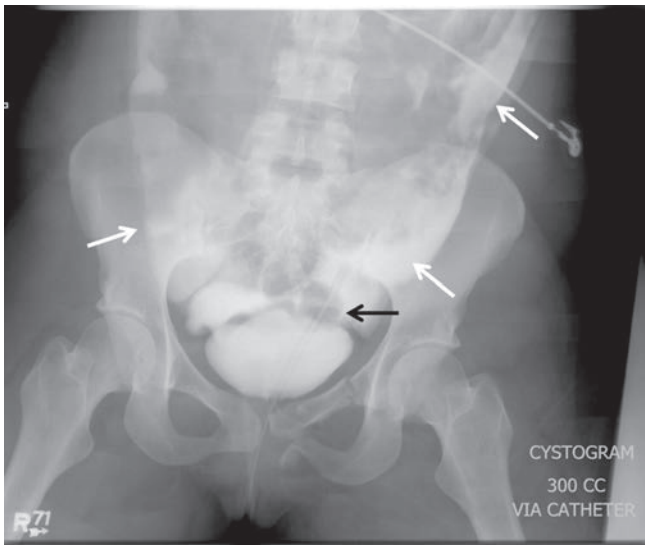


C

D



E



F

FIGURE 19-30 (*Continued*) (**C**) Coronal CT image from a CT cystogram reveals a focal defect in the bladder dome (black arrowhead) and free flow of contrast into the peritoneal cavity (white arrows) consistent with an intraperitoneal bladder injury. (**D, E**) Extraperitoneal bladder rupture in another patient following blunt trauma. Axial (**D**) and sagittal (**E**) CT cystogram images demonstrate a focal defect in the anterior bladder wall (black arrowhead) and leak of urinary contrast into the perivesicular space (asterisk). The leaked contrast is confined to the extraperitoneal space by the peritoneal reflection superiorly (white arrows). (**F**) Conventional cystogram from another patient with an intraperitoneal bladder injury. Radiograph demonstrates a large amount of intraperitoneal contrast outlining loops of bowel (white arrows). Close inspection of the image demonstrates the bladder catheter balloon (black arrow) outside of the bladder, traversing the bladder wall through a dome injury. Careful inspection of all images, both CT and film, is necessary during the cystogram planning process to ensure proper bladder catheter positioning prior to the initiation of the examination.

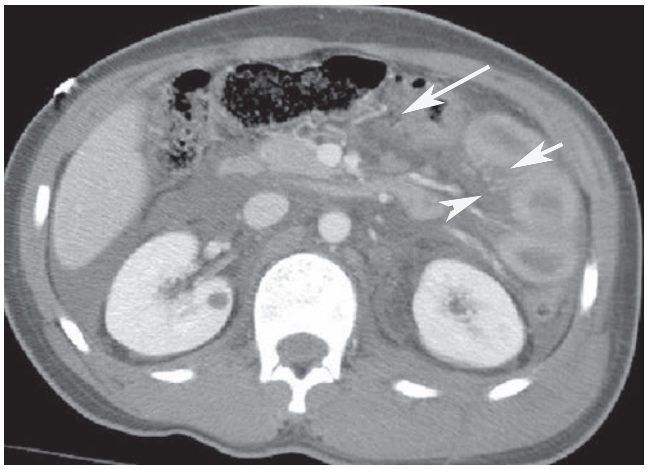


FIGURE 19-31 Small bowel perforation: A 14-year-old male, unhelmeted bicycle rider hit by a car sustained a small bowel perforation. Intravenous contrast-enhanced axial computed tomography shows three findings consistent with small bowel (jejunal) injury: (1) diffusely enhancing and thickened jejunum loops within the left side of the abdomen, with a focal hypoenhancing segment compatible with at least partial transmural injury (short arrow); (2) high-density interloop fluid within the mesentery adjacent to abnormal bowel (arrowhead) strongly suggesting transmural bowel laceration; and (3) small amount of pneumoperitoneum (long arrow) collecting within mesentery. Extra-alimentary air almost always correlates with transmural laceration of bowel.

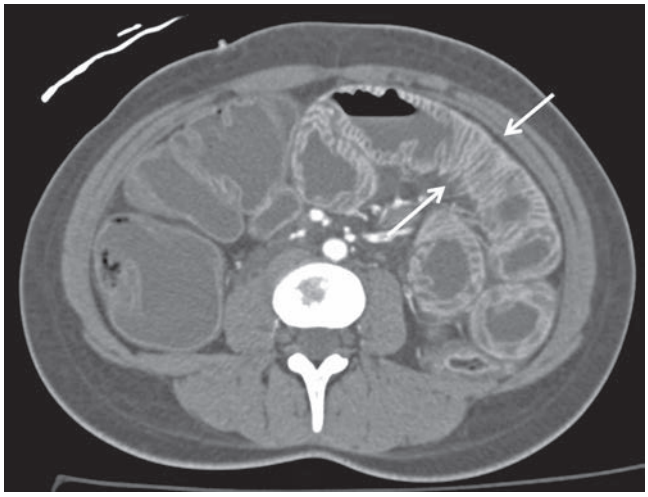
A



B

FIGURE 19-32 Hypoperfusion shock complex/shock bowel syndrome. (**A**) Axial postcontrast computed tomography (CT) demonstrates a thin, slit-like inferior vena cava (arrow) and pancreatic edema (the pseudo-pancreatitis sign) with peripancreatic fluid (arrowheads). (**B**) Axial postcontrast CT from the same patient also demonstrates dilated bowel with thickened and intensely enhancing bowel wall (arrows). There is also diffuse mesenteric edema. Reduced splanchnic blood flow due to underresuscitation results in capillary leak and prolonged transit time for intravenous contrast. This constellation of findings is consistent with hypoperfusion shock complex/shock bowel syndrome.

their relation to each other and the femoral head. Assessment of the posterior through anterior walls, the ischium for the posterior column, the pubis and symphysis for evaluation of the anterior column, the iliac wing for superior extension, and congruence between the femoral head and acetabular cup allows for a more complete recognition of fracture fragments. There are 10 types of acetabular fractures based on the Judet and Letournel classification scheme. Fortunately, approximately 90% fall into one of five fracture patterns, divided into two groups based on the presence (both-column and T-shaped) or absence (transverse, transverse with posterior wall, and isolated posterior wall) of involvement of the obturator ring.[91]

APPENDICULAR SKELETON

Conventional Radiography

Conventional radiography remains the imaging standard for the evaluation of long bones showing obvious deformity, instability, palpable crepitus, pain, and swelling. For periarticular regions, conventional x-rays are indicated for deformity, instability, decreased range of motion, pain, and swelling. The Ottawa ankle and knee clinical prediction rules add considerable precision to specificity.[92-94]

For long bones (Fig. 19-38), two orthogonal views are obtained, including an AP view and lateral projection centered at the midshaft. Projections should include both the proximal and distal joints. Joints should be imaged with two orthogonal views at a minimum, with additional optional one or two oblique views, centered at the midportion of the articulation (Figs. 19-38 to 19-43).

Analysis of the long bone should allow assessment of the direction of the force that created the fracture pattern (eg, twisting injuries result in spiral fractures; bending injuries result in wedge fractures). In general, higher-energy injuries

FIGURE 19-33 Pelvic ring fracture: lateral compression type. A 54-year-old female passenger involved in a T-bone motor vehicle collision. (**A**) Anteroposterior (AP) radiograph of pelvis shows disruption of right sacral wing (black arrows), bilateral iliopubic rami (white arrows), and bilateral ischiopubic rami (arrowheads). (**B**) Axial computed tomography (CT) shows a comminuted fracture of the right sacral ala through the neural arches (arrow). Frequency of injury to sacral nerve roots is greatest when fractures involve medial aspect of the neural canal (Denis zone 3), lowest when lateral to the neuroforamen (Denis zone 1), and intermediate when involving neural foramina (Denis zone 2). (**C**) Axial CT image at the level of the femoral heads again demonstrates fractures of the superior iliopubic rami (arrows). (**D**) Axial CT image demonstrates fractures of the bilateral ischiopubic rami (arrowheads). (**E**) Subsequently performed CT cystogram demonstrates a defect in the anterior bladder wall (black arrow) with leak of contrast into the perivesicular space consistent with an extraperitoneal bladder rupture, an injury often seen in association with midline pelvic ring fractures.

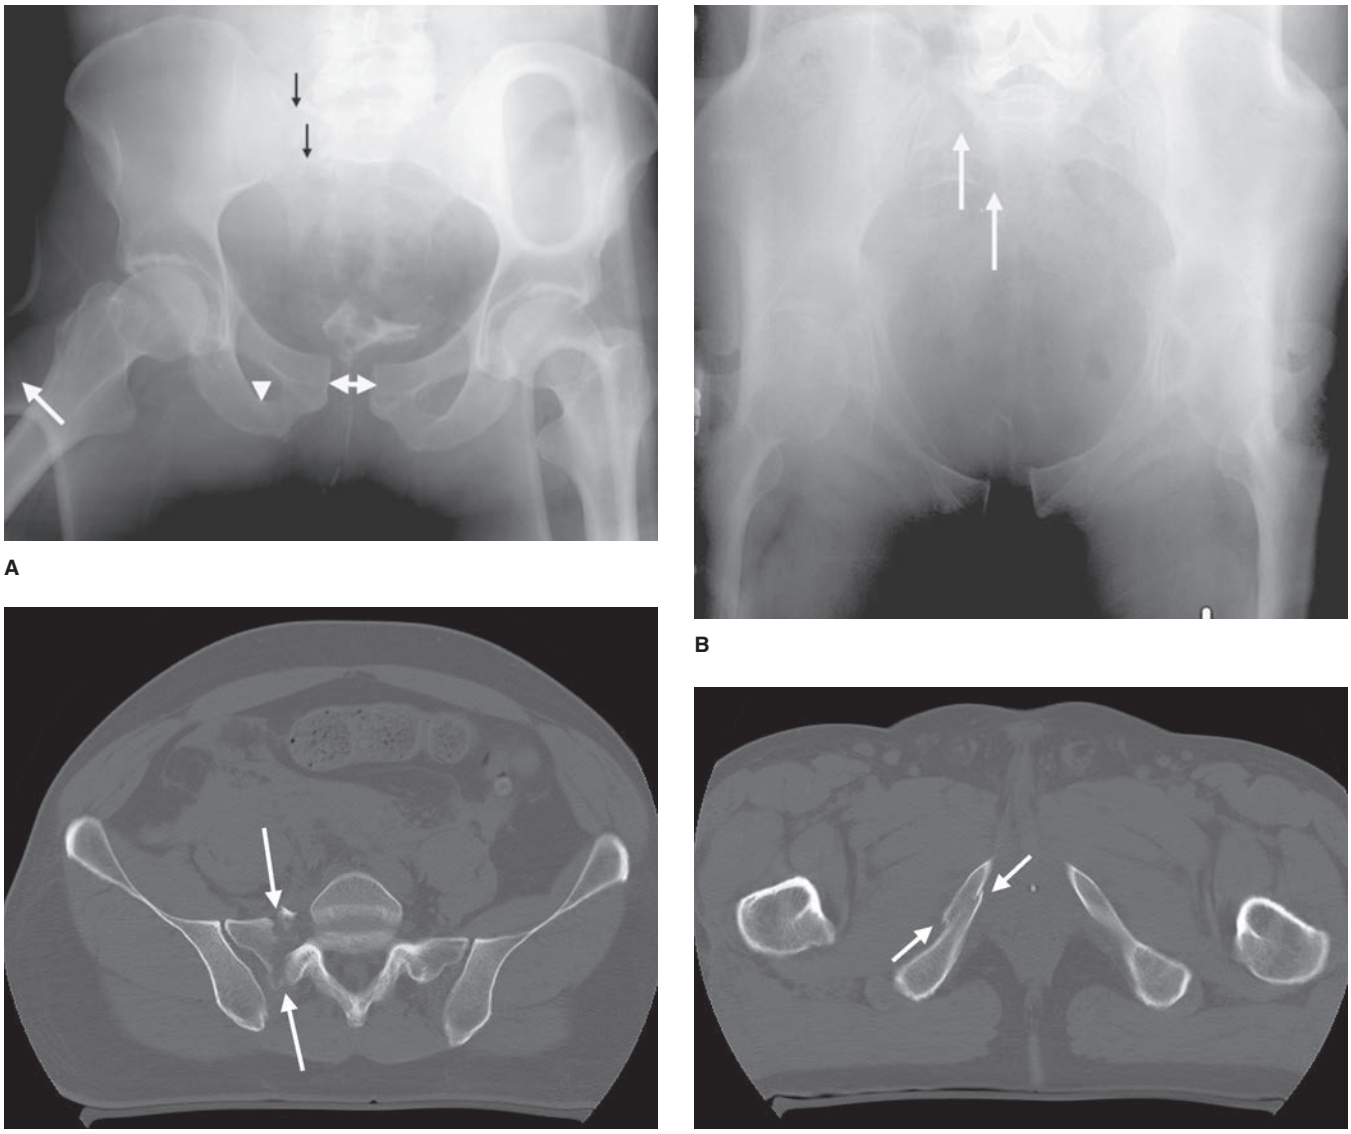

FIGURE 19-34 Pelvic ring fracture: anteroposterior (AP) compression type. This 55-year-old male sustained an injury during a 7-m fall onto concrete. (**A**) AP radiograph of pelvis shows symphyseal diastasis (double-ended arrow); right ischiopubic ramus fracture, which is minimally displaced (arrowhead); and disruption of right sacral arcuate lines (black arrows). Right femur is abducted (white arrow), a finding that is common with fractures of femoral shaft that this patient also sustained. (**B**) Inlet view of pelvis (obtained with 45° angulation caudally) better shows disruption of arcuate lines (white arrows) and again shows pubic symphyseal diastasis. (**C**) Axial computed tomography (CT) at the lumbosacral junction shows through-and-through fracture (arrows) of right lateral mass of S1 with 6 mm of lateral and 8 mm of anterior translation. (**D**) Axial CT image at ischial tuberosities shows oblique sagittal fracture through right ischial pubic ramus (white arrows). Orientation of ischial fractures often reflects mechanism injury (sagittal plane fractures due to AP compression or vertical shear; transverse or axial plane fractures due to lateral compression).

tend to be more comminuted and displaced. If there is a mismatch between the apparent amount of comminution and the reported energy of the injury, osteoporosis or otherwise pathologic bone should be suspected. The degree of displacement and angulation of the predominant fracture fragments, as well as fracture line involvement of an articular surface, must be noted.

Periarticular regions should be evaluated for fracture involvement as well as for partial or complete loss of congruity of the joint. The appearance of a superimposed white line due to overlapping of bones may indicate a dislocation and disruption of expected alignment of adjacent articulating structures (Fig. 19-38E).

