Both hormonal and mechanical changes in pregnancy contribute to increased minute ventilation. As the gravid uterus enlarges, it displaces the diaphragm superiorly approximately 4 cm, decreasing functional residual capacity. Elevated progesterone levels cause increased tidal volume and hyperventilation, which augment minute ventilation. It is common for a woman in her third trimester to have hypocapnia ($Paco_2$ of 30 mm Hg) and a compensated respiratory metabolic alkalosis. It is important to recognize that a pregnant patient with a $Paco_2$ of 35 to 40 mm Hg may be exhibiting signs of impending respiratory failure. The baseline hyperventilation of pregnancy also reduces the mother's ability to compensate for metabolic acidosis.

Renal System

To compensate for the increased blood volume in pregnancy, the renal plasma flow and glomerular filtration rate (GFR) both increase. Paired with hemodilution from a 50% increase in plasma volume, the serum creatinine concentration decreases by an average of 0.4 mg/dL. In pregnancy, a normal creatinine ranges from 0.4 to 0.8 mg/dL.[17] The increased GFR leads to excretion of other metabolic products that may exceed the tubular reabsorption capability and result in proteinuria and glucosuria. As the uterus grows, it can cause partial ureteral obstruction and physiologic hydronephrosis, particularly in the late stages of gestation. The right side is more affected than the left, due to the cushioning of the left ureter by the sigmoid colon.[15]

Coagulation System

Thrombosis in pregnancy is related to two components of Virchow's triad—stasis and hypercoagulability. Stasis occurs as the uterus grows and compresses venous outflow; however, the risk of venous thromboembolic events is the same throughout all stages of pregnancy, suggesting that hypercoagulability is the more significant factor. Increased concentrations of clotting factors cause hypercoagulability in pregnancy and may protect the mother from hemorrhage at childbirth or miscarriage. Pregnant women are at higher risk of thromboembolic events, with a three- to fourfold increase in arterial thromboembolism and four- to fivefold increase in venous thromboembolism.[18] Of interest, deep venous thrombosis represents 80% and pulmonary embolus 20% of venous events. In pregnancy, deep venous thrombosis is more likely to be proximal, massive, and on the left.[18]

Gastrointestinal System

Nausea and vomiting are common in pregnancy. Gastric emptying is unchanged, but pregnant women are more susceptible to aspiration with anesthetics. Alterations in liver function tests include a mild generalized decrease of aspartate transaminase, alanine transaminase, γ-glutamyl transpeptidase, and bilirubin.[19] Alkaline phosphatase activity increases, particularly in the third trimester, whereas serum albumin concentration decreases throughout pregnancy due to hemodilution and can be as low as 3.0 g/dL in the third trimester. Total-body albumin, however, is elevated.[20] As the fetus grows, maternal nutrition needs to increase, so a pregnant patient who is to remain nil per os (NPO [nothing by mouth]) for an extended period of time should receive supplemental nutrition with a goal of 36 kcal/kg/d.[21]

INITIAL ASSESSMENT AND MANAGEMENT

The first priority in treating an injured pregnant patient is the mother. Early and aggressive maternal resuscitation directly correlates with improved fetal outcomes.[22] Fetal mortality increases with the severity of maternal injuries and is more likely after direct fetoplacental injury, maternal shock, pelvic fracture, maternal injury to the brain, or hypoxia.[15] Preterm delivery is a significant risk, and a fetus delivered before 23 weeks is generally considered not viable.

Prehospital Care

The initial assessment of the mother in the field should be the same as with any injured patient. The National Center for Injury Prevention and Control recommends that pregnant women over 20 weeks gestation be transported to a center capable of timely and thorough evaluation and initial management of potentially serious injuries.[23] Evaluation at a designated trauma hospital has been associated with a lower incidence of preterm labor, low birth weight, and meconium at delivery.[24] Supplemental oxygen should target a maternal Sao_2 of greater than 95% to prevent fetal hypoxia.[25] Small improvements in maternal oxygen saturation have a greater effect on the fetus due to fetal hemoglobin's higher affinity for oxygen. Fluids and/or blood products should be given liberally to compensate for blood loss, and during transport, woman who are more than 20 weeks gravid should have a wedge placed beneath their right side or the uterus should be manually displaced to the patient's left to alleviate caval compression. If injuries to the spine are suspected, the wedge can be placed beneath a carefully secured backboard, allowing spine precautions to be maintained while offloading the inferior vena cava.

Regional and institutional protocols may differ, but pregnant trauma patients with a viable fetus (≥23 weeks) and without life- or limb-threatening injuries may be considered for transport directly to a labor and delivery unit with a trauma or orthopedic consultation placed from there, as appropriate. Pregnant patients should be transferred to an emergency department or trauma unit when the severity of injury is unknown, the viability or gestational age of the fetus is unknown, or injuries are known to be severe, or if the mother shows signs of instability.[25]

Primary Survey

The primary survey is performed as for all trauma patients. Lower doses of succinylcholine are required during rapid sequence intubation due to the lower concentration of pseudocholinesterase during pregnancy.[26] Once the patient's breathing has been addressed, two large-bore intravenous catheters are placed. If central venous access is necessary, the femoral vessels should be avoided due to compression of the inferior vena cava by the uterus, which can alter the distribution of fluids and medications.[27] The relative hypervolemia of the mother may mask the clinical signs of shock as previously noted. Resuscitation should be started once intravenous access is secured. Rh-negative blood should be used exclusively until maternal blood typing has been completed. Vasopressors should be reserved only for instances of intractable hypotension unresponsive to aggressive volume resuscitation due to their deleterious effect on uteroplacental perfusion.[25]

Secondary Survey and Maternal Assessment

The secondary survey should begin with a thorough history and physical examination, including a complete obstetric and prenatal history. A history of preterm labor, placental abruption, or placental previa should be ascertained.

Obstetric consultation provides assistance with the evaluation of any fetus deemed potentially viable by gestational age. Urgent consultation is recommended in women greater than or equal to 23 weeks pregnant who present with uterine contractions, suspected placental abruption, or uterine rupture. Measuring fundal height allows estimation of gestational age, particularly when the mother is unresponsive. A discrepancy between the fundal height and known gestational age can also be a sign of uterine trauma, specifically uterine rupture or hemorrhage. The pelvic examination should include a speculum exam, especially if a pelvic fracture is suspected and vaginal bleeding or hematuria is present.[22] If vaginal bleeding is present, placenta previa should be excluded by an ultrasound examination prior to a manual or speculum exam.

X-rays should be ordered as in any trauma evaluation. The uterus is shielded when not being directly evaluated. The focused assessment with sonography for trauma (FAST) examination is a safe and efficient modality to evaluate for intra-abdominal fluid. In a retrospective cohort of more than 2300 FAST exams, the sensitivity and specificity for the detection of free fluid or intra-abdominal injury in pregnant and nonpregnant trauma patients were similar.[28] In addition, fetal ultrasound assesses activity, gestational age, fetal position, and placental location. Fig. 41-2 provides a useful algorithm summarizing the initial evaluation and management of the pregnant trauma patient.

Radiographic Evaluation

The choice of imaging in the pregnant trauma patient should be similar to the nonpregnant patient if life-threatening injuries are suspected. The risk of a missed injury or delayed diagnosis in the fetus is much greater than the risk of radiation. As noted, FAST is a useful tool in the early evaluation of the mother and fetus but has limitations. Computed tomography (CT) remains the mainstay for evaluation of trauma patients and should be used if clinically indicated in the pregnant patient. Effort should be made to decrease unnecessary scans, reduce the overlap of body sections, and avoid multiple passes when possible.[29] Low-dose protocols often give little diagnostic information and should be avoided.