Careful attention to soft tissues (eg, focal swelling, obliteration of normal fat pads, joint effusions) is helpful for subtle or otherwise occult fractures (eg, elbow, knee, and wrist). A search for foreign bodies in soft tissue in the setting of an open fracture or soft tissue injury should be performed.

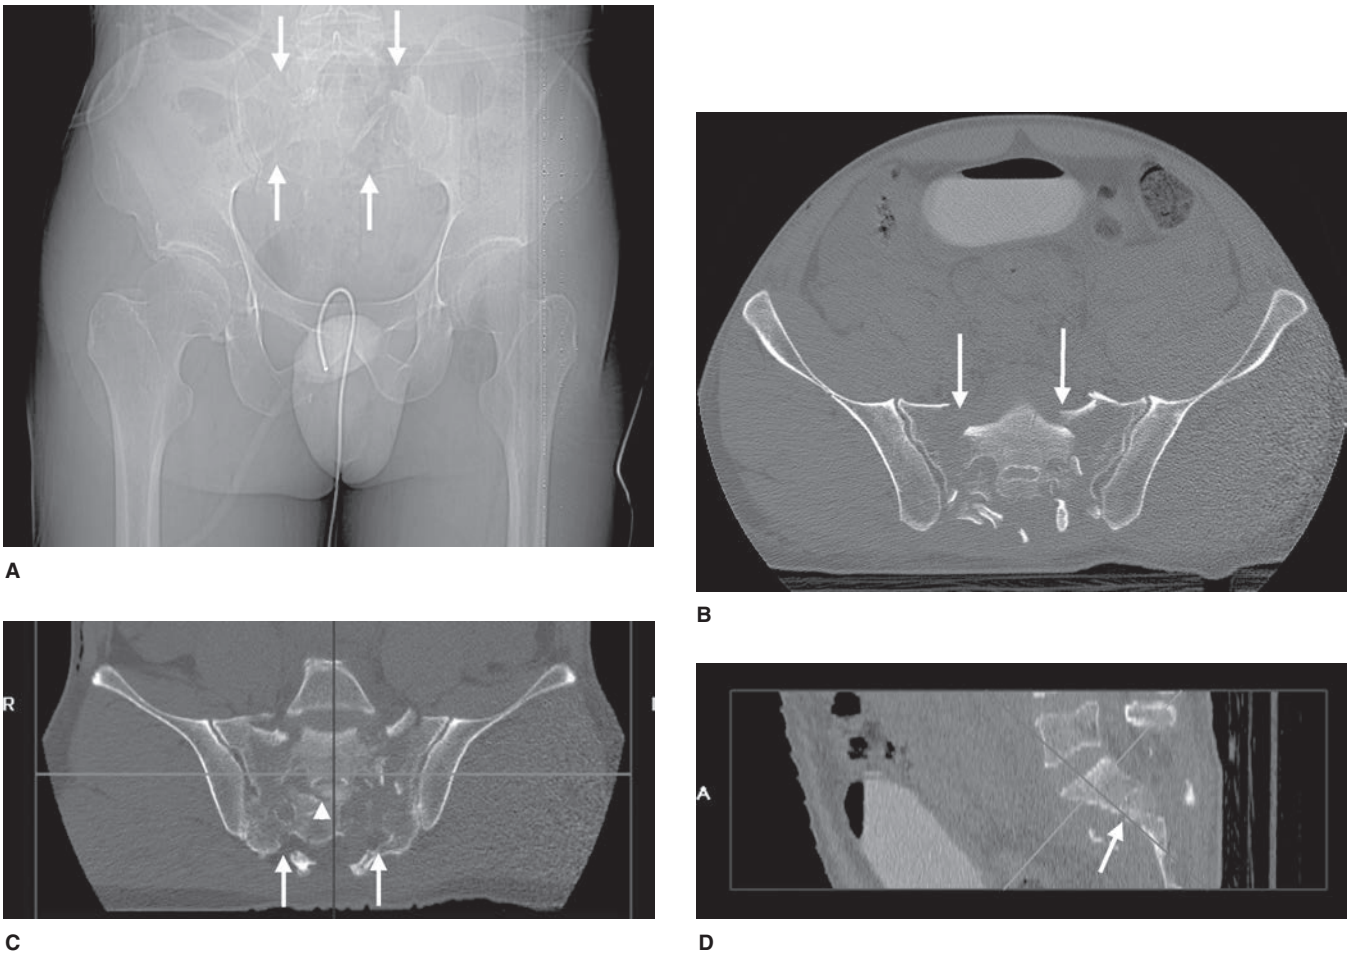

FIGURE 19-35 Vertical shear injury with unstable sacral fracture. An H-shaped sacral fracture was sustained in 40-ft fall. This was associated with right calcaneus and T12 compression fractures. (**A**) Anteroposterior (AP) pelvis computed tomography (CT) scout shows disruption of arcuate lines bilaterally (arrows). Such a finding requires excellent lateral view of sacrum to exclude transverse components of the fracture to create either H- or U-shaped sacral fractures, which are typically biomechanically unstable. This can rarely be obtained. CT better evaluates this area as coronal reformations of thin-section axial CT. (**B**) Axial CT shows bilateral through-and-through sacral fractures (arrow) that are transforaminal in their course. At this level, no transverse fracture is appreciated. (**C**) Coronal oblique CT reformation shows bilateral lateral mass fractures (arrow), as well as a portion of transverse fracture (arrowhead). (**D**) Sagittal CT reformation clearly shows transverse fracture (arrow).

Computed Tomography of Appendicular Joints

CT of appendicular joints, particularly the shoulder, tibial plateau, pilon, midfoot, and calcaneus, is indicated for "displaced" intra-articular fractures (eg, 1–2 mm at the wrist, scapula, or glenoid; 5–10 mm at the tibial plateau) or unstable fracture patterns (Figs. 19-39 and 19-41 to 19-43). CT is a valuable surgical planning tool and is very helpful in the detection of otherwise occult fractures, particularly of the midfoot.

In most patients, CT should be performed after provisional placement of traction or reduction, if feasible. Use of traction prior to imaging allows ligamentotaxis to indirectly reduce fracture fragments and support indirect assessment of the integrity of soft tissue attachments to major bony fragments. Specifically, bone fragments that do not move or reduce on stretch are presumed to be no longer attached to soft tissue and may require debridement or direct repositioning.

Because acquisition of isotropic image data of modern MDCT scanners allows for reconstruction of images in any conceivable plane, the joint in question no longer needs to be precisely positioned in the CT scanner gantry. Thus, "axial" images of a joint are not necessarily oriented in the axial plane of the body, but instead are oriented in the "axial" plane of the joint. Orthogonal images in both the sagittal and coronal planes are reconstructed from the joint-specific axial plane, usually at 1- to 2-mm slice thickness using a bone algorithm.

Peripheral Vascular Injuries

Vascular injuries in the extremities compose between 40% and 75% of vascular injuries observed in civilian trauma

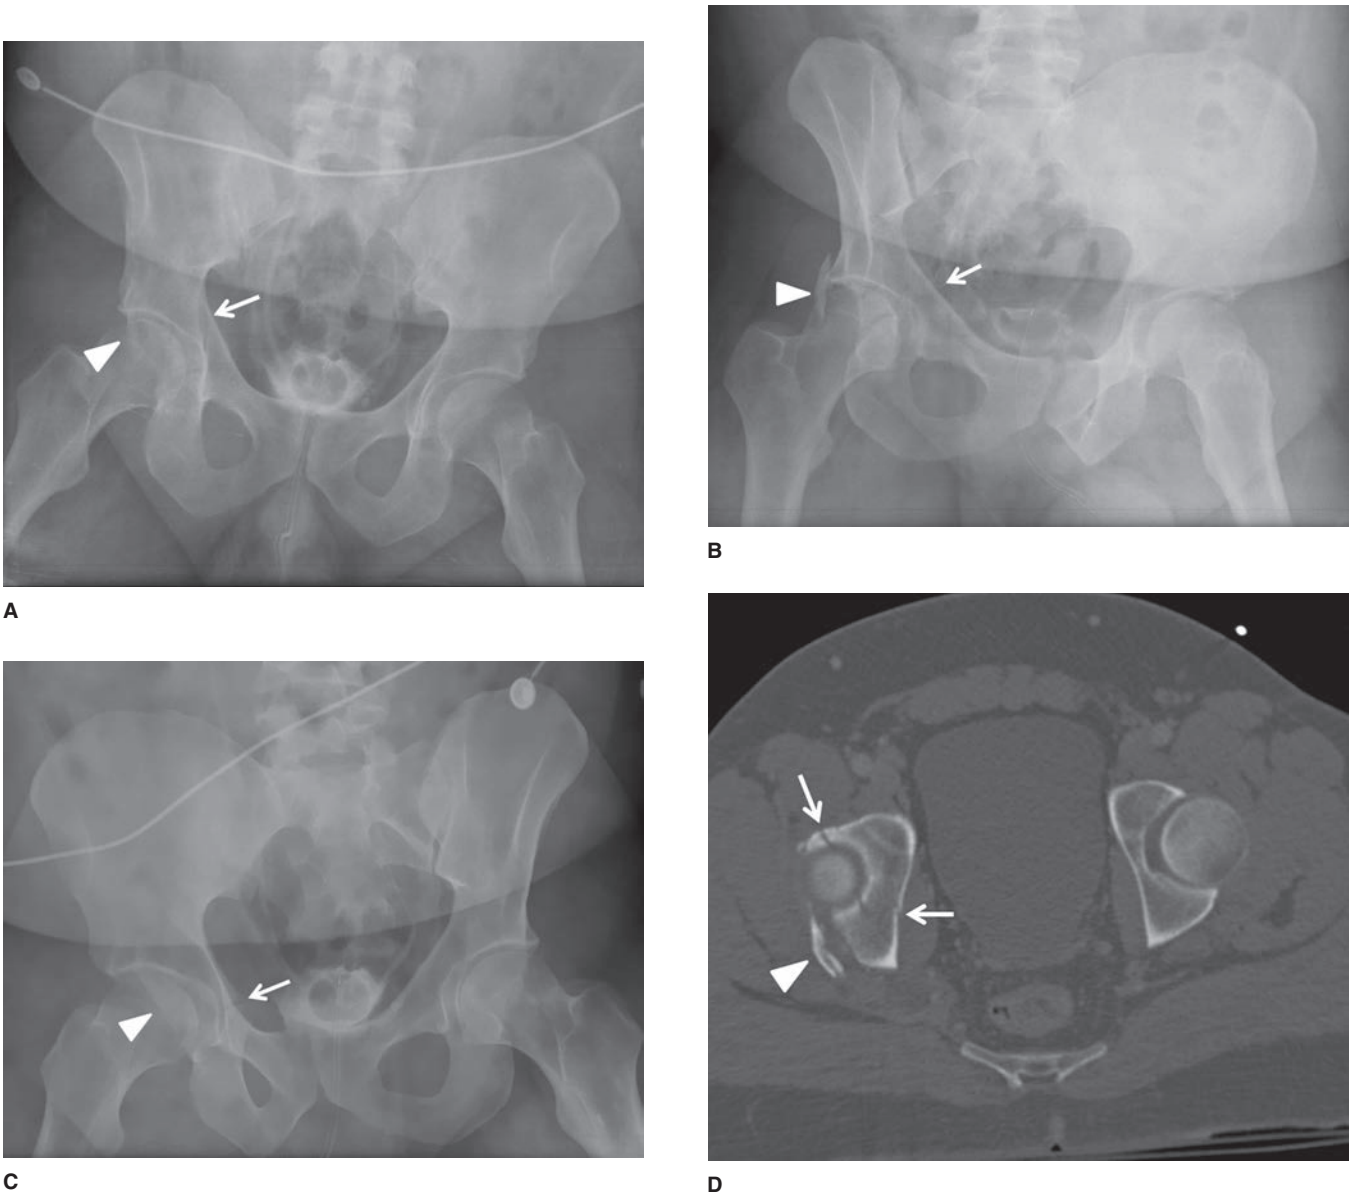

FIGURE 19-36 Transverse acetabular fracture with associated posterior wall fracture. (**A**) Anteroposterior (AP) view of pelvis shows disruption of iliopectineal line adjacent to acetabulum (arrow), with an eyebrow-shaped radiodensity projecting over the femoral head (arrowhead), which is a displaced posterior wall fragment. Bilateral Judet (**B, C**) oblique radiographs again show transverse fracture (arrow) and a posterior wall fragment (arrowhead). (**D**) Axial computed tomography (CT) image at the level of the acetabular roof shows a sagittal plane fracture (arrows) characteristic of transverse fractures of acetabulum. The posterior wall fracture fragment is again seen (arrowhead).

centers, with a majority of these (approximately two-thirds) involving the femoral or popliteal arteries. Approximately three-fourths of peripheral vascular injuries are the result of penetrating trauma, with 70% to 80% secondary to projectiles such as gunshot wounds and shrapnel. Fatal exsanguination, multiorgan failure secondary to hemorrhagic shock, and limb loss are catastrophic consequences of peripheral vascular injuries; thus, rapid identification and appropriate triage are of paramount importance. Vigorous or pulsatile external active hemorrhage, a rapidly expanding hematoma, and loss of distal pulses mandate emergent operative exploration.[95]

The imaging strategy for patients with suspected peripheral vascular injuries depends on a variety of factors that are primarily related to clinical presentation, hospital course, associated injuries, mechanism of injury, and signs of circulatory shock. Imaging modalities available include catheter angiography, CTA, Doppler ultrasound, and MR angiography (MRA).

AP (**E**) knee radiograph demonstrates overlap and increased density of the femoral condyles and tibial plateau (arrows). Lateral (**F**) knee radiograph demonstrates anterior dislocation of the tibia-fibula with respect to the distal femur. Postreduction sagittal computed tomography angiogram image (**G**) demonstrates popliteal artery transection with active bleeding (arrow).

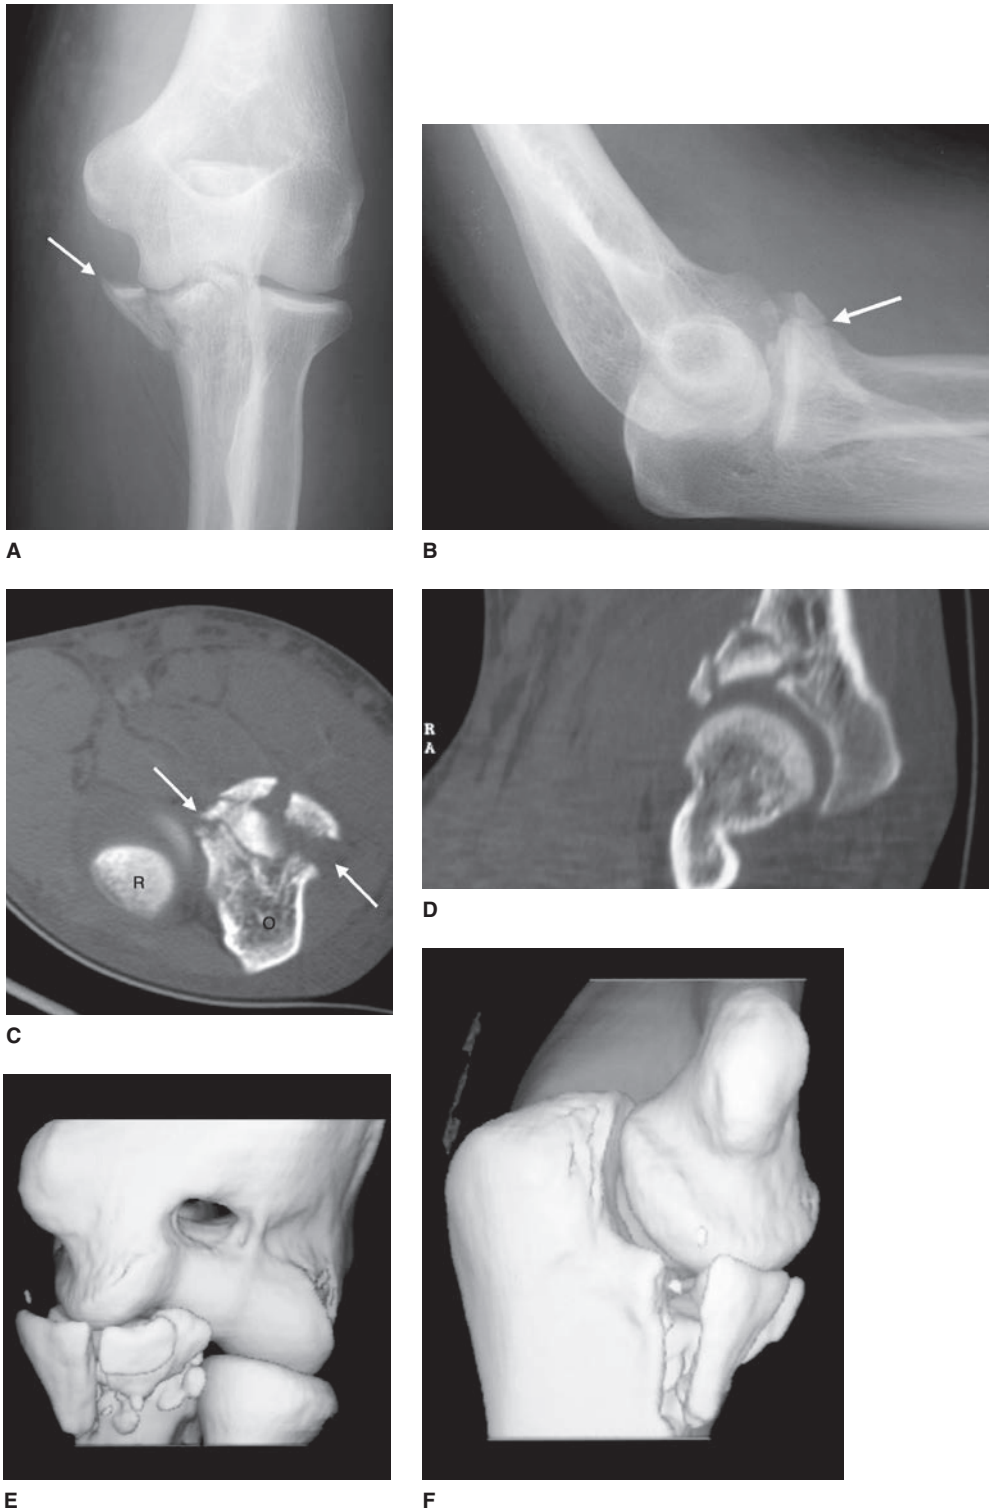

FIGURE 19-39 Periarticular fracture: coronoid process fracture of elbow. (**A**) Anteroposterior (AP) radiograph of left elbow shows displaced coronoid process (arrow). Elsewhere, joint appears congruent. (**B**) Lateral view of left elbow shows tip of coronoid process fracture (arrow). Coronoid process fractures can be graded by amount of coronoid process involved, such that larger coronoid process fracture fragments are more likely to result in elbow instability. (**C**) Axial computed tomography (CT) obtained because mismatch between radiographic and clinical findings of instability shows highly comminuted fracture of coronoid process (arrows). Radial head (R) and olecranon process (O) appear normal. (**D**) Sagittal CT reformation shows nearly all the coronoid process is involved in fracture. Secondary congruence between trochlea and olecranon-coronoid process is fair. (**E, F**) Three-dimensional surface-rendered CT reformations more graphically demonstrate transverse and distal extent and displacement of coronoid process fracture.

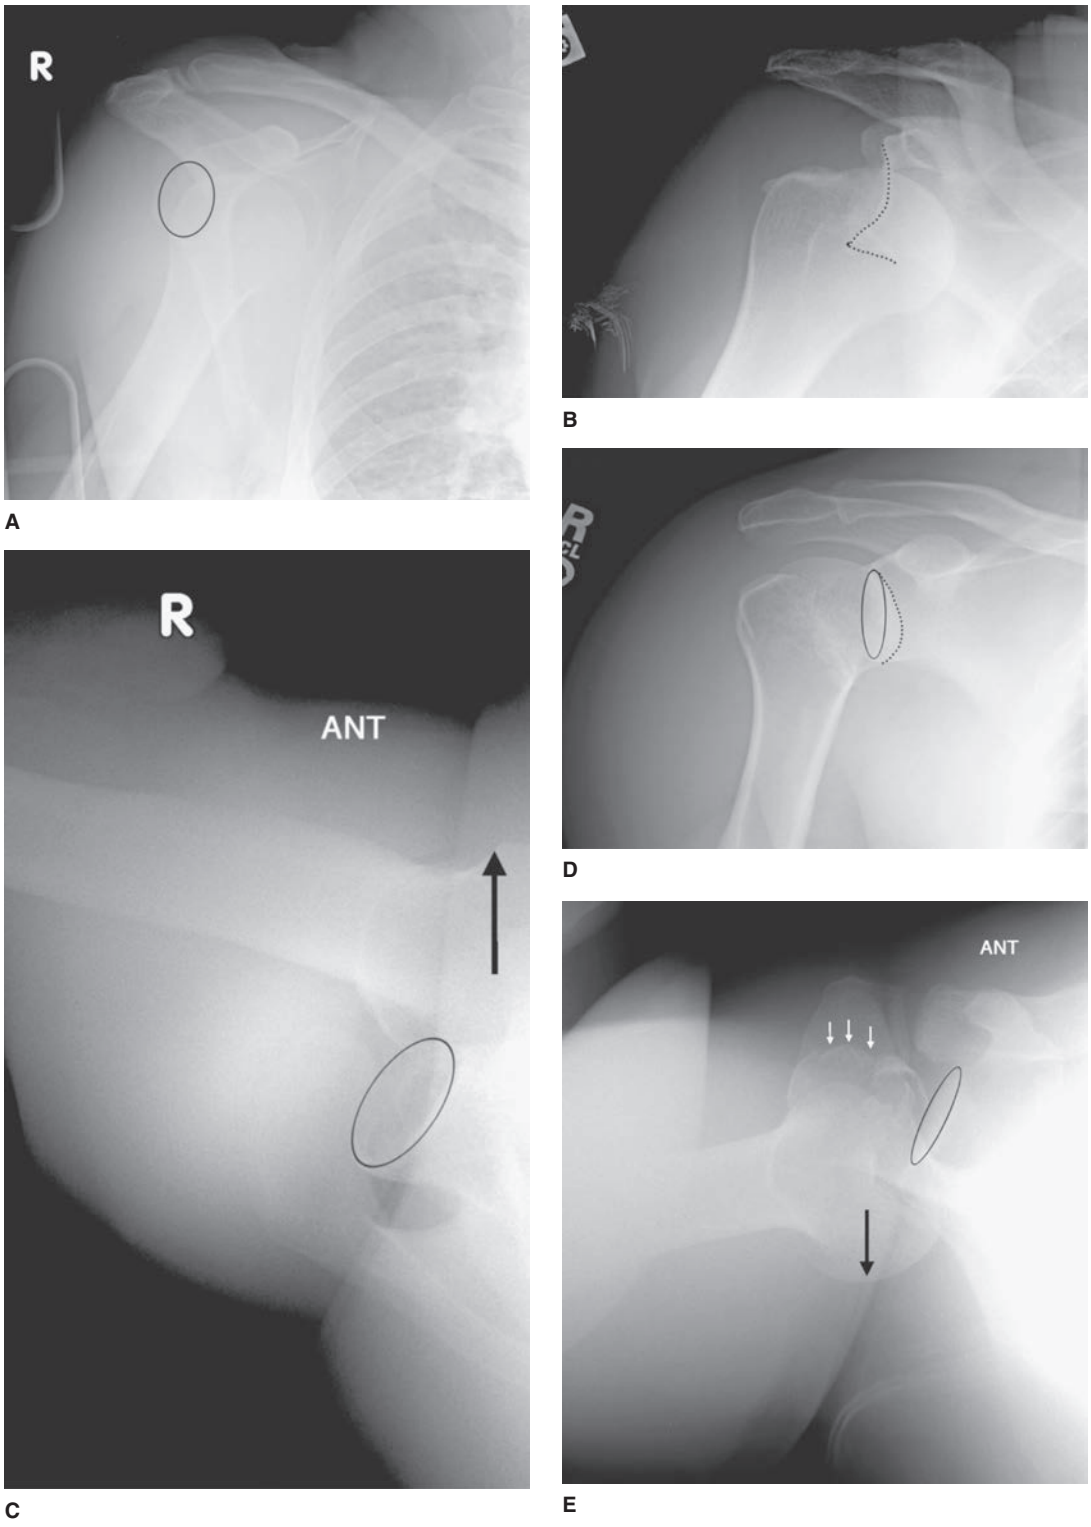

FIGURE 19-40 Periarticular injury: shoulder dislocation. (**A–C**) Anterior dislocation sustained by a 52-year-old struck by a falling tree on his back. (**A**) An anteroposterior (AP) radiograph with medial location of humeral head relative to glenoid (circle). (**B**) Postero-oblique radiograph of humeral head and glenoid (dotted line). Note that amount of overlap of scapula is less on this posterior oblique view than it is on anterior view (**A**), characteristic of anterior dislocation. (**C**) An axillary view; shows anterior location of humeral head relative to glenoid (upward pointing arrow and circle, respectively) on axillary lateral view. (**D, E**) Posterior dislocation sustained in a 42-year-old man who fell during a seizure. Posterior oblique radiograph (**D**) shows overlap of glenoid (circle) and medial aspect of humeral head (dotted line). (**E**) An axillary projection that shows the location of the humeral head posterior to glenoid (oval). Posterior margin of the head is denoted by downward pointing black arrow. Three downward pointing white arrows show impaction on anterior margin of humeral head, so-called trough fracture or reverse Hill-Sachs deformity.