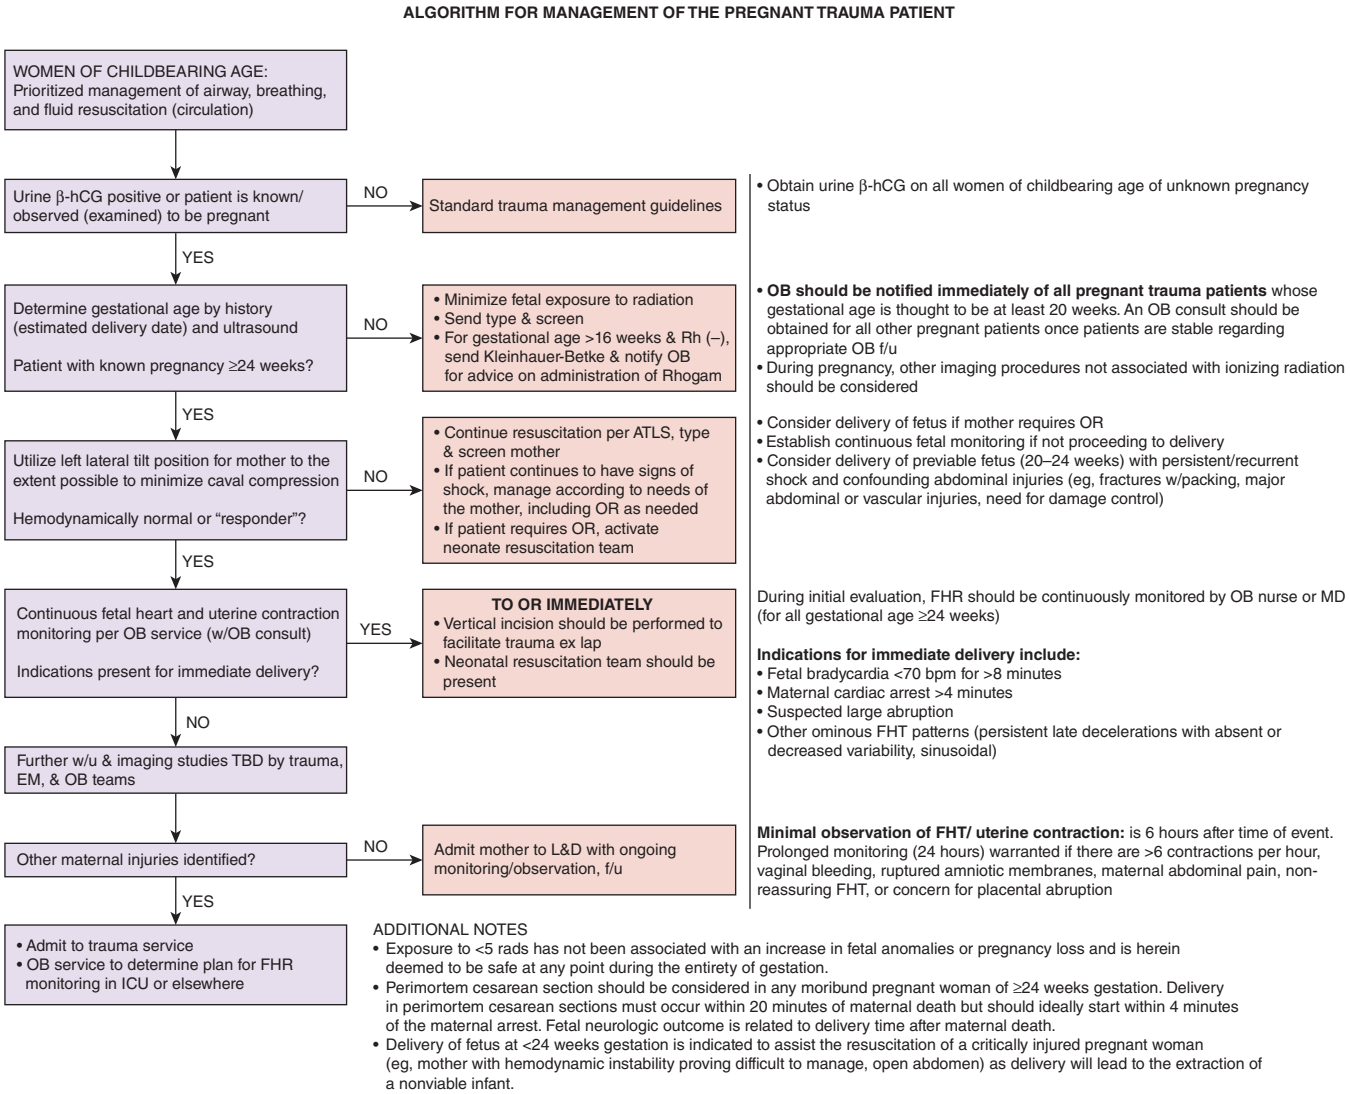

FIGURE 41-2 Algorithm for the management of the pregnant trauma patient. ATLS, Advanced Trauma Life Support; EM, emergency medicine; ex lap, exploratory laparotomy; FHR, fetal heart rate; FHT, fetal heart tone; f/u, follow-up; hCG, human chorionic gonadotropin; ICU, intensive care unit; L&D, labor and delivery; OB, obstetrician; OR, operating room; TBD, to be determined; w/u, workup.

Fetal risks from ionizing radiation include developmental delay, small head size, organ malformations, cancer, and death.[30] The average background radiation that a fetus is exposed to over 9 months of gestation is approximately 1 mGy (0.1 rad). Table 41-2 shows the estimated radiation exposure to the fetus during many common radiographic procedures used to assess injured patients. As expected, radiation exposure increases substantially when the fetus is in the field of view. Radiation dose and gestational age are the two main variables in the risk assessment of the fetus. Data from survivors of the atomic bomb blasts indicate that the risk is greatest between 8 and 15 weeks gestation, the period of fetal organogenesis and neuronal development.[31] There is no proven risk when less than 8 weeks or greater than 25 weeks gestation. Guidelines from the American College of Obstetricians and Gynecologists (ACOG) for imaging during pregnancy and lactation emphasize that exposure to less than 5 rad (50 mGy) has not been associated with fetal abnormalities or pregnancy loss. The complete guidelines are shown in Table 41-3. Radiation exposure is similar whether using 16-slice or 64-slice CT scanners.[32]

EVALUATION OF THE FETAL-PLACENTAL UNIT

Fetal death after maternal trauma results from direct fetal injury, placental abruption, maternal hypotension leading to fetal malperfusion, or trauma-induced preterm delivery. Findings on clinical examination that should raise concern of fetal-placental injury include vaginal bleeding, ruptured membranes, a bulging perineum, presence of contractions, and an abnormal fetal heart rate or rhythm. Vaginal bleeding

TABLE 41-2: Estimated Fetal Exposure from Common Radiologic Procedures

Procedure	Fetal exposure
Chest XR (AP and lateral)	0.00002–0.00007 rad[a]
Abdominal XR (single AP view)	0.1 rad[a]
Pelvis XR (single AP view)	0.25–1.5 rad[a]
Hip XR (single view)	0.2 rad[a]
Complete spine XR series	0.37rad[a]
CT pulmonary angiogram	0.003–0.022 rad[b]
CT abdomen/pelvis	0.47–0.55 rad[b]
CT trauma protocol (head, neck, chest, abdomen, pelvis)	1.01–1.12 rad[b]

AP, anteroposterior; CT, computed tomography; XR, x-ray.

is abnormal before labor and can indicate placental abruption, early labor, premature cervical dilation, or placenta previa, where the placenta's position covers a portion of the cervical os. Rupture of the amniotic sac should be suspected when there is cloudy white or green discharge, which increases the risk of infection. A ruptured amniotic sac can also lead to prolapse of the umbilical cord, which is an obstetric emergency requiring immediate cesarean section.