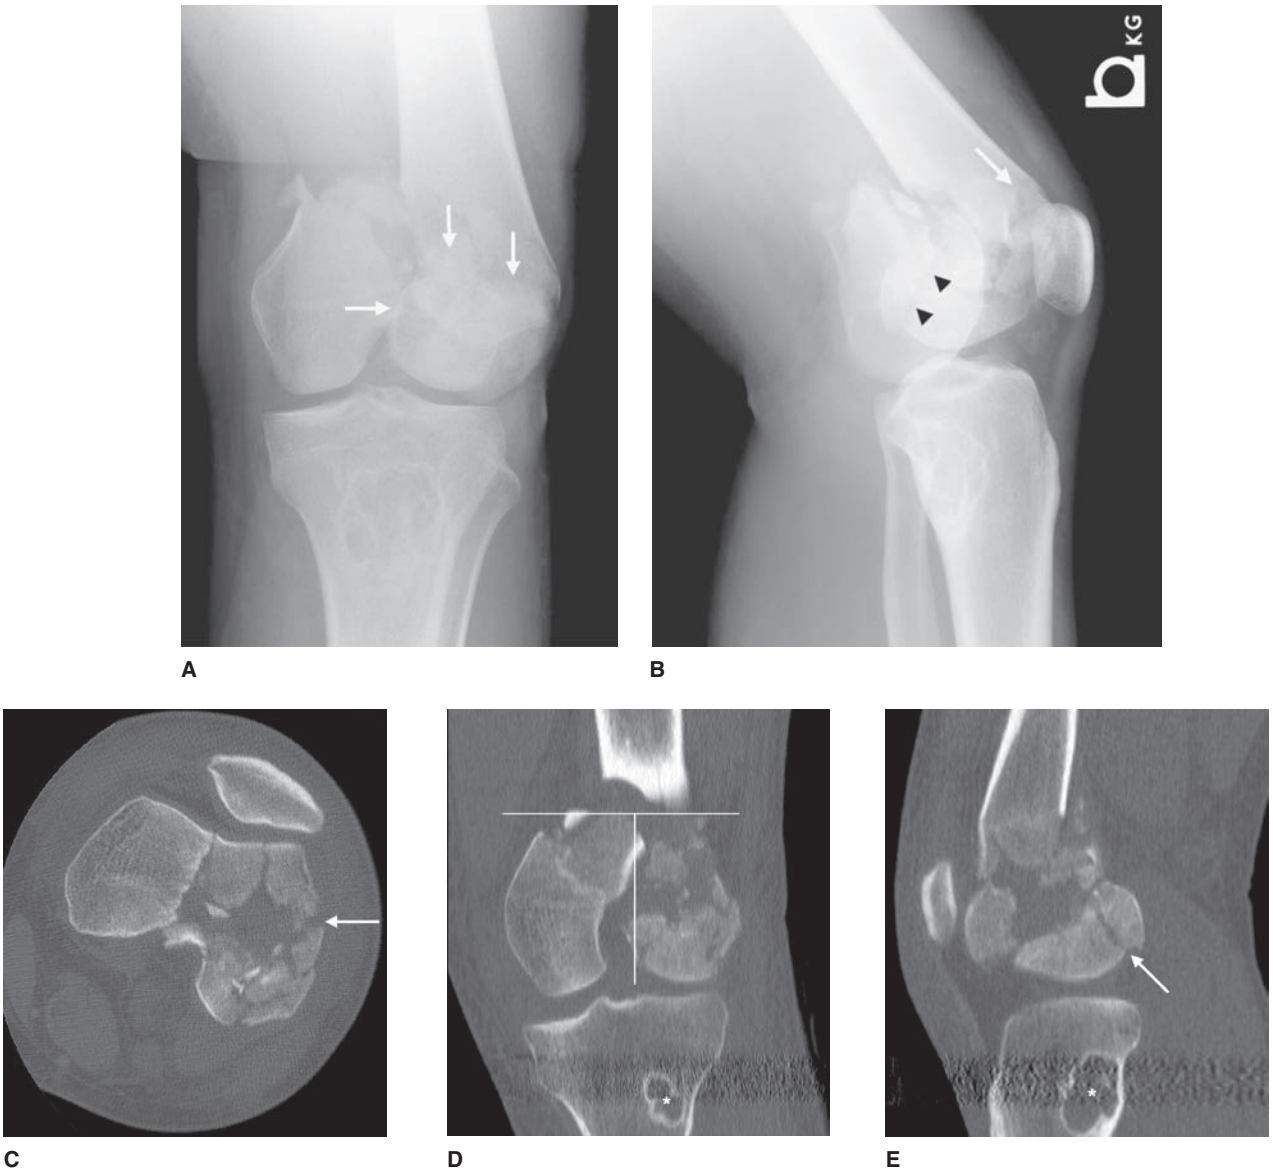

FIGURE 19-41 Periarticular fractures: intra-articular intercondylar distal femur fracture. This 20-year-old man was involved in a high-speed motor vehicle crash as a belted driver. (**A**) Anteroposterior (AP) radiograph of knee shows transverse T-type fracture of distal supracondylar femur, with intra-articular extension into intercondylar notch (arrows). (**B**) Lateral radiograph of knee shows transverse supracondylar component (arrow), from which femoral condyles have dissociated. In addition, lateral femoral condyle shows coronal plane, comminuted fracture of posterior aspect of condyle (arrowheads). In up to 40% of intra-articular intracondylar fractures caused by high-energy mechanisms, such coronal plane fractures (Hoffa fracture) may be overlooked. (**C**) Axial computed tomography (CT) shows a sagittal plane fracture extending into midportion of trochlea of the patellofemoral joint and a comminuted coronal plane fracture of posterior aspect of lateral femoral condyle (arrow). (**D**) Coronal plane reformation from axial CT shows T-type intra-articular fracture with dissociation of medial and lateral femoral condyles (white lines). Asterisk marks developmental variant, nonossifying fibroma. (**E**) Sagittal reformation from axial CT in central portion of lateral knee joint compartment shows coronal plane fracture of posterior femoral condyle (Hoffa fracture), as marked by arrow. Asterisk notes nonossifying fibroma, a benign developmental variant.

Doppler ultrasound may be a useful adjunct but is not widely used, primarily because of its decreased sensitivity and accuracy for peripheral vascular injuries when compared to catheter angiography. This, coupled with the operator-dependent nature of the examination and limited visualization of the entire vascular system for a variety of reasons (eg, external fixator devices, overlying split or cast material, and associated soft tissue injuries and gas), makes the utility of Doppler ultrasound for peripheral vascular injuries quite limited.

MRA is useful for the assessment of chronic peripheral vascular disease but is not widely used in the acute setting for the following reasons: (1) it may not be available at all centers at all times of the day; (2) it is technically challenging

D

FIGURE 19-42 Periarticular fractures: tibial plateau fracture (Schatzker 4). This is a 57-year-old woman who was hit by a car. (**A**) Anteroposterior (AP) radiograph of the knee shows a comminuted oblique fracture through the tibial plateau extending into the medial cortex (arrows). There is lateral subluxation (double arrow) of the tibial plateau with respect to the femoral condyles. (**B**) Cross-table lateral radiograph demonstrates the tibial plateau fracture (arrow) and lipohemarthrosis (triangle). The presence of a fat fluid level in the suprapatellar joint space indicates that the fracture line extends to the tibial plateau surface, thus liberating the fatty elements of the bone marrow into the joint space. Coronal (**C**) and axial (**D**) computed tomography (CT) images demonstrate the extent of intra-articular comminution and persistent fracture fragment subluxation despite closed reduction.

E

FIGURE 19-42 (*Continued*) (**E**) Three-dimensional surface-rendered CT image nicely demonstrates the fracture lines and relationships between the primary fracture fragments.

to effectively manage severely traumatized patients while they are in the magnetic resonance magnet; (3) the presence of metallic foreign bodies may limit patient and operator safety; and (4) even if not ferromagnetic, foreign bodies may still cause extensive artifact, obscuring the adjacent soft tissues. Thus, CT or catheter angiography is the primary imaging choice for patients with extremity injuries and suspected peripheral vascular injuries.

CTA FOR SUSPECTED PERIPHERAL VASCULAR INJURIES

CTA is an extremely useful adjunct for suspected peripheral vascular injuries in patients without indications for immediate surgical exploration. It is readily available, fast, convenient, noninvasive, and reliable. In addition, CTA can be easily integrated into the imaging workup of a traumatized patient, performed either as a stand-alone examination or integrated as part of a whole-body CT for polytrauma. CTA has high sensitivity, specificity, and accuracy when compared to catheter angiography (which remains the reference gold standard). In addition, CT capabilities allow for global evaluation of the adjacent structures and can thus be used to detect and characterize associated nonvascular injuries. The inability to immediately perform interventions on an injured vessel is a major limitation of CTA compared to catheter angiography.

The overall performance of CTA for peripheral vascular injuries compared to catheter angiography is certainly a concern for the trauma surgeon, as there is very little tolerance for missed or mischaracterized vascular injuries. A meta-analysis by Jens et al[96] pooling data from 11 studies from both the radiology and surgical literature and using a variety of scanner types documented that peripheral CTA for extremity vascular injuries had a sensitivity of 96.2% and specificity of 99.2% compared to catheter angiography. The rate of nondiagnostic CTA examinations was 4.2% in this meta-analysis. Thus, in patients without indications for immediate surgical exploration, CTA is useful to exclude peripheral vascular injuries and to characterize injuries that are present.

The CTA signs of a vascular injury include pseudoaneurysm, active bleeding, occlusion, intimal injury, dissection, and arteriovenous fistula (Fig. 19-38G). Imaging findings that raise the likelihood of an injury include a perivascular hematoma, a vessel within a projectile wound tract, and projectile fragments within 5 mm of a vessel. The latter two findings should typically prompt further investigation with catheter angiography.

Extremity CTA should be performed using MDCT with thin-section acquisition, peripheral IV access or a power injectable central line, and a high contrast injection rate (4–5 mL/s) and should be acquired during the systemic arterial phase. Images are reconstructed in the true axial plane to the long axis of the extremity at 1- to 3-mm slice thickness, with additional sagittal and coronal images reconstructed with respect to the axial plane. Coronal MIPs (or thick slab images) at 5- to 10-mm slice thickness are extremely valuable in displaying vessels along their long axis using a relatively small number of slices. Thin images should be reviewed as well, because small intimal vascular injuries may not be apparent on MIP images due to volume averaging. Liberal use of a 3D volume viewing station is encouraged, as some vascular injuries may be best displayed on nontraditional planes.

It should be noted that vascular injuries near highly mobile joints, such as the knee, are poorly treated with endovascular techniques. Thus, the decision to image with CTA over catheter angiography must be weighed against patient stability and the need for urgent surgical vascular repair. Despite this, the wide availability of stent grafts has also increased the utilization of angiography as a prelude to nonoperative management of some clinically significant vascular injuries.

CATHETER ANGIOGRAPHY

Catheter angiography (whether based in the radiology suite, operating room, or a hybrid operating theater) remains the reference gold standard for the definitive evaluation of arterial blood vessels for injury, as well as identifying active arterial hemorrhage, pseudoaneurysms, and arteriovenous fistulas. Although CTA is frequently favored for the initial imaging of many traumatic vascular lesions in stable patients, it is limited

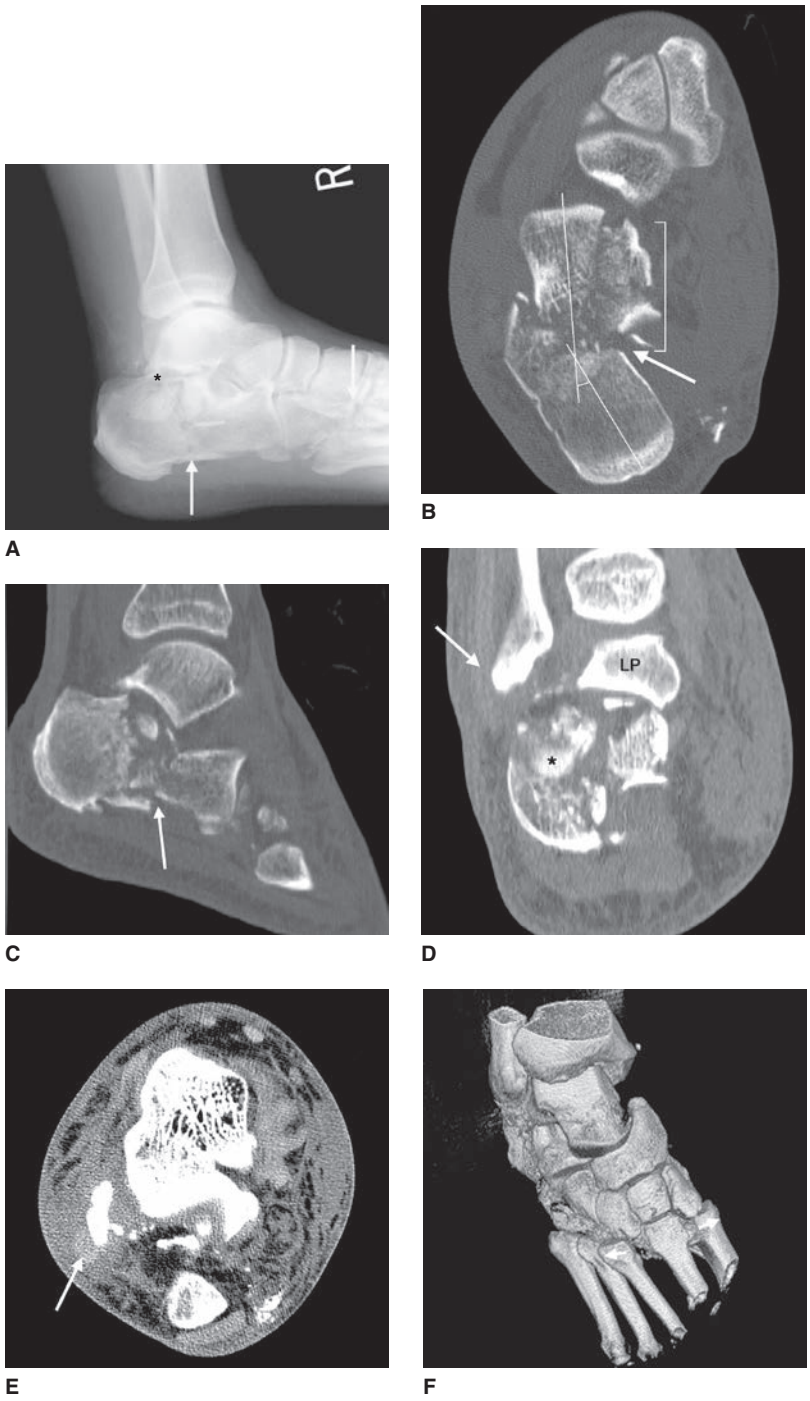

FIGURE 19-43 Periarticular fractures: calcaneus and Lisfranc fractures of midfoot. This 51-year-old restrained driver in a high-speed motor vehicle crash sustained multiple extremity and torso injuries. (**A**) Lateral conventional radiograph shows intra-articular fracture of calcaneus (upward pointing arrow denotes primary fracture plane; asterisk shows double density of central lateral fragment of posterior subtalar joint of calcaneus). Downward pointing arrow shows displacement of one of the metatarsal bases with an adjacent cuneiform fracture. (**B**) Axial computed tomography (CT) image at level of base of sustentaculum tali shows varus deformity through primary fracture (arrow). Secondary fracture plane extends toward anterior process (bracket). It is important to note continuity of cortex of medial wall of anterior process, as it influences distal extent of necessary fixation. (**C**) Sagittal reformation from axial CT shows primary fracture plane (upward arrow) with centrolateral fragment rotated into its superior extent. (**D**) Coronal reformation shows comminuted fracture of posterior facet of calcaneus due to bursting of body by lateral process (LP) of the talus. Centrolateral fragment is shown by asterisk. White arrow denotes lateral dislocation of peroneal tendons from peroneal groove in posterior fibula. (**E**) Axial CT at level of sinus tarsi, soft tissue window, shows lateral and anterior dislocation of peroneal tendons surrounded by hemorrhage and edema (white arrow). (**F**) Three-dimensional reformation from axial CT, medial oblique projection, shows divergent dislocations of great toe and third to fifth metatarsal bases (arrows).

by the inability to immediately intervene in the event of a positive study. CTA performance is very high, but not yet as accurate as catheter angiography. Catheter angiography is used as a problem-solving tool for equivocal CT examinations and for definitive therapy of some acute vascular conditions.

There are many advantages of catheter angiography. It allows simultaneous detection and treatment of a wide variety of traumatic vascular injuries. It is a very specific method of identifying bleeding at the submillimeter diameter of vessel. It can evaluate many sites of bleeding simultaneously. It has an excellent safety record, especially when using iso-osmolar nonionic contrast agents, coaxial micropuncture access, digital subtraction techniques, coaxial microcatheters, and steerable guidewires.

The disadvantages of catheter angiography are cost, the delay necessary to assemble the interventional radiology team (composed of radiologists, technologists, and nurses), the lack of suitability as a screening test for most traumatic conditions, and the risks of radiation exposure. Technical expertise is limited to predominantly subspecialty-trained interventional radiologists. These disadvantages are magnified when the likelihood of injury is low. Thus, noninvasive vascular techniques such as CTA should be entertained when considering the patient's overall management.

Transcatheter Endovascular Therapies

Endovascular techniques have become a broadly accepted way of controlling traumatic hemorrhage for a variety of reasons. Catheter-based hemostasis allows precise control from a remote site that avoids exacerbation of venous hemorrhage, introduction of pathogens, and hypothermia that may result from open exposure. It is especially valuable for hemorrhage that is remote or hidden from view and requires laborious time-consuming exposures or that is the result of multiple small bleeding sites that are not easily detected or controlled during operative exploration.

Endovascular techniques include embolization, stenting, stent grafting, and temporary balloon occlusion and may be definitive in nature or an adjunct to operative exposure. The methods of embolization include particulate or microcoil embolization of small vessels, proximal and distal control of a bleeding vessel, and coil occlusion to cause selective temporary hypotension of the bleeding zone.

Stenting, which facilitates blood flow beyond an injury, has largely been replaced by covered stent grafts that exclude lacerations, transections, and arteriovenous fistulae while maintaining flow through the conduit. Endografts are made of a variety of porous materials such as expanded polytetrafluoroethylene and are reinforced by a metallic skeleton that apposes the stent graft to the native artery. Reports of midterm patency, while limited at this time, are beginning to show that these are durable options to vascular repairs.

Contraindications to endovascular techniques are highly dependent on skills, teamwork, and hemodynamics; however, there are some injuries that are difficult for rapid surgical control and for which endovascular techniques have a role, even in the unstable patient.

Arch Angiography for Acute Blunt-Force Traumatic Aortic Injury

Screening and diagnostic arch angiography for blunt traumatic aortic injuries has largely been replaced by chest CTA, particularly with the widespread availability of MDCT technology.[67] Arch angiography, however, does have a role in the evaluation of equivocal findings on chest CTA and in potential endovascular stent graft therapy. If patients are going directly to angiography for evaluation of disruptions of the pelvic ring and the mediastinum is not normal on a chest x-ray, catheter arch angiography is the preferred "screening" modality; otherwise, CT is preferred. Modern CTA techniques are quite exquisite in demonstrating aortic injuries as well as providing coronal and sagittal reformations that can illustrate the important relationships and variants necessary for surgeons to create a treatment plan. Among many patients sustaining aortic injury, endovascular stent grafts have been advocated as definitive therapy.

Typically, a 5F pigtail catheter is guided to the ascending aorta via a femoral arterial approach. Patients are positioned and imaged in both 35° right anterior oblique and left anterior oblique projections, using injection rates of approximately 25 to 30 mL/s for a 40- to 60-mL volume (depending on hemodynamic status) and positioning to include the great vessels and diaphragm.

The angiographic appearance is classical. Linear filling defects indicate torn and ruffled intimal lining, with expansion of the lumen (typically at the ligamentum arteriosum) indicating the presence of a pseudoaneurysm (Fig. 19-44). The tear of the aortic wall may be segmental or circumferential and is sometimes associated with distal narrowing of the contrast column (pseudocoarctation). Minimal aortic injuries, as discussed earlier in this chapter, may be very difficult to visualize angiographically, and a "negative" aortogram following a positive chest CTA for a minimal aortic injury does not exclude the diagnosis.

Associated mediastinal vascular injuries should also be identified. Injuries of the arch arteries may occur instead of, or in association with, an aortic injury. Bleeding from the internal mammary or the intercostal arteries may be easily overlooked without diligence.

Hepatic Angiography for Blunt-Force Lacerations

Visceral catheter angiography is appropriate to evaluate hepatic lacerations (Fig. 19-45), particularly in patients with a labile hemodynamic status or those with active extravasation or vascular abnormalities as seen on a contrast-enhanced CT. Visceral catheter angiography may have a role after a "damage control" operation. Gross hemodynamic instability and profound shock, however, usually mandate urgent celiotomy.

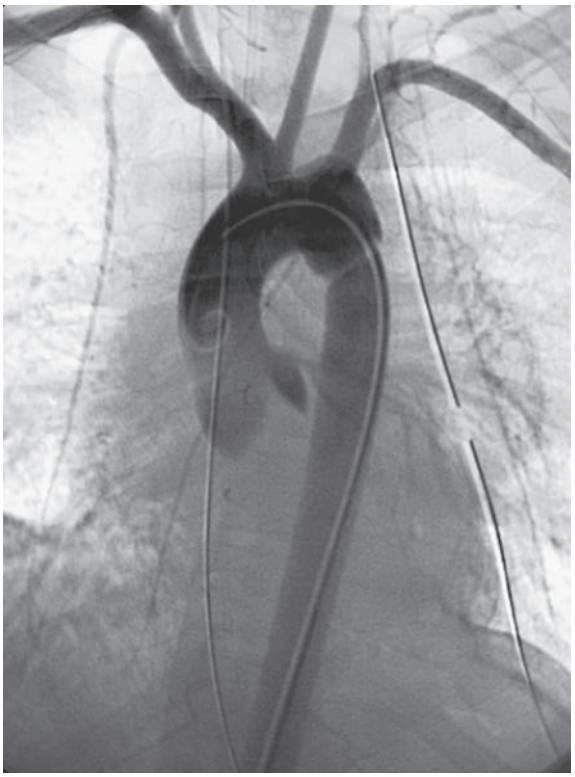

FIGURE 19-44 Traumatic aortic pseudoaneurysm. A 30-year-old man following a high-speed motor vehicle accident. Left anterior oblique digital subtraction arch aortogram shows traumatic aortic pseudoaneurysm extending proximal to the left subclavian artery. Of note, the aortic diameter and the distance from the left subclavian artery are important when considering endovascular therapy.

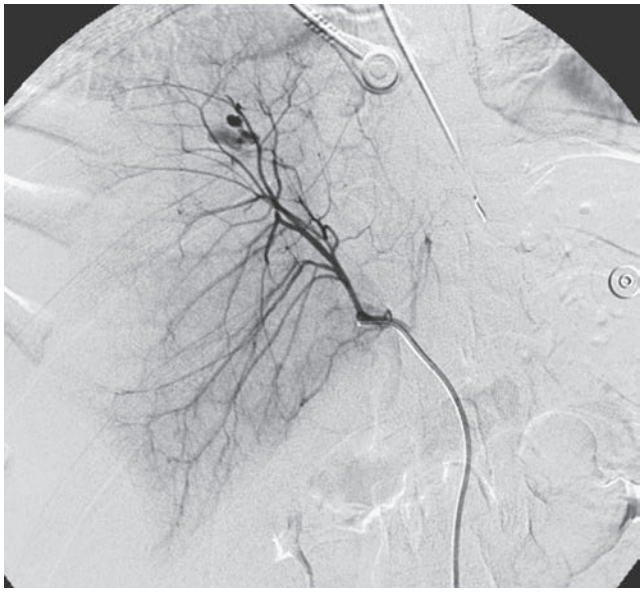
On CT, hepatic fracture lines that traverse the hepatic triad result in bleeding more often than those that run parallel to the triad. Contrast extravasation on CT tends to be associated with a positive arteriogram, but the decision to use angiography should primarily be based on clinical status rather than the CT appearance. Lack of enhancement of liver segments on CT is a very important finding, as these regions represent an intraparenchymal hematoma, occlusion of the portal triad, or injury of the hepatic outflow from that segment. It is vital to distinguish nonenhancement from a hematoma, which can be challenging. A large hepatic hematoma pushes the hepatic fragments away from each other and lacks hepatic vessels. If the area of nonenhancement has vessels running through it, it suggests an occlusion of the portal vein and hepatic artery or injury to a hepatic vein. Therefore, CT nonenhancement of the liver is an indication for angiography to confirm such injuries and to control ongoing arterial hemorrhage. As surgical exploration of damaged hepatic veins may be quite difficult, hepatic embolization and observation of a nonbleeding hepatic venous injury can be lifesaving. Hepatic angiography can also be helpful in the management of penetrating liver injuries that are isolated to the liver.

A



B

FIGURE 19-45 Liver laceration. (**A**) Computed tomography of the upper abdomen reveals a grade V liver laceration with pseudoaneurysm of the right hepatic lobe in this 18-year-old man status post high-speed motor vehicle accident. (**B**) Right hepatic angiogram identified the pseudoaneurysm. Note the size of the feeding vessel in relation to the 5F diagnostic catheter. Selective coil embolization was performed through a microcatheter. When selective catheterization is not possible, the liver is quite tolerant of wide arterial embolization due to the dual blood supply, provided the portal veins are patent.

Selective catheterization of both the celiac trunk and the superior mesenteric artery (SMA) is essential due to the high rate of hepatic vascular variants, particularly the aberrant replaced right hepatic artery from the SMA (15%–20%). Imaging should be continued through the late portal venous phase to evaluate for slowly bleeding vessels. There should be careful inspection for abnormal parenchymal enhancement and intrahepatic portal venous filling, as these are features of hepatic arterial-portal venous fistulae, which can easily be overlooked.[97]

Critical findings include arterial extravasation, spasm and occlusion, or shunting and fistula to portal or hepatic venous structures. Embolization of discretely abnormal vessels can be performed using a number of methods. A diffusely abnormal parenchymal injury with arterial bleeding may be safely embolized with Gelfoam due to the dual blood supply of the liver (hepatic arterial and portal venous). Embolization of hepatic arteries in the absence of portal flow increases the risk of developing an infarction or abscess. Depending on the location of bleeding and on the difficulty with catheterization, particulate embolization is the fastest technique; however, single microcoil embolization is preferred if time and circumstances allow. While formation of a postprocedure abscess is a complication of embolization, outcomes are favorable by integrating percutaneous image-guided drainage into the scheme.

Splenic Angiography for Blunt-Force Lacerations

Patients with splenic injuries diagnosed on CT are candidates for nonoperative management with overall good salvage rates, particularly when combined with splenic angiography and embolization.[77,98] When CT demonstrates active arterial extravasation or a parenchymal vascular abnormality (eg, an intraparenchymal pseudoaneurysm), one should consider angiography, as these are independent predictors of failure of nonoperative management.[99] It is thought that there was poor correlation between the CT grading system and outcome of treatment, as many grade IV injuries can be observed, and some grade I injuries become worse, rebleed, and require definitive procedural therapy. However, there is emerging evidence that a CT-based grading scheme, in combination with clinical parameters (eg, Abbreviated Injury Scale score), may be helpful for patient triage.[100,101] The treatment algorithms for patients with splenic injuries in the absence of active bleeding or other vascular lesions vary greatly by institution. The absence of arteriographic extravasation is a highly reliable predictor of successful nonoperative therapy regardless of injury grade. Identification of active arterial extravasation is the standard indication for endovascular treatment.

Diagnostic angiography of the celiac trunk is followed by selective splenic artery catheterization with a 5F catheter. If splenic artery anatomy permits and a solitary pseudoaneurysm or focus of extravasation is seen, distal coil embolization at the site of injury can be attempted. This is especially true in a patient in whom the extravasation extends beyond the splenic capsule into the peritoneal cavity. One should note that distal superselective embolization is associated with the development of more postprocedure splenic infarctions and abscess, although these complications are uncommon. Finally, most patients have tortuous splenic arteries, and most extravasations are multiple.

Diffuse intrasplenic extravasation is far more common, and superselective occlusion of these multiple sites would be very time consuming and less effective. In addition, the splenic tortuosity that results from medial displacement of the spleen by the perisplenic hematoma often prevents rapid catheterization (Fig. 19-46). In such cases, embolization of the proximal splenic artery by coils or other occlusion devices placed distal to the dorsal pancreatic branch and proximal to the pancreatic magna branches is advocated to reduce the arterial pressure head at the injury site while allowing perfusion through collateral vessels. Such collaterals prevent splenic infarction by maintaining splenic perfusion through connections between the left gastric and the short gastric arteries, between the dorsal pancreatic artery and the greater pancreatic artery branches, between the right and left gastroepiploic vessels, and others.

FIGURE 19-46 Splenic intraparenchymal false aneurysms. Digital subtraction angiogram of the splenic artery reveals multiple focal extravasations in this 56-year-old man status post motor vehicle accident. Selective embolization is not desirable because so many vessels are injured and selective catheterization would be difficult due to splenic artery tortuosity. In such cases, proximal splenic artery coil embolization proximal to the pancreatic magna branch is usually successful in controlling this hemorrhage.

Complications are uncommon when proximal splenic artery embolization is performed. A poorly selected coil size may result in hilar occlusion if the selected coil is too small and migrates distally. Coils that are too large may migrate proximally to occlude the celiac axis or embolize into the aorta. As noted earlier, distal microembolization bypasses the collateral circulation and results in more loss of immune function. It should be noted, however, that splenic blood flow is maintained in most patients via a combination of intact left gastroepiploic and short gastric arteries. This preserves immune function of the spleen, as well as distal flow. Occlusion of the pancreatic branches may result in pancreatic necrosis and

pancreatitis, although these complications are rare and can be avoided by careful review of the angiographic images if main splenic artery embolization is considered.

Interventions for Renal Trauma

Many renal injuries are usually well tolerated and do not require angiography, especially when caused by blunt trauma. Initial nonoperative management of blunt renal injuries with an intact pedicle is the current accepted management standard. High-grade injuries that result in massive hemorrhage may necessitate nephrectomy. Angiography for embolization of active bleeding is appropriate for hemodynamically stable patients. Angiography is recommended for patients with CT evidence of a major renal injury and ongoing blood loss or persistent gross hematuria. Peripheral wedge-shaped regions of nonenhancement on CT suggest a segmental or distal renal artery injury, often due to avulsion injury or intimal stretch resulting in distal platelet embolization. Penetrating renal injuries are more aggressively approached by angiography if nonoperative management is undertaken. Large perinephric hematomas, areas of nonenhancement, and active bleeding on CT warrant angiography following penetrating trauma.

Aortography is helpful to assess injury of the origin of the renal artery, to exclude renal parenchymal injury perfused by accessory renal arteries, and to look for associated bleeding sites. A selective renal arteriogram using a 5F catheter is then performed. Most injuries will require use of a coaxial microcatheter and embolization of small branches. Coils are preferred as they can be carefully placed to prevent infarction of adjacent noninjured renal tissue, but surgical gelatin pledgets can be used as well. Because renal branches are end vessels with little collateralization, infarction is likely, and the goal is to reduce these infarctions to a minimum.

The treatment of vascular injury in the renal pedicle continues to be a vexing problem, especially because delays in revascularization usually result in a renal infarction or renovascular hypertension. Partial wall injuries that result in a pseudoaneurysm or segmental infarction often went unrecognized prior to the widespread use of CT. Such injuries are routinely detected before complete arterial thrombosis and renal infarction occur. Therefore, arteriography is indicated when an injury in the renal artery is suspected. When such injuries are detected, treatment options are many, including operative revascularization, antiplatelet therapy and observation, and the application of covered stent grafts. Stent grafts can effectively seal full-thickness injuries and cover exposed media that results in embolic infarctions. Although long-term follow-up of series of these patients is lacking, the mid-term (1–5 years) patency of stent grafts throughout the body remains high (Fig. 19-47).

Angiography for Pelvic Hemorrhage

Pelvic fractures are potentially life-threatening injuries that are caused by high-energy impact trauma and are the third most common lethal injury following motor vehicle crashes. The majority of patients with pelvic fractures do not require massive transfusion as bleeding in most cases is likely to be venous or osseous in nature and often self-limited. Radiologic intervention is not commonly required in patients with routine pelvic fractures. Severe hemorrhage, however, occurs in 3% to 10% of patients, and mortality rates may be as high as 40% in patients with unstable pelvic fractures.[102] Thus, the use of angiography in patients with pelvic fractures is highly dependent on the hemodynamic status, the type of pelvic fracture pattern, the transfusion requirements, and the presence or absence of pelvic hematoma.