TABLE 41-3: American College of Obstetricians and Gynecologists Guidelines for Diagnostic Imaging During Pregnancy and Lactation

- Ultrasonography and magnetic resonance imaging (MRI) are not associated with risk and are the imaging techniques of choice for the pregnant patient, but they should be used prudently and only when use is expected to answer a relevant clinical question or otherwise provide medical benefit to the patient.
- With few exceptions, radiation exposure through radiography, computed tomography (CT) scan, or nuclear medicine imaging techniques is at a dose much lower than the exposure associated with fetal harm. If these techniques are necessary in addition to ultrasonography or MRI or are more readily available for the diagnosis in question, they should not be withheld from a pregnant patient.
- The use of gadolinium contrast with MRI should be limited; it may be used as a contrast agent in a pregnant woman only if it significantly improves diagnostic performance and is expected to improve fetal or maternal outcome.
- Breastfeeding should not be interrupted after gadolinium administration.

Fetomaternal Hemorrhage

Suspicion of blunt uterine trauma raises concern for transmission of fetal hemoglobin into the maternal circulation. This poses significant risk in Rh-negative mothers who may then form antibodies to the red blood cells of present and future pregnancies. The Kleihauer-Betke (KB) test is used to detect the presence of fetal blood in maternal circulation. Acid is placed on a maternal blood smear to dissolve adult hemoglobin, but fetal hemoglobin, if present, persists and can be quantified. A 300-mcg dose of Rh immune globulin should be administered for every 30 mL of fetal blood estimated in maternal circulation and should be administered within 72 hours of the time of injury.

At least one study has challenged the utility of KB testing in trauma, citing higher rates of positive tests in low-risk pregnancies compared to a population of pregnant trauma patients.[33] Still, the most current recommendations from the Eastern Association for the Surgery of Trauma (EAST) support routine KB testing for all pregnant trauma patients greater than 12 weeks gestation, regardless of Rh status.[34] Some institutions elect to give a 300-mcg dose of Rh immune globulin to all Rh-negative pregnant trauma patients and add additional doses if indicated based on KB test results. ACOG, however, cites that the principal utility of the KB test is in its ability to restrict the use of Rh immune globulin to only those mothers who need it and to identify patients for whom a single 300-mcg dose is insufficient.[35]

Fetal Monitoring/Nonstress Testing

Fetal heart tones can be detected as early as 12 weeks of gestation and are normally between 110 and 160 bpm. Initially, fetal hypoxia manifests as tachycardia, but as the arterial oxygen content decreases, the fetus becomes bradycardic and any rate less than 120 bpm should be recognized as fetal distress. EAST recommends at least 6 hours of fetal heart monitoring for all pregnant trauma patients greater than 20 weeks gestation.[34] Fetal bradycardia or prolonged or late heart rate decelerations during nonstress testing should prompt a trial of resuscitative measures including intravenous fluids, oxygen supplementation, and maternal repositioning. Failure of such interventions to resolve fetal stress should prompt consideration of fetal-placental injury and the possible need for emergent obstetrical intervention. All trauma patients greater than or equal to 23 weeks pregnant who have been observed for at least 6 hours after injury should undergo a formal obstetrical ultrasound prior to discharge.

Placental Abruption

Placental abruption occurs when the relatively inelastic placenta separates from the elastic uterine myometrium, compromising oxygen transfer to the fetus. Clinical examination is often unreliable in diagnosing placental abruption, and vaginal bleeding is present in only 35% of patients.[36] Placental

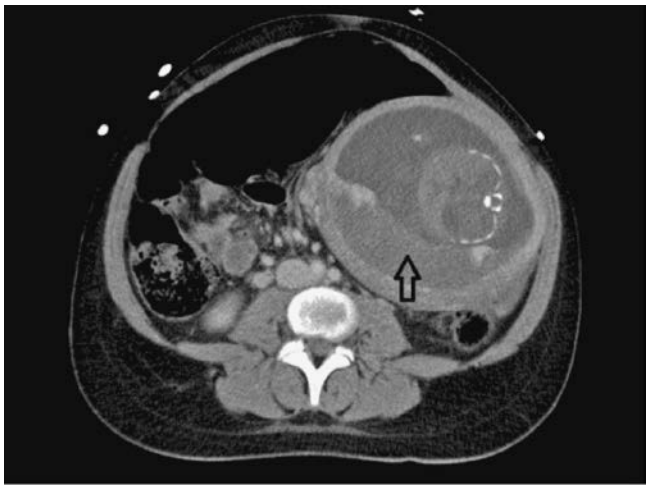

FIGURE 41-3 Example of placental abruption on computed tomography.

abruption may not present until as many as 24 hours after injury but is typically accompanied by at least one contraction every 10 minutes within 4 hours of presentation.[3,37] Monitoring of patients without such contractions can be limited to 6 hours, but should continue for a minimum of 24 hours if frequent contractions, vaginal bleeding, ruptured amniotic membranes, maternal abdominal pain, or nonreassuring fetal heart rate patterns are present. CT is a reliable means of diagnosing and grading placental abruption and should be considered in pregnant patients with abdominal ecchymoses, pain, or tenderness.[38] Fig. 41-3 shows an example of placental abruption on CT. One study in pregnant trauma patients suggested that emergent delivery at the first sign of fetal distress improved fetal outcomes in third-trimester mothers with 50% or less placental surface area contrast enhancement on CT, indicating moderate to severe placental abruption.[39]

MANAGEMENT OF SPECIFIC INJURIES DURING PREGNANCY

Thoracic Trauma

Injuries to the thorax are treated the same in pregnant and nonpregnant patients. It is important to remember that the gravid uterus elevates the diaphragm approximately 4 cm when performing procedures such as a tube thoracostomy. The insertion point for a chest tube should be one to two rib spaces above the usual fifth intercostal space.[22]

Blunt Abdominal Trauma

Similar to thoracic injuries, blunt abdominal injuries are treated the same in pregnant patients as in nonpregnant patients. The primary focus should be on the evaluation and rapid treatment of the mother because maternal shock is associated with an 80% fetal mortality.[5] Injury to a solid organ can be safely observed if the mother remains hemodynamically stable; however, if signs of shock or infection develop, early operative intervention is indicated, as a delay in treatment leads to worse fetal outcomes.

The most devastating fetal injuries following blunt trauma include placental abruption and uterine rupture. Abruption is thought to complicate 1% to 6% of minor injuries and up to 50% of major injuries.[3,15] Uterine rupture is rare, occurring in less than 1% of pregnant trauma patients, and is usually associated with direct impact with substantial force.[15] A previously scarred uterus is more likely to rupture, and the risk increases with gestational age as the uterus grows and becomes an abdominal organ. The increased blood flow that accompanies advanced pregnancy makes rupture a severe complication, which can lead to extensive hemorrhage.[22] The extent of uterine damage is typically not apparent clinically and must be evaluated with operative exploration. Injuries to the skull and brain of the fetus are uncommon but are more likely to occur if there is a maternal pelvic fracture and when the fetal head is engaged within the pelvis.