BLUNT PELVIC FRACTURES

Blunt pelvic fractures with crushing or shearing tear the small branches of the internal iliac artery that accompany ligaments, muscles, and tendons. Injuries tend to be multiple and bilateral and from several branches. In addition, bony fragments can penetrate or perforate vascular structures. Examples include a fracture of the superior pubic ramus injuring the internal pudendal or obturator artery, a fracture of the iliac wing through the sciatic notch injuring the superior gluteal artery, and disruption of the sacroiliac joints injuring the lateral sacral arteries.

Most of the indications for angiography in blunt pelvic trauma have remained the same for many decades and include the following:

1. Hemodynamic instability in a patient with a pelvic fracture with no or little hemoperitoneum detected by FAST or DPL.
2. Pelvic fracture and transfusion requirement of greater than 4 units in 24 hours or 6 units in 48 hours.
3. Pelvic fracture and a large or expanding hematoma identified during celiotomy.
4. CT evidence of large retroperitoneal hematoma with extravasation of contrast.
5. Need for detection and treatment of other injuries during angiography.

The presence of contrast extravasation on MDCT has been used as an indication for follow-up pelvic angiography. Although it should not delay angiography that is already indicated for pelvic hemorrhage, CT is helpful in localizing the vessels likely to be bleeding not only in the pelvis, but also from the solid organs and thoracic cavity. Correlations of location of the hematoma and site of vascular injury include obturator space and obturator artery, presacral space and lateral sacral artery, space of Retzius and internal pudendal artery, and buttock and gluteal artery.

Femoral access is the preferred approach; however, catheterization may be difficult because of hypotension, tachycardia, and difficulty in palpating the vessels as the pelvic hematoma expands. Ultrasound or fluoroscopic guidance is very helpful in these situations. A 5F aortic flush catheter is used for flush abdominopelvic aortography. This is valuable

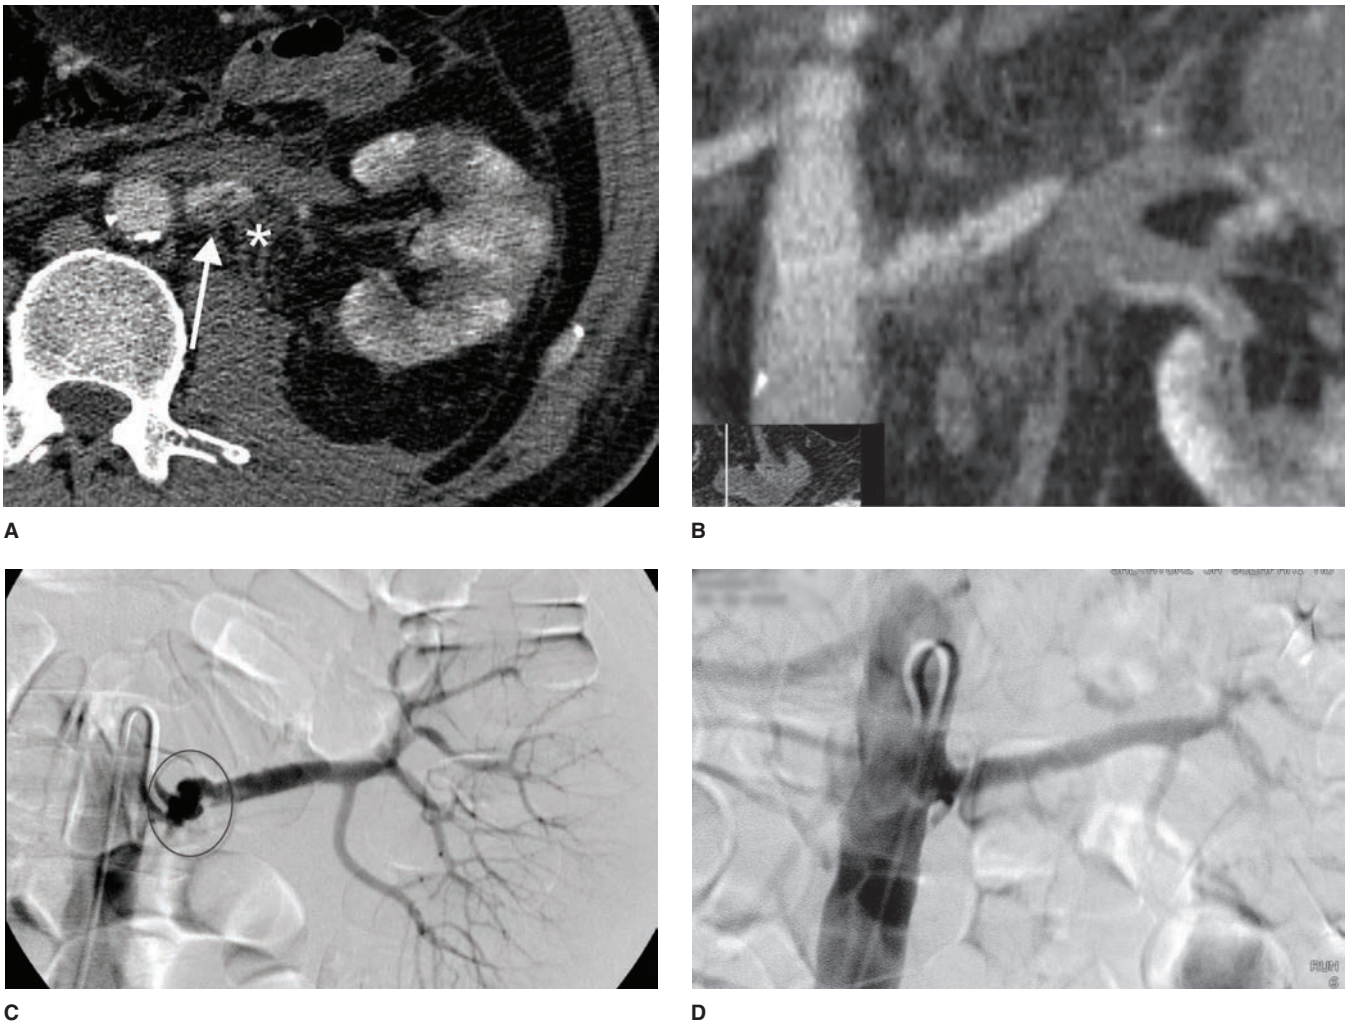


FIGURE 19-47 Renal artery injury. A 56-year-old man fell from a height of about 10 m. (**A**) During computed tomography evaluation, inhomogeneous enhancement of the spleen was detected. Central perinephric hemorrhage (asterisk) and irregularity of the renal artery (arrow) were seen. (**B**) Coronal reformation shows irregularity of the renal artery and thickening of its wall. (**C**) Aortography shows irregular enlargement of the proximal renal artery near the ostium (circled). Slight extravasation was seen on the later images. (**D**) Therefore, a stent graft was placed over the area of injury. The vessel wall was then smooth, and no extravasation was seen. Two-year follow-up arteriography showed continued patency and no stenosis.

to screen the abdominal viscera and mesentery, to exclude aortoiliac and other retroperitoneal bleeding sources, and as a road map of the pelvic vessels. Selective bilateral internal iliac arteriography is mandatory to exclude bleeding sites since aortography may not identify all bleeding. From one access, both internal iliac arteries are sequentially catheterized and opacified. Then, external iliac arteriography is used to evaluate the external pudendal and external obturator vessels.

It is common to identify multiple areas of extravasation during pelvic angiography. These may be bilateral and may involve multiple vascular beds. Extravasation is often punctate but can be large and coarse, and the size of such extravasations may not correlate with the degree of blood loss. Vascular occlusions due to transection or dissection with subsequent occlusion can be present as well. It can be difficult to differentiate between arterial injury due to thrombosis and vasospasm. Failure to treat these occlusions may result in recurrent hemorrhage when vasospasm resolves. Arteriovenous fistulas can occur but are more common in penetrating trauma.

Because bleeding is usually multifocal and originates from multiple small blood vessels, embolization requires small particulate embolization. Large coil occlusion is as ineffective as surgical ligation of the internal iliac artery because bleeding soon resumes through numerous collateral circuits. Surgical gelatin pledgets are ideal because they are inexpensive, readily available, and often temporary, lasting only a few weeks and allowing reestablishment of normal blood flow after the

tissue has healed (Fig. 19-48). Permanent particulate emboli, however, are often used because of their ease of use through a microcatheter (Fig. 19-49). Embolization is technically successful in more than 90% of patients, and hemorrhage control is highly effective. Survival depends on many other factors including associated injuries, the presence of an open fracture, transfusion requirements, and delays to embolization.

PENETRATING PELVIC TRAUMA

Penetrating trauma is an uncommon indication for pelvic angiography, as many patients are hemodynamically unstable or have clear indications for immediate exploratory celiotomy, often due to injury to a large vessel. Because the extraperitoneal space has been exposed by a penetrating wound, intraperitoneal bleeding is likely, and direct exploration is typically warranted. Occasionally, angiography is valuable when operative control cannot be initially accomplished and damage control has been performed. Angiography and embolization prior to unpacking can aid in decreasing blood loss at a reoperation.

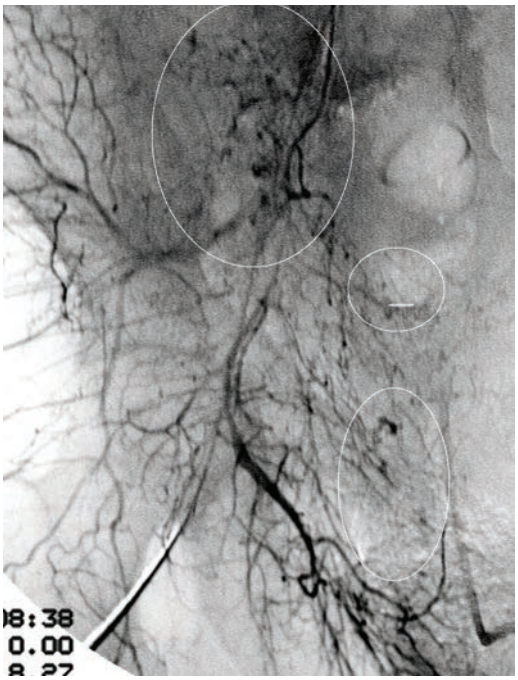
Injuries to large vessels require a very different endovascular strategy than small vessels or end organ vessels. When an injury to a noncritical internal iliac artery or branch has been missed at operation but detected on postoperative angiography, coil occlusion of both the proximal and distal end of the vessel (whenever possible) is the standard treatment.

Catheter Angiography for Peripheral Vascular Injuries

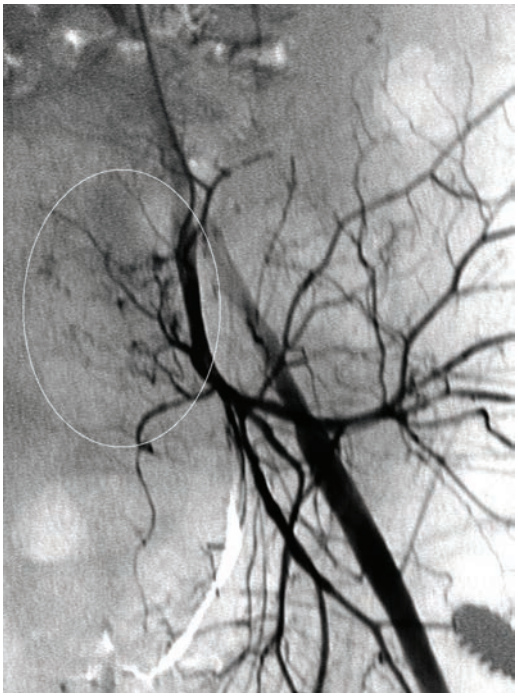
Almost all peripheral vascular injuries can be reached using a 5F catheter from femoral access provided a long enough catheter is available. Angiography should be done in multiple projections with opaque marking of surface wounds demonstrating that the entire course of the wounding agent is within the field of view. Iso-osmolar nonionic contrast medium is the optimal agent for visualization. Multiple images in the arterial, capillary, and venous phases are necessary.

There is a body of literature demonstrating that the combination of physical exam findings and noninvasive tests (eg, ankle-brachial index and Doppler ultrasound) is reliable in the exclusion of significant peripheral vascular injuries for patients with low likelihood of vascular injury. The overall incidence of extremity vascular injuries in the setting of penetrating trauma for asymptomatic patients is relatively low (3%–4%). Thus, screening CTA or angiography for "proximity" injuries is likely to be low yield in the absence of "hard" clinical signs.

Vascular injuries resulting from fractures and dislocations are uncommon. Clinical evaluation is often difficult because the hematoma from a fracture may be quite large and indistinguishable from one associated with a vascular injury. Crush wounds, angulation deformities, and fracture hematomas may cause a pulse deficit by kinking, entrapping the vessel, or inducing spasm without an intrinsic vascular injury.



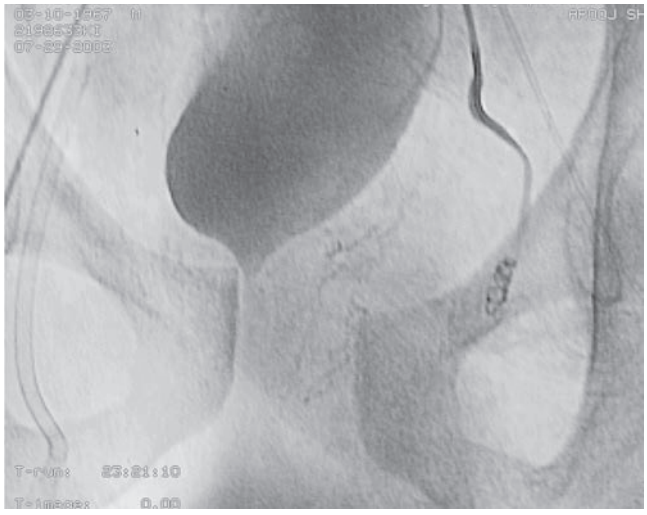
A



B

FIGURE 19-48 Multiple bleeds from pelvic fractures: 48-year-old male driver in a motor crash sustained pelvic fractures requiring transfusions. (**A**) Circles surround multiple bleeding sites from the region of the sacroiliac joint; from the pelvic side wall on the right hemipelvis emanate anterior and posterior branches of the right internal iliac artery and in the region (**B**) multiple points of extravasation were detected (circle). They are emanating from the left lateral sacral artery. Such diffuse hemorrhage is not amenable to superselective embolization because it would be too time consuming. Pledgets of surgical gelatin, 2 to 3 mm in size, can occlude these vessels effectively.

A



B

FIGURE 19-49 A 26-year-old motorcyclist sustained unstable pelvic fractures during a crash. He developed expanding perineal and scrotal hematomas requiring red cell transfusion. (**A**) Left internal iliac arteriogram reveals a source of bleeding from the left internal pudendal artery (curved arrow). The more medial contrast stain (straight arrow) is a normal finding. It represents the blush of the perineal body and root of the ischiocavernosa muscle that is frequently seen on internal iliac arteriography of males. (**B**) Because this was focal hemorrhage, selective embolization via 2.8F catheter placed coaxially through the 5F catheter was attempted and successfully achieved hemostasis.

A laceration into muscle may result in external blood loss without major vascular injury. The natural history of many injuries cannot be predicted by the angiographic appearance alone. Therefore, observation of some injuries is warranted. Equivocal findings such as luminal narrowing can be assessed by repeating angiography, after infusion of an intra-arterial vasodilator, on a subsequent day. Small irregularities and intimal tears that do not restrict flow may be treated by antiplatelet therapy and will generally heal (Fig. 19-50).

Treatment of angiographically diagnosed vascular injuries is based on the anatomic role of the bleeding vessel; its size, location, and accessibility; the hemodynamic condition of the patient; and the specific type of lesion. Small vessels that are not essential for tissue perfusion can be treated by small-particle embolization, using surgical gelatin pledgets or more permanent smaller agents. Permanent agents have no advantage but, in some instances, are more easily administered through microcatheters than surgical gelatin. These agents are delivered by flow direction toward the path of least resistance, which is usually toward the bleeding site. Microcoils can be used for injury to a small vessel provided they can be delivered near enough to the injury site to avoid collateral recruitment that permits continued bleeding. Examples of vessels that can be treated by embolization of small particles include hemorrhage from a pelvic fracture, multifocal hepatic arterial hemorrhage, and injuries to muscular branches such as those of the profunda femoris artery in the lower extremity.

Injury to larger vessels such as those greater than 3 mm in diameter requires two techniques, one for essential vessels and one for expendable vessels. The treatment of essential vessels mandates repair of the bleeding site while allowing continued blood flow. Thus, stent grafts can be deployed to cover the injured segment while allowing antegrade flow (Fig. 19-51).

Nonessential conduits, such as branches of the profunda femoris artery or the brachial artery, or one of the arteries in the shank, can be safely embolized. Particulate embolization will flow past the injury and penetrate deep into the vascular bed. When conduits are injured, this insult to the vascular bed is unnecessary. Therefore, large-vessel agents are used to occlude the damaged segment of the conduit while the vascular bed is perfused through collaterals (Fig. 19-52).

Coils in various sizes, some containing threads or fibers to accelerate thrombosis, are the most common devices used to occlude a large vessel. A coil is sized to have a diameter large enough to prevent distal migration, but not too large to end up recoiling into a parent, nontarget vessel.

The technique of arterial isolation attempts to occlude both the proximal and distal vessels around the area of injury by coiling (Fig. 19-52). The goal is to exclude the vascular defect and prevent rebleeding through collateral vessels. This is highly desirable in most circumstances, but mandatory when treating arteriovenous fistulas. The guidewire is carefully maneuvered distal to the injured segment but proximal to any branches, and coils are delivered. The catheter is then withdrawn, and coils are placed in the proximal segment.

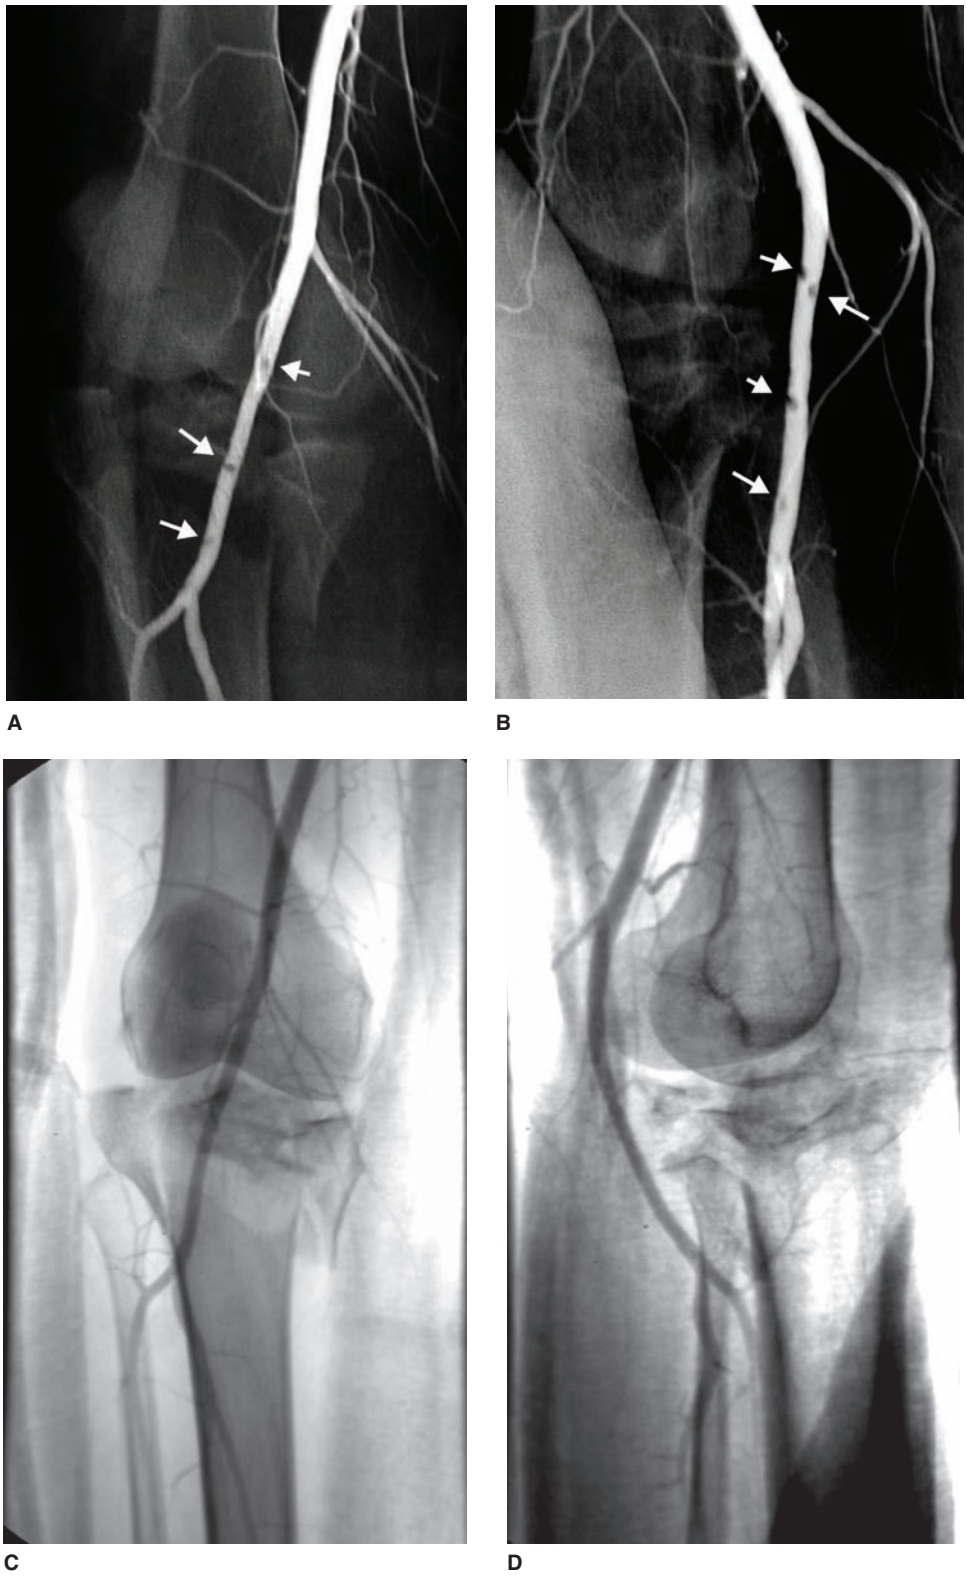


FIGURE 19-50 "Minimal injury" of the popliteal artery. Pedestrian who was struck by a motor vehicle sustained comminuted tibial plateau fracture of the left knee. Pulses were diminished and angiography was sought after incomplete reduction. (**A, B**) Initial popliteal arteriogram showed numerous filling defects consistent with intimal tears (white arrows). Patient was treated with aspirin. (**C, D**) Arteriogram 1 week later showed healing of the intimal tears.

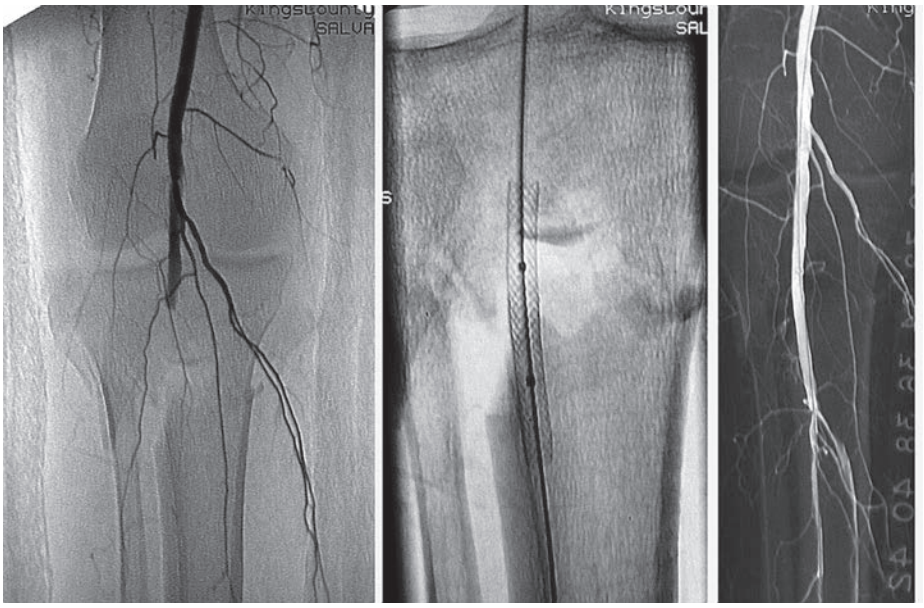
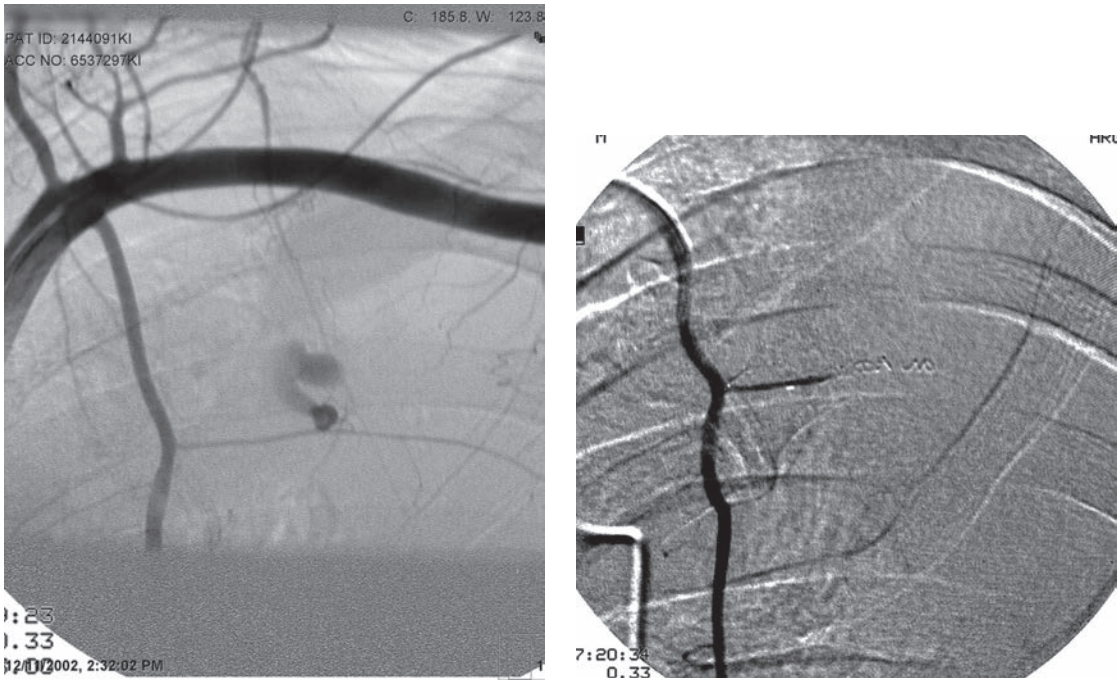


A B C

FIGURE 19-51 Thrombosis of popliteal artery with endovascular repair. A 46-year-old morbidly obese woman sustained comminuted tibial plateau fractures after a fall from curb. Pulses were absent. (**A**) Popliteal arteriogram shows complete occlusion of the mid-popliteal artery. (**B**) The catheter was quickly advanced to a location just above the occlusion, and a guidewire was advanced easily into the posterior tibial artery. An expanded polytetrafluoroethylene–reinforced stent graft was deployed between proximal and distal extent of the occlusion. (**C**) Follow-up popliteal arteriogram showed restoration of direct line flow. The entire procedure took less than 1.5 hours.



A B

FIGURE 19-52 Example of vascular isolation by proximal and distal coil occlusion. A 22-year-old man sustained a single stab wound of the upper left chest resulting in a very large hemothorax. (**A**) Subclavian arteriogram shows that there is active arterial hemorrhage from a lacerated fourth anterior intercostal branch of the left internal mammary artery. (**B**) Because there was continuity between anterior and posterior intercostals, it was necessary to advance a 2.8F microcatheter across the laceration into the distal segment to deliver a coil distally before withdrawing the catheter and delivering a coil proximally.

Principles of Anesthesia and Pain Management in Trauma Patients

Ron E. Samet • Justin E. Richards • Ian R. Slade

KEY POINTS

- Anesthesia in trauma care is the practice of perioperative resuscitation.
- Anesthesiologists, surgeons, and emergency medicine and critical care physicians must communicate and collaborate effectively to provide comprehensive continuous trauma care.
- Anesthesiologists blend clinical pharmacology expertise and advanced physiologic monitoring to optimize resuscitative outcomes in trauma patients.
- Standard anesthetic objectives of anxiolysis, analgesia, hypnosis/amnesia, and immobility often require creative modification to accommodate trauma physiology.
- Regional anesthesia techniques should be incorporated earlier in trauma care to facilitate patient comfort, assessment, procedural care, and transport without impairing cognitive function.
- Multimodal analgesia techniques are proving increasingly valuable in reducing the harmful impacts of opioid use, both in the acute hospitalized trauma patient and in the immediate postdischarge phase.