Orthopedic Trauma

Maternal orthopedic injuries are common, and one study found that 6% of 1067 pregnant women had an orthopedic injury, and this led to an increased risk of preterm birth, placental abruption, and fetal mortality.[40]

Pelvic Fractures

A pelvic fracture is the most common maternal injury that results in fetal death. In a study of 101 pregnant women with pelvic fractures, the fetal mortality rate was 35%.[41] Causes of death included direct fetal injury (20%), placental abruption (32%), and maternal shock (36%). Maternal mortality in the same study was 9% as dilated retroperitoneal vessels place the mother at high risk of bleeding from pelvic fractures. Angiography and embolization of these bleeding vessels often deliver a higher dose of radiation than is usually considered safe, and these women should be counseled on the risk. Operative fixation of both pelvic and acetabular fractures is generally considered safe during pregnancy. Most women can safely attempt vaginal delivery after a pelvic fracture, even in the third trimester. Relative indications for a cesarean delivery include fractures of the pubic rami adjacent to the urethra or bladder, severe lateral compression fractures, and acute fractures of the pelvis with marked displacement.[41]

Penetrating Injuries

In contrast to blunt trauma, maternal mortality is more favorable after penetrating injury as the gravid uterus protects the mother's vital organs from injury.[42] Conversely, fetal mortality is increased and has been reported to be as high as 73%.[43] The thick uterus, however, provides protection to the mother and fetus from low-velocity stab injuries. Although

gunshot wounds to the uterus are much more likely to cause fetal injury, visceral injuries are less likely when the entry site is anterior and below the uterine fundus.[44] Potential abdominal injuries from thoracoabdominal wounds should be suspected at a higher level than normal given displacement by the uterus. Exploration should be considered for any gunshot or stab wound to the upper abdomen, particularly because peritoneal irritation is blunted during pregnancy.[15] Diagnostic laparoscopy is reasonable in the hemodynamically stable patient.

Neurologic Injuries

A moderate or severe traumatic brain injury is associated with an adverse fetal outcome. Ikossi et al[45] found that a Glasgow Coma Scale score less than or equal to 8 was a significant risk factor for death of the fetus. The range of hyperventilation used for traumatic brain injury should be decreased in a pregnant patient because this causes a mechanical reduction in venous return and, therefore, cardiac output, which can have negative effects on the fetus. Hypothermia and mannitol should also be avoided, but the use of hypertonic saline has no known deleterious effects.[46]

Thermal Injuries

Burn injury in the pregnant patient presents a unique management challenge because it causes increased capillary permeability and can lead to rapid fluid loss and hypovolemia. Fetal survival is dependent on fetal age and the extent of maternal injury. It is estimated that once the total body surface area of a burn exceeds 40%, the risk of mortality for the mother and fetus approaches 100%.[47] Early delivery is recommended in the third trimester if the mother has extensive burns.[48]

Wound care in the pregnant patient should limit the use of silver sulfadiazine because it can potentially cause kernicterus in the newborn; however, one author has shown successful use without any adverse effects.[49]

Preparing for the Operating Room

If operative intervention is indicated, it is crucial to operate immediately because a delay in treatment puts the fetus further at risk. Fetal viability should be documented using fetal heart tones or ultrasound pre- and postoperatively, and on-site obstetric consultation is recommended. Intubation can be difficult in the pregnant patient due to physiologic oropharyngeal edema, and inhalation anesthesia has a more rapid onset in pregnant patients, requiring an adjustment in dose.

Presently, there are no conclusive data or expert recommendations regarding the use of tranexamic acid (TXA) for traumatic hemorrhage in pregnant patients. TXA is classified as a pregnancy category B drug. Although a 2011 meta-analysis indicated its use was associated with less blood loss following vaginal and cesarean section deliveries and reduction in postpartum blood transfusion requirements, its safety and efficacy have not been examined in the pregnant trauma population. The CRASH-2 trial did not specifically exclude pregnant patients; however, the study design left the decision of TXA administration to the discretion of prescribing physicians. Females composed only 16% of the study population, and no mention of pregnancy status was included in the study's analysis.[50] A 1993 retrospective study of 256 patients treated with TXA for a bleeding disorder during pregnancy demonstrated no increased risk of thromboembolic complications compared to an untreated cohort of pregnant patients with similar bleeding disorders.[51]

During a laparotomy for trauma, the goals should be the same as in a nonpregnant patient—control of hemorrhage and contamination. The uterus should be retracted inferiorly while exploring the other abdominal organs. Once completed, the uterus is thoroughly inspected for any injuries, particularly in the setting of penetrating trauma. Small lacerations to the uterus can be repaired with chromic sutures. If the laceration extends into the uterus and the fetus is at a survivable age, then a cesarean delivery should be performed. Such delivery can also be considered if the gravid uterus prevents adequate exploration of the mother. After significant blunt trauma, a uterine rupture may occur. Attempts should be made to repair the uterus primarily if possible, but if there is extensive uterine damage or hemorrhage cannot be controlled, hysterectomy should be performed. Fetal survival after extensive uterine damage is rare.[22] An injury to the gastrointestinal tract increases the risk of loss of the pregnancy, and the abdomen should be irrigated extensively in addition to the administration of perioperative antibiotics.[22]

Cesarean Section Following Injury

Indications for cesarean delivery after trauma are vague and must be made on an individual basis. The three possible goals when a caesarean section is indicated include save the mother, save both the mother and child, and save only the child. Cesarean section prior to 23 weeks usually results in fetal death and should only be done to allow successful resuscitation of the mother.[37] After 23 weeks, cesarean section should be performed if fetal distress outweighs the risk of prematurity or if the uterus prevents repair of maternal injuries during laparotomy.[52] A cesarean delivery is not automatically indicated with exploratory laparotomy for trauma, but it is important to have the obstetrical team available for any unforeseen problems.

Cardiopulmonary Resuscitation in Pregnancy

The America Heart Association (AHA) recommends four key interventions to prevent a possible cardiopulmonary arrest in the critically injured pregnant patient as follows: (1) place the patient in full left lateral position to relieve aortocaval compression; (2) give 100% oxygen; (3) establish intravenous catheter access above the diaphragm; and (4) assess for hypotension, defined as systolic blood pressure less than 100 mm Hg, which

reduces placental perfusion.[53] If cardiopulmonary resuscitation (CPR) is required, the mother should be taken out of a left lateral tilt because this reduces the efficacy of chest compressions.[22] To relieve aortocaval compression, manual left lateral and upward displacement of the uterus can be done by a member of the treating team. Chest compressions should be performed slightly higher than normal due to the upward displacement of the thoracic and abdominal structures by the uterus.[54] In one retrospective study, three of seven pregnant patients who achieved return of spontaneous circulation following CPR sustained hepatic lacerations that required surgical or endovascular intervention.[55] The rate of compressions and the use of defibrillation and cardiac medications remain unchanged from the recommendations in a nonpregnant patient.

The AHA and ACOG both recommend cesarean delivery be considered within 4 minutes of maternal cardiopulmonary collapse if there is no return of spontaneous circulation.[52,56,57] Delivery within 5 minutes in women beyond 20 weeks is encouraged in order to facilitate maternal resuscitation. This recommendation is based on the assumption that the compression of the vena cava and aorta by the gravid uterus may interfere with maternal hemodynamics. In one case review, 12 of 18 patients had sudden and often profound improvement in hemodynamic status with return of blood pressure and pulse immediately after a cesarean delivery,[58] changing the concept of delivery from a postmortem cesarean to perimortem cesarean. The 4-minute time frame advocated for postmortem cesarean delivery is often unmet, yet neonatal survival is still likely if delivery occurs within 10 or even 15 minutes of arrest.[57] Earlier cesarean delivery theoretically benefits both mother and neonate by minimizing ischemic neurologic damage.