Anesthesiologists are perioperative physicians who are responsible for preoperative evaluation and preparation, intraoperative anesthetic and critical care medicine, and acute postoperative care.[1] Whereas elective surgical patients benefit from comprehensive preoperative evaluation, medical optimization, and a multitude of safe and comfortable anesthetic options, management of the acute trauma patient can be remarkably different. Limited planning time, unknown patient variables, and rapidly changing patient and surgical conditions demand a more adaptive approach. The trauma patient's physiologic instability from ongoing hemorrhage and multiorgan injury demands the prioritization of resuscitative medicine and may require significant adaptations of traditional anesthetic approaches. These patients require a dynamic balance of perioperative goals with consideration of type and depth of anesthesia, medication selection and dosing adjustments, airway management techniques, continuous resuscitative assessment and treatment, and postoperative disposition and pain management. With unique challenges in trauma anesthesia care, this chapter highlights the key considerations and modifications to standard anesthetic practice for each phase of care in the acute trauma patient.

PREOPERATIVE ASSESSMENT AND MANAGEMENT

Anesthetic planning begins preoperatively and must consider preoperative, intraoperative, and postoperative objectives. Information about a patient's current medical and surgical condition is gathered to appraise risk at the organ-system level, predict likely changes from evolving injury, and formulate a dynamic anesthetic prescription (and contingency plans) to manage perioperative risks. In busy trauma centers, anesthesiology presence at the initial phases of care allows for direct participation in early resuscitation and helps allocate resources (eg, staff, space, time, equipment, blood availability) to facilitate emergent surgical interventions; this is particularly crucial when triaging multiple-casualty incidents.[2] For trauma patients without immediate surgical needs, early anesthesiology assessment remains a valuable opportunity to document future anesthetic options and discuss medical optimization with other providers. Finally, trauma patients with complex pain management requirements can also be identified at the onset and offered regional anesthesia techniques to ameliorate the need for large-dose opioids or other sedative medications.[3]

General Principles of Preoperative Evaluation

Standard preoperative anesthesia evaluation involves a focused history, physical examination, and review of laboratory and radiology tests, if available. Particular attention is given to planned surgical procedure and urgency; comorbidities; previous medical and surgical histories; previous anesthetics and their complications; the airway, cardiovascular, and lung exam; and whether the patient has been optimized for surgical fitness. In the conscious trauma patient, gathering this information may be straightforward. Otherwise, the anesthesiologist must rely on reports from first responders, family members, medical personnel, or other available records. Special attention to emergency medical services reports as to the mechanism of injury, blood loss at the scene, airway, and resuscitative interventions are of utmost value because prehospital details can dramatically alter in-hospital interventions. Some use the AMPLE mnemonic: *a*llergies, *m*edications, *p*ast medical/surgical history, *l*ast meal, and *e*vents/*e*nvironment leading to injury. Physical examination may provide some important clues, such as scars from previous traumatic injury or repair, medic alert bracelets, sternotomy scars, palpable pacemakers, insulin pumps, and general body habitus (obesity, pregnancy).

Because many drugs routinely used in anesthetic care induce vasodilation and hypotension, careful attention is given to baseline cardiovascular disease and perturbations in volume status, especially in trauma patients who may be hypovolemic due to ongoing hemorrhage. Preoperative evaluation enables close consideration of factors influencing choice of anesthetic induction technique, airway management, vascular access, hemodynamic monitoring, and fluid management. These interests for anesthesiologists align closely with the Advanced Trauma Life Support primary survey, with special attention to airway status, examination for impediments to airway management such as potential coexisting cervical spine injury with the presence of a cervical collar, blood in the airway, and general functional capacity. The presence of the anesthesiology team on the patient's arrival and during the primary survey, therefore, expedites this portion of early assessment.

Shared Role in Early Resuscitation

In conjunction with the entire trauma team, anesthesiologists often have a key role in joint resuscitation of patients in the preanesthetic phase. Particular contributions of the anesthesia team can include airway securement; establishment of arterial and large-bore venous access; planning of ongoing resuscitative needs, such as obtaining a blood sample for type and crossmatch; assessment of coagulation parameters; blood gas analysis and ventilator management; coordinating vasoactive infusions; and transfusion management. Effective early resuscitation aimed at restoring circulating volume, organ perfusion, and oxygen delivery can reduce the risk for profound hypotension upon induction of general anesthesia and prolonged circulatory shock. Volume and blood resuscitation, in combination with early prevention and treatment of hypothermia and coagulopathy, helps prepare patients for the risk of further physiologic disruption as their injuries evolve and in the course of surgical care. Patients needing massive transfusion can be quickly identified, and blood bank resources can be mobilized and initiated promptly. In some circumstances, anesthetic care may even commence in the emergency department when operative procedures need to be conducted in the trauma bay. By having already participated in assessment and early resuscitation, anesthesiologists are particularly well positioned to assume the resuscitative responsibilities of the trauma team as the patient transfers to the operating room.

INTRAOPERATIVE ASSESSMENT AND MANAGEMENT

Intraoperative anesthesia management is often triphasic with induction, maintenance, and emergence phases. Induction involves administration of induction drugs and doses, techniques to secure the airway, and management of hemodynamic perturbations from the preceding two interventions. Maintenance focuses on maintaining the anesthetized state and homeostasis, whereas emergence defines the task of smoothly transitioning patients to an awake and comfortable state. The anesthesiologist is responsible to provide modulation of physiologic functions, monitoring, and when applicable, anxiolysis, analgesia, hypnosis, amnesia, and immobility. Given that nearly all analgesic and anesthetic medications risk inducing further hypotension via vasodilation, negative cardiac inotropy, or obliteration of the catecholamine response, it is often said that a patient in traumatic shock must "earn" their anesthetic medications as resuscitative efforts restore adequate perfusion. In severe injuries, the anesthesiologist may not administer any classical "anesthetics" and functions more as a traumatologist practicing resuscitative medicine.[4] A review of intraoperative anesthetic goals and commonly used anesthetic agents follows, with particular attention to their benefits and risks in the acute trauma patient.

Intraoperative Resuscitation

In acute trauma patients, the primary responsibility of a trauma anesthesiologist is to resuscitate and restore macro- and microcirculatory perfusion while simultaneously preparing the patient for surgical hemorrhage control and repair. Constant communication with the trauma surgeon, observation of operative progress, and inquiry of identified and repaired injuries help anticipate further resuscitative needs. Institution-specific massive transfusion events (Fig. 20-1A), often activated preoperatively, should be continued intraoperatively, such that protocol-driven balanced volumes of red blood cells, plasma, and platelets are rapidly delivered to the patient when needed. Viscoelastic laboratory testing (Figs. 20-1B and C) and markers of anemia, coagulation, and

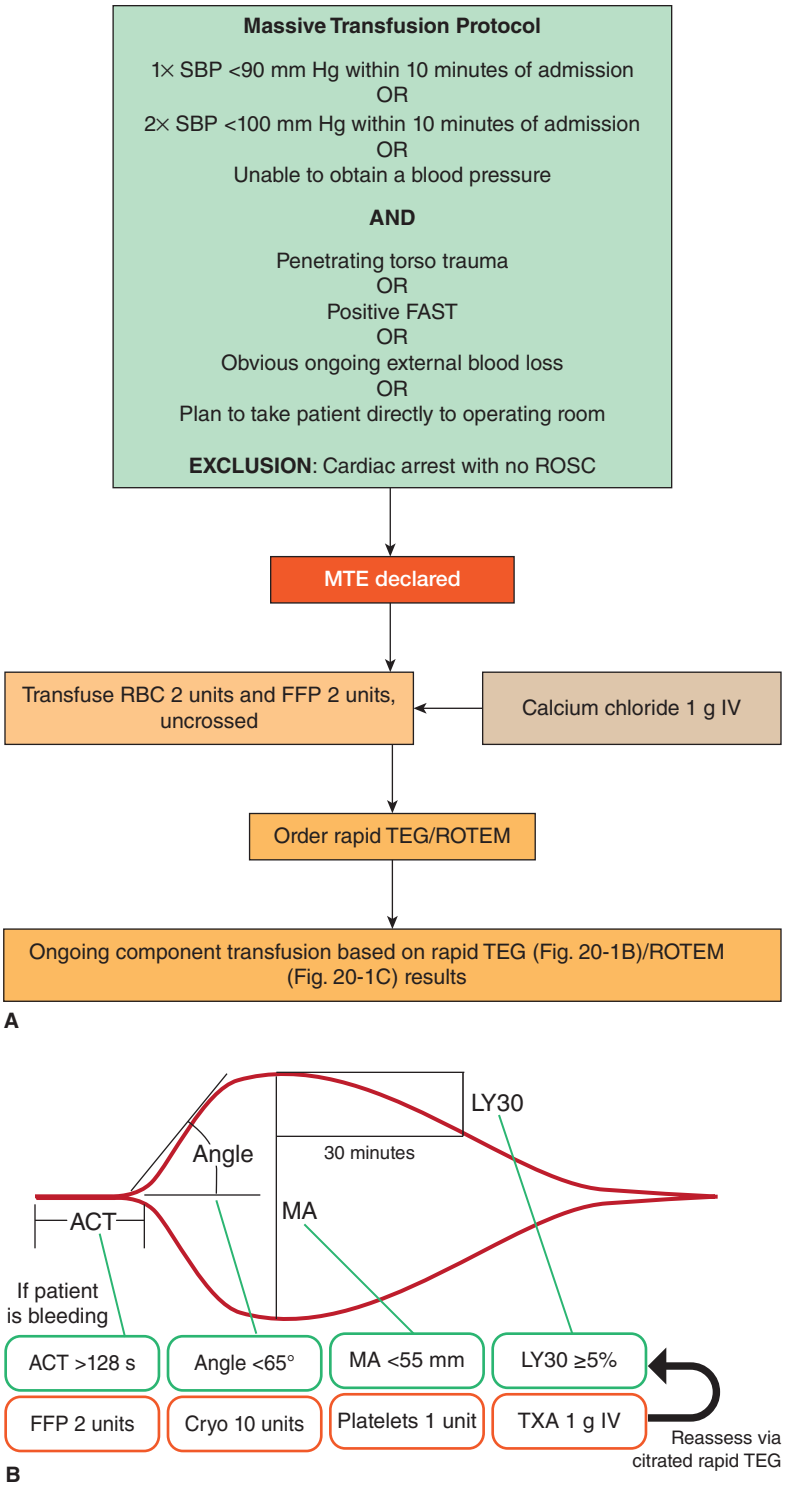

FIGURE 20-1 (**A**) Massive transfusion protocol. (**B**) Rapid TEG. (**C**) ROTEM. ACT, activated clotting time; CT, clotting time; Cryo, cryoprecipitate; EXTEM, extrinsically activated test with tissue factor; FAST, focused assessment with sonography in trauma; FIBTEM, fibrin-based extrinsically activated test with tissue factor and the platelet inhibitor cytochalasin D; FFP, fresh frozen plasma; IV, intravenous; LY30, clot lysis after 30 minutes; MA, maximum amplitude; MCF, maximum clot firmness; MTE, massive transfusion event; RBC, red blood cell; ROSC, return of spontaneous circulation; ROTEM, rotational thromboelastometry; SBP, systolic blood pressure; TEG, thromboelastography; TXA, tranexamic acid. end-organ perfusion should direct appropriate intraoperative blood product transfusion, factor concentrates, and antifibrinolytics.[5] Although excessive crystalloid administration (ie, >2 L) should be avoided in an acutely injured trauma patient,[6] balanced crystalloid solutions are acceptable when necessary.[7,8]

Large-bore intravenous access is critical for successful resuscitation. When two peripheral intravenous lines (18-gauge or greater) cannot be obtained, an interosseous line can be placed until more definitive central venous access is secured. In the patient with multiple injuries, the insertion site for intravenous access should be in a location that will effectively restore intravascular volume and deliver medications to the systemic circulation without interfering with the operative procedure. It is routine in our institutions to insert large-bore intravenous access above the diaphragm in patients with intra-abdominal or pelvic injuries due to the risk of possible extravasation of much needed resuscitation fluid and supportive medications infused via femoral lines. Similarly, in patients with severe extremity injuries, intravenous access should be obtained at sites other than the injured extremity. Rapid infusion systems should be used when available to restore intravascular volume quickly. Furthermore, invasive hemodynamic monitoring with an arterial catheter is essential for the hypotensive trauma patient to provide continuous hemodynamic monitoring and frequent arterial blood gas measurements to assess metabolic status and resuscitative success. Invasive arterial access must also consider whether resuscitative endovascular balloon occlusion of the aorta (REBOA) (see Chapter 13) or eventual angiographic intervention will be necessary, because this will require arterial cannulation of specific vessels. The use of ultrasound frequently facilitates insertion of intravascular monitors and can be critical in severely hypovolemic patients, burn patients, or those with a history of intravenous drug use.[9]

True resuscitative goals and optimal hemodynamic and laboratory targets are hard to substantiate due to limited data. However, Dutton[10] has described early (prior to hemorrhagic control) and late (after surgical hemostasis) resuscitative objectives as a useful way of organizing intraoperative goals and treatment priorities (Table 20-1). More recent expert consensus opinion recommends a systolic blood pressure of 100 to 110 mm Hg until hemorrhage control is achieved.[11] The rate of volume resuscitation should be such that intravascular volume is administered in order to adequately support cardiac filling pressures, allow for sufficient end-organ perfusion, and support a mean arterial blood pressure (MAP) of at least 65 mm Hg.[12] Once hemostasis is obtained, it is reasonable to target a MAP of greater than 65 mm Hg because prolonged hypotension and hypoperfusion are associated with

TABLE 20-1: Early and Late Goals of Resuscitation

Resuscitation goals *prior to* hemorrhagic control	Resuscitation goals *after* surgical hemostasis
• Systolic blood pressure 90 mm Hg	• Systolic blood pressure >100 mm Hg
• Heart rate <120 bpm	• Heart rate <90 bpm
• Pulse oximeter functioning, Sao_2 >95%	• Pulse oximeter functioning, Sao_2 >97%
• Urine output present	• Urine output >0.5 mL/kg/h
• $Paco_2$ <50 torr	• $Paco_2$ <40 torr
• pH >7.25	• pH >7.35
• Hematocrit >25%	• Hematocrit >20%
• Lactate stable and decreasing	• Lactate normal
• Ionized calcium >1.0 mmol/L	• Ionized calcium >1.0 mmol/L
• International normalized ratio <1.6	• International normalized ratio <2
• Platelets >50,000/mm^3	• Platelets >50,000/mm^3