Emergency cesarean delivery should be performed at the location of arrest. Time should not be taken to check for fetal viability or to move to an operating room. CPR should continue during the procedure in case maternal circulation is restored. Gestational age can quickly be estimated, as the uterine fundus should be two finger breadths above the umbilicus at 24 weeks.[59] To perform delivery, a large midline skin incision from xiphoid to pubis is made, and the uterus is opened with a vertical incision through the upper portion. The surgeon should then place his or her hand between the fetal head and pubic symphysis to deliver the baby and placenta.[15] The uterus should be closed with a single layer of running chromic suture followed by quick closure of the fascia. CPR should continue well after the procedure, and if successful, the mother should be transported to the intensive care unit for recovery. A summary of the guidelines for perimortem cesarean section is provided in Table 41-4.

TABLE 41-4: Predictors of Successful Fetal Outcome Following Postmortem Cesarean Section

1. Duration of gestation.
   Fetal viability generally is defined as 26–28 weeks gestation. This corresponds to a fundal height of approximately 26–28 cm above the pubis and/or uterus, halfway between the umbilicus and costal margin. At this age, the fetus, under optimal conditions, has a 40%–70% estimated chance of survival without major handicap; therefore, cesarean section is indicated shortly after maternal death.
2. Time between maternal death and delivery.
   <5 min, excellent
   5–10 min, good
   10–15 min, fair
   15–20 min, poor
   20–25 min, unlikely

Procedure

1. Establish viability.
2. Complete the CPR sequence.
3. Make a vertical midline incision through the abdominal layers into the uterus.
4. Remove the fetus from the uterine cavity, clamp the cord, and hand the neonate to appropriate personnel for resuscitation.
5. Remove the placenta.
6. Continue CPR and assess for maternal signs of life; maternal survival is still possible after the uterus has been emptied and the supine hypotension syndrome has been resolved.

CPR, cardiopulmonary resuscitation.

INTIMATE PARTNER VIOLENCE IN PREGNANCY

Intimate partner violence (IPV) is the most common form of intentional trauma in pregnancy and poses a significant risk to both the mother and fetus. ACOG believes that reported rates of IPV during pregnancy do not reflect the magnitude of the problem in our society.[60] Voluntarily reported rates of IPV may be as low as 3.2%,[61] but other estimates range as high as 28%.[62] Risk factors associated with IPV include maternal or intimate partner substance abuse, low socioeconomic status, low maternal education level, unintended pregnancy, history of domestic violence prior to pregnancy, history of witnessed violence as a child, and unmarried status.[44] The National Violent Death Reporting System demonstrates that 54.3% of pregnancy-associated suicides and 45.3% of pregnancy-associated homicides were directly attributable to IPV.[63]

A comprehensive meta-analysis on the impact of IPV on adverse infant outcomes identified twice the rate of preterm birth and low birth weight and a nearly 40% increased risk that a baby would be born small for gestational age.[64]

The prevalence of domestic violence involving pregnant women that results in serious injury has been estimated to be between 10% and 30%.[65] The abdomen is the most common target associated with assault, increasing the likelihood of an intra-abdominal injury and fetal morbidity and mortality. Women who deliver during a hospitalization for assault are at higher risk for preterm birth, maternal death, fetal death, and

TABLE 41-5: Sample Intimate Partner Violence Screening Questions

While providing privacy, screen for intimate partner violence during new patient visits, annual examinations, initial prenatal visits, each trimester of pregnancy, and the postpartum checkup.

Framing Statement

"We've started talking to all of our patients about safe and healthy relationships because it can have such a large impact on your health."*

Confidentiality

"Before we get started, I want you to know that everything here is confidential, meaning that I won't talk to anyone else about what is said unless you tell me that…(insert the laws in your state about what is necessary to disclose)."*

Sample Questions

"Has your current partner ever threatened you or made you feel afraid?"

(Threatened to hurt you or your children if you did or did not do something, controlled who you talked to or where you went, or gone into rages)†

"Has your partner ever hit, choked, or physically hurt you?"

("Hurt" includes being hit, slapped, kicked, bitten, pushed, or shoved.)†

For women of reproductive age:

"Has your partner ever forced you to do something sexually that you did not want to do, or refused your request to use condoms?"*

"Does your partner support your decision about when or if you want to become pregnant?"*

"Has your partner ever tampered with your birth control or tried to get you pregnant when you didn't want to be?"*

For women with disabilities:

"Has your partner prevented you from using a wheelchair, cane, respirator, or other assistive device?"‡

"Has your partner refused to help you with an important personal need such as taking your medicine, getting to the bathroom, getting out of bed, bathing, getting dressed, or getting food or drink or threatened not to help you with these personal needs?"‡

uterine rupture, whereas those who are discharged and deliver during a subsequent hospitalization remain at increased risk for placental abruption and hemorrhage compared to mothers with no history of having been assaulted.[66]

The impact of IPV persists long beyond delivery for both mother and child. Nearly half of mothers subjected to IPV during pregnancy meet criteria for postpartum depression.[67] Adverse effects of IPV may persist for years and could preclude effective parenting. IPV victims are at risk for functional disorders such as irritable bowel syndrome, fibromyalgia, and chronic pain syndromes, as well as psychosocial issues such as substance abuse, eating and sleeping disorders, physical inactivity, poor self-esteem, and posttraumatic stress disorder.[68] Mothers who suffer IPV during pregnancy remain at risk of homicide for up to 24 months after delivery compared to the general population.[69]

Victims of IPV are at risk for delayed and inadequate perinatal care, and the interaction with medical providers during a presentation for trauma offers a fleeting opportunity to engage expectant mothers in initiating and continuing appropriate care during pregnancy. ACOG recommends universal screening of all pregnant women regarding IPV, and any pregnant woman who presents with a vague or suspicious history of trauma should raise a concern for assault.[70] Warning signs include frequent office or emergency department visits, depression, substance abuse, discrepancy between injuries and given history, and a partner's insistence on being present for the interview and examination.[12] A guide for IPV screening is provided in Table 41-5.[70]

Trauma Damage Control

Chad G. Ball • David V. Feliciano

KEY POINTS

- *Damage control* is a US Navy term defined as the "capacity of a ship to absorb damage and maintain mission integrity."
- An abbreviated laparotomy with diffuse intra-abdominal packing in patients with significant intra-abdominal injuries and an intraoperative coagulopathy was first described by H. Harlan Stone, MD, at Grady Memorial Hospital, Atlanta, Georgia, in 1983.
- In the modern era, agreed-upon indications for a damage control laparotomy include temperature less than 34°C; arterial pH less than 7.2; an international normalized ratio, prothrombin time, or partial thromboplastin time greater than 1.5 times normal; or a clinically observed coagulopathy in the pre- or intraoperative setting.
- The early coagulopathy of trauma, as demonstrated on laboratory testing, is present upon admission in over 25% of injured patients with a base deficit greater than –6.
- Examples of thoracic damage control include cross-clamping the hilum, a hilar twist after division of the inferior pulmonary ligament, and pulmonotomy with selective vascular ligation.
- Examples of abdominal damage control include perihepatic packing, suture repair and packing of grade I or II splenic injuries, and Whipple procedure or distal pancreatectomy delayed to reoperation.
- Examples of vascular damage control anywhere in the body include insertion of temporary intraluminal shunts, ligation of selected major veins, and early fasciotomy in high-risk patients with injuries to the extremities.
- Abdominal compartment syndrome is defined as a sustained intra-abdominal pressure greater than 20 mm Hg that is associated with new organ dysfunction or failure.
- The temporary silo over open abdomen technique was initially described by Oswaldo Borraez G. at the San Juan de Dios Hospital in Bogota, Colombia, in 1984.
- Indications for an emergent return to the operating room after a damage control laparotomy performed in a patient with blunt trauma include a normothermic patient who is bleeding greater than 2 units of packed red blood cells per hour or the development of an abdominal compartment syndrome with ongoing blood loss.
- Maintenance of the peritoneal domain and prevention of adherence of the viscera to the underside of the abdominal wall are critical to allow progressive closure of the linea alba after an open abdomen.

HISTORY AND DEFINITION

Damage control is a US Navy term defined as "the capacity of a ship to absorb damage and maintain mission integrity."[1] When applied to surgery and critically ill patients, abdominal damage control surgery (DCS) incorporates fundamental tenets that include the following: (1) stopping surgical hemorrhage; (2) controlling gastrointestinal spillage; (3) inserting surgical packs; and (4) applying a temporary abdominal closure. This truncated operation is then followed by immediate transfer to the intensive care unit with subsequent rewarming, hemodynamic stabilization, correction of coagulopathy, and general supportive care for stunned organs. A return to the operating room then occurs 6 to 48 hours later for definitive repairs, exploration for missed injuries, insertion of a feeding tube, and primary fascial closure, if possible. In essence, a typical operative sequence is interrupted by completing only the most crucial aspects during the first operation.

The history of the innovation of DCS mirrors that of the history of trauma surgery in general (Table 42-1). The DCS concept represents one of the most significant innovations in the history of surgery and has now influenced the practices of a large number of surgical subspecialties and radiology.[2] DCS was first initiated due to a growing appreciation from the surgical community in the 1970s to 1990s that major

Era 4: 1990s–2018: Assessment of damage control techniques	

definitive operations were often futile after injured patients developed hypothermia, metabolic acidosis, and a coagulopathy. In addition, rapid conservative operative techniques were associated with improved outcomes in select major trauma patients. Although the adaption of the contemporary *damage control* term to the field of traumatology can be specifically credited to Rotondo, Schwab, McGonigal, and colleagues from the University of Pennsylvania in 1993,[3] its dominant principles are more accurately rooted in the 1975 presentation to the American Association for the Surgery of Trauma by Drs. Charles E. Lucas and Anna Ledgerwood.[4] More directly, they expanded on Pringle's 1908 report of perihepatic packing by describing a small series of patients who underwent laparotomy pad packing of major hepatic injuries.[4] Although many surgeons in the early 20th century placed packs directly into hepatic tears to facilitate hemostasis (sometimes with the parenchyma loosely approximated over top in order to create a "tampon"), this updated technique involved reconstituting the liver as a solid structure by packing around the organ in a compressive fashion. This concept was reiterated shortly thereafter by Calne et al,[5] as well as Feliciano et al in 1981[6] and 1986.[7] Despite these small series outlining the success of perihepatic packing, the visionary extrapolation of this principle to patients with multiple concurrent life-threatening injuries and major coagulopathy was not published until 1983.[8] At that time, Harlan Stone retrospectively described 31 injured patients who developed major bleeding diatheses during an emergency laparotomy at Grady Memorial Hospital in Atlanta, Georgia.[8] Of these, 17 patients were managed with damage control principles of arresting surgical hemorrhage and abbreviating the operative intervention. This led to the survival of 11 patients who were predicted to have a lethal coagulopathy. Once DCS was born, it was quickly marketed into other disciplines that included, but were not limited to, neck,[9] vascular,[10] orthopedic,[11] thoracic,[12] and military injuries[13] because it was clear that the DCS approach leads to improved survival in patients who are approaching intraoperative physiologic exhaustion after sustaining blunt and penetrating injures.[14]

INDICATIONS FOR DAMAGE CONTROL

Despite its obvious utility, the widespread propagation of DCS throughout the trauma community has led to overutilization of the technique. More specifically, multiply injured patients who are *not* approaching physiologic exhaustion are not uncommonly exposed to the potential risks associated with an open abdomen and the DCS process. As a result, the pertinent question remains: Who truly requires DCS? The succinct response is: a patient who is more likely to die from an uncorrected shock state than from failure to complete organ repairs. Depending on the center, these "metabolic cripples" encompass 3% to 8% of all *severely* injured patients (penetrating vs blunt; military vs civilian). In essence, they continue to suffer the sequelae of tissue shock that is manifest as *persistent* hypothermia, *persistent* metabolic acidosis, and nonmechanical (ie, nonsurgical) bleeding. Although this description appears straightforward, opinions regarding the specific indications for DCS remain debated across both global trauma centers (Table 42-2) and an assorted quality of peer-reviewed literature.[15] Further, clinical recognition of these patients based on prehospital reports or on initial glance upon arrival in the trauma bay is notoriously inaccurate.[15] The DCS triggers with most agreement, however, include core temperature less than 34°C, arterial pH less than 7.2, and laboratory-confirmed (international normalized ratio, prothrombin time, and/or partial thromboplastin time >1.5 times normal) or clinically observed coagulopathy in the pre- or intraoperative setting. Other triggers include the administration of greater than 10 units of packed red blood cells (RBCs), requirement for a resuscitative thoracotomy in the emergency department, or identification of a juxtahepatic venous injury or devascularized or destroyed pancreas, duodenum, or pancreaticoduodenal complex during operation.[15] It must be emphasized, however, that not all patients with initial physiologic deficits will need DCS. With rapid arrest of hemorrhage, as well as ongoing resuscitation, some patients will dramatically improve in all parameters on repeated intraoperative blood gases and evaluations. In other words, patients with *unresolved* metabolic failure despite the arrest of hemorrhage via suture, resection, or packing remain our primary targets for DCS. In addition, it should be stated that patients with multiple intra-abdominal injuries do not always develop metabolic failure.

The natural extension of DCS has been damage control *resuscitation* (DCR). This concept includes DCS, but also the early transfusion of blood products, reduced administration

TABLE 42-2: Published Candidate Indications for Use of Damage Control Surgery in Adult Civilian Trauma Patients Who Were Rated to be Appropriate by the Majority of Respondents

Indication
Degree of physiologic insult in the pre- or intraoperative setting
Persistent systolic BP <90 mm Hg or a successfully resuscitated cardiac arrest during transport to hospital
Persistent systolic BP <90 mm Hg in the preoperative setting or during operation
Preoperative core body temperature <34°C, arterial pH <7.2, or INR/PT >1.5 times normal (with or without a concomitant PTT >1.5 times normal)
Core body temperature <34°C and arterial pH <7.2 at the beginning of operation
Persistent core body temperature <34°C or persistent arterial pH <7.2 during operation
INR/PT and PTT >1.5 times normal during operation
Clinically observed coagulopathy during operation
Core body temperature <34°, arterial pH <7.2, and laboratory-confirmed (INR/PT and/or PTT >1.5 times normal) or clinically observed coagulopathy in the preoperative setting, at the beginning of operation, or during the conduct of operation
Estimated blood loss and amount or type of resuscitation provided
Estimated blood loss >4 L in the operating room
>10 units of PRBCs were administered to the patient in the preoperative or preoperative and intraoperative settings
Injury pattern identified during operation
An expanding and difficult-to-access pelvic hematoma
A juxtahepatic venous injury
An abdominal vascular injury and at least one major associated abdominal solid or hollow organ injury
A proximal (ie, Fullen zone I or II) superior mesenteric artery injury
Devascularization or destruction of the pancreas, duodenum, or pancreaticoduodenal complex with involvement of the ampulla/proximal pancreatic duct and/or distal CBD
Multiple blunt or penetrating injuries spanning across more than one anatomic region or body cavity that each require surgery with or without angioembolization

BP, blood pressure; CBD, common bile duct; INR, international normalized ratio; PRBC, packed red blood cell; PT, prothrombin time; PTT, partial thromboplastin time.

of crystalloid fluids, permissive hypotension in selected populations, and immediate control of hemorrhage (whether operative or angiographic). In summary, DCR is a structured, mobile intervention that can be delivered to a critically ill patient in any location (emergency department, interventional radiology suite, operating room, and/or intensive care unit). Basic principles include arresting hemorrhage, restoring blood volume, and correcting hypothermia, acidosis, and coagulopathy.

MASSIVE TRANSFUSION

Although the traditional definition of a massive transfusion is 10 or more units of packed RBCs within a 24-hour period, this has been modified with regard to both the amount of blood products and the associated time interval.[16-18] The 3% and 8% of civilian and military casualties, respectively, who require a massive transfusion have high mortality rates as well (27%–51%).[18] Furthermore, the early coagulopathy of trauma as demonstrated on laboratory testing is a well-recognized entity that is present upon admission in over 25% of injured patients with a base deficit greater than –6.[19] In addition, although coagulopathy was historically viewed as a byproduct of resuscitation, hemodilution, and hypothermia (Table 42-3), the "bloody vicious cycle" is now understood to be significantly more complex.[20] Tissue trauma, shock, hemodilution, hypothermia, acidemia, and inflammation all play key trigger roles in the acute coagulopathy of trauma shock.[19] The improved understanding of interrelationships and recognition of these six key initiators of a coagulopathy support the modern use of massive transfusion protocols (MTPs). In brief, a modern MTP aims to approximate delivery of close to a 1:1:1 ratio of RBCs to fresh frozen plasma to platelets.[20] By addressing the early coagulopathy of trauma, MTPs have been shown to improve mortality in multiply injured populations.[21,22] Although the specific structure of MTPs varies slightly from center to center, they are all approximations of the late George Sheldon's fresh whole blood resuscitation principles from 1975.[22,23] It should also be noted that reasonable scientific concern remains with regard to the apparent improvement in survival associated with MTPs.[24] The possibility of a strong survival bias (ie, surviving long enough to receive the most RBC units) is significant.[24]

Additional benefits of a formal MTP include earlier administration of blood products during resuscitation, improved efficiency of blood banking, decreased utilization of total blood products during a hospital stay, and significant economic savings.[25] Another major benefit is avoiding excess administration of crystalloid fluids.[26,27] This reduction in crystalloid volume during resuscitation minimizes multiple associated

TABLE 42-3: Maneuvers to Prevent or Reverse Hypothermia During Damage Control Operations

Increase operating room temperature to >85°F (29.4°C)
Infuse blood products through a warming device such as a Level 1 fluid warmer
Cover patient's head with a turban or warming device
Cover body parts out of the operative field with a warming device
Employ a heated mattress pad underneath the patient
Irrigate nasogastric and thoracostomy tubes with warm saline during laparotomy
Irrigate open pericardial cavity, pleural cavities, and peritoneal cavity during simultaneous sternotomy or thoracotomy and laparotomy

side effects, including reperfusion injury, increased leukocyte adhesion and inflammation, associated acidosis, and resultant acute respiratory distress syndrome, systemic inflammatory response syndrome, and multiorgan failure.[26-29] In addition, excess administration of crystalloid fluids continues to be an obstacle to obtaining early definitive fascial closure secondary to edema of the abdominal viscera and wall.[30,31]

Interestingly, the evolution of MTP and DCR now appears to be focused upon individual variances between patients in regard to their precise responses to a significant injury. More specifically, using various point-of-care measures such as thromboelastography will assist in providing a significantly more granular analysis of which resuscitation factors a given critically injured patient requires. This would include both the type and amount of a given blood product, in addition to the immediate response to a particular intervention.

In summary, if the initiation of an MTP is accurately based on rapid recognition of physiologic exhaustion secondary to persistent hemorrhage, then it also typically acts as a trigger for the entire damage control process. It must be reemphasized, however, that some severely injured patients will improve dramatically with an MTP and reverse their physiologic derangements to an extent that allows the surgeon to complete operative repairs and closure of the abdominal incision at the first operation.

THORACIC DAMAGE CONTROL TECHNIQUES

Lung (See Chapter 28)

Exsanguinating hemorrhage from the lung is most rapidly controlled by the application of a DeBakey aortic clamp to the hilum.[32] Similarly, a Duval lung clamp is an excellent instrument for more peripheral and readily visible hemorrhage. Another technique that may be helpful in either the emergency department or the operating room includes twisting the hilum after division of the inferior pulmonary ligament to kink the major hilar vessels. This technique is rarely used when manual hand/finger or clamp control works. It is also challenging given the anatomic limitations associated with the inferior pulmonary ligament.

When the site of the blood loss has been a stab wound deep into the pulmonary parenchyma or a gunshot wound completely through a lobe, the technique of pulmonotomy (sometimes referred to a tractotomy) is employed.[33-35] This maneuver requires division of the pulmonary parenchyma between noncrushing vascular clamps or via the use of a linear stapler/cutter to expose injured vessels. After selective ligation of bleeding vessels, the pulmonary parenchyma can be closed using a continuous 2-0 absorbable suture, with reinforcement material added to the staple line, as needed.

Heart (See Chapter 30)

Although compression with a finger is always recommended as the quickest and safest way to control hemorrhage from a small wound or rupture of a ventricle in the emergency department or operating room, application of 6-mm-wide skin staples (Auto Suture 35 W; United States Surgical Corporation, Norwalk, CT) may also be employed.[36,37] It should also be noted that some wounds such as large-caliber holes or injuries proximate to the coronary arteries are not appropriate for stapling. If desired, formal cardiac repair with Teflon pledgets and sutures may be completed over the staples or as they are sequentially removed in the operating room. Larger wounds or ruptures of a ventricle in patients surviving by virtue of a tamponade may be controlled by insertion of a Foley balloon catheter into the hole.[38] With the balloon inflated and extremely gentle traction applied to the catheter, Teflon-pledgeted sutures can then be passed through the ventricle from side to side over the balloon. The thin wall of the right ventricle puts the inflated balloon at significant risk of puncture as each suture is placed. Pushing the catheter and balloon into the ventricle with each bite of the suture will mitigate this complication, although blood loss may be significant. An alternative option is to use a cuffed endotracheal tube. This provides the advantage of increased manual stability while sewing. It must be emphasized, however, that excessive traction on either device can enlarge the initial laceration and create a nonrecoverable scenario. Clamping of the balloon catheter (or endotracheal tube) is also essential to prevent massive blood loss via the lumen of the tube, unless the surgeon wishes to use direct venous access through the catheter by connecting it to intravenous tubing (ie, for medication boluses).

With a longitudinal perforation or significant rupture of a ventricle, the time-honored technique of inflow occlusion is useful in avoiding cardiopulmonary bypass.[39] Curved aortic or angled vascular clamps are first applied to the superior and inferior vena cavae. As the heartbeat slows, horizontal mattress sutures can be inserted rapidly on either side of the defect and then crossed to control hemorrhage if this is still occurring. A continuous suture is then placed to close the defect, and before it is tied down, air is vented out of the elevated ventricle by releasing the clamps on the cavae. The surgeon should ensure internal paddles and all resuscitation tools are readily available, as successful restoration of a perfusing rhythm is unlikely after 3 minutes of occlusion.[40] For injuries to more vulnerable or friable myocardium, manually compressing the right atrium will result in partial inflow occlusion necessary to repair the ventricle.[41] Injuries occupying the lateral wall of the left ventricle, left pulmonary veins, left atrial appendage, or left pulmonary artery are accessed through a "cupping" maneuver to lift the ventricles out from the pericardial well. This should be done fairly slowly to avoid any rapid hypotension by running the fingers of the right hand between the pericardium and the right ventricle and then sweeping them posteriorly and cephalad. The hand cups the apex of the left ventricle, which is subsequently elevated anteriorly and out of the pericardial well. Meanwhile, placing several pericardial retraction sutures is important in order to maximize exposure. Finally, wounds to the posterior heart are particularly challenging. To access these sites, the heart must often be "flipped up" prior to suture repair.

Close communication with the anesthesiologist and rapid surgical technique are essential given the typical induction of complete cardiac arrest after positioning the heart for repair. As a result, intermittent restoration of the heart back into its natural position may be required for cardiac relief during prolonged repairs. Caution in technique is also essential if cardiac massage is required to promote prograde perfusion. An open hand methodology prevents punctures of the heart with excited fingers.

VASCULAR DAMAGE CONTROL TECHNIQUES

General

Although it is clear that stopping ongoing hemorrhage is the most crucial aspect of DCS, *vascular* damage control has been traditionally limited to vessel ligation. More recently, however, balloon catheter tamponade and temporary intravascular shunts (TIVS) have increased in popularity. The impressive utility of balloon catheters for tamponade of exsanguinating hemorrhage has a long history dating back more than 50 years.[2] Although this technique was originally described for esophageal varices,[42,43] it was quickly extended to patients with traumatic vascular and solid organ injuries. Since the initial treatment of an iliac arteriovenous lesion in 1960,[33] balloon catheters have also been used for cardiac,[38,44] aortic,[45] pelvic,[46] neck (carotid, vertebral, and jugular),[47,48] abdominal vascular,[49] hepatic,[50] subclavian,[51] vertebral,[48] and facial trauma.[52] Although this technique was originally intended as an intraoperative endovascular tool, it has since been employed as an emergency department maneuver with the balloon being placed outside of the lumen of the injured vessel such as at the base of the skull.[53,54]

Modern indications for this damage control technique are limited. This is primarily because routine methods for controlling hemorrhage, such as direct pressure, are typically successful. As a result, indications for catheter tamponade currently include the following: (1) inaccessible (or difficult to access) major vascular injuries; (2) large cardiac injuries; and (3) deep solid organ parenchymal hemorrhage (liver and lung). Of interest, the type of balloon catheter (Foley, Fogarty, Blakemore, or Penrose over red rubber Robinson), as well as the duration of indwelling, can vary significantly.

In conclusion, balloon catheter tamponade is a valuable tool for damage control of exsanguinating hemorrhage when direct pressure fails or tourniquets are not applicable. It can be employed in multiple anatomic regions and for variable patterns of injury. Prolonged catheter placement for maintenance of hemostasis is particularly useful for central hepatic gunshot injuries.[54]

TIVS are intraluminal synthetic conduits that offer nonpermanent maintenance of arterial inflow and/or venous outflow.[55] As a result, they are frequently life- and limb-saving when patient physiology is hostile. By bridging a damaged vessel and maintaining blood flow, they address both acute hemorrhage and critical warm ischemia of distal organs and limbs.

Although Eger et al[56] are commonly credited for pioneering the use of TIVS in modern vascular trauma, this technique was initially employed by Nobel Prize winner Alexis Carrel in animal experiments.[57] The first documented use in humans occurred in 1915 when Tuffier employed paraffin-coated silver tubes to bridge injured arteries.[58] This technique evolved from glass to plastic conduits in World War II[59] and continues to vary both in structure and material among today's surgeons.[60]

Modern indications for TIVS include the following: (1) replantation; (2) open extremity fractures with concurrent extensive soft tissue loss and arterial injury (Gustilo IIIC); (3) peripheral vascular damage control; (4) truncal vascular damage control; and (5) temporary stabilization prior to transport.[60,61] Although use of TIVS for military and civilian indications is increasing, the optimal shunt material, dwell time, and anticoagulation requirements remain poorly studied.[60] It can be noted, however, that TIVSs are remarkably durable and rarely clot unless they are too small (diameter), kink because of inappropriate length, and/or are placed in an extremity without appropriate (or shunted) venous outflow (venous hypertension leads to arterial thrombosis).[60,62] Although the literature contains many case series and practical experience using TIVS, one of the most dramatic examples of their utility is the near complete disappearance of limb loss that often followed ligation of the common and/or external iliac arteries in the past.[61] More specifically, despite similar injury and patient characteristics, the improvement in amputation rate from 47% to 0% in 22 patients with the introduction of TIVS at a high-volume penetrating trauma center is remarkable.[61] Further advantages included an observed reduction in fasciotomies (93% to 43%) and extra-anatomic bypasses (six bypasses to zero bypasses).[61]

Of interest, the majority of TIVS (64%) in a series from the National Trauma Data Bank (NTDB) were used in patients injured via a blunt mechanism.[63] Although the kinetic force of a motor vehicle crash (MVC) or MVC-pedestrian collision can be tremendous, TIVS has most often been discussed in the context of extremity damage control for gunshot wounds in patients with hostile physiology.[63] This recent NTDB analysis, however, indicated that most extremity TIVSs are actually placed for blunt vascular trauma associated with extensive orthopedic and/or soft tissue injuries (74%). This is usually a temporizing maneuver to provide distal flow to a limb while orthopedic injuries are assessed and fixated. In the patients who did not undergo TIVS for fractures and soft tissue defects, shunting was employed as an extremity damage control technique in patients with hemodynamic instability and severe base deficits (26%).[63] These patients displayed a much lower level of subsequent amputation when compared to patients after blunt trauma with concurrent fractures and soft tissue trauma who were not shunted.

In addition to using TIVS in patients with blunt injuries, the report from the NTDB also indicates that this technique has been used unevenly across a wide range of hospitals.[63] Of 111 trauma centers employing TIVS, only six used five or more shunts throughout the study period. Additionally, only three centers employed more than 10 shunts.

In conclusion, TIVS appear to be useful in any scenario with a major vascular injury and concurrent hostile patient physiology. This includes patients with blunt trauma with concurrent severe fractures and/or soft tissue injuries in the extremities.

Abdominal Arteries (See Chapter 38)

In any patient with multiple upper abdominal visceral and vascular injuries, a significant injury to the celiac axis is treated with ligation. An injury to the renal artery is also best treated with ligation and nephrectomy in the presence of a palpably normal contralateral kidney and multiple associated injuries. Depending on the comfort of the surgeon, segmental loss of the supra- or infrarenal aorta can be addressed by inserting a large TIVS (ie, thoracostomy tube) or rapid insertion of a 12-, 14-, or 16-mm woven Dacron or polytetrafluoroethylene (PTFE) interposition graft. The superior mesenteric artery or common or external iliac artery is smaller in young trauma patients, and an intraluminal Argyle, Javid, or Pruitt-Inahara TIVS may be rapidly inserted.[64] Should ligation be required for injuries to the common or external iliac artery, a rapid ipsilateral two-incision, four-compartment below-knee fasciotomy may prevent myonecrosis with its associated renal and septic problems in the short term. If the patient survives, the patient should undergo extra-anatomic revascularization within 6 hours.

When life-threatening arterial hemorrhage from either a blunt pelvic fracture or a penetrating wound occurs in the deep pelvis and cannot be controlled by packing, several approaches can be considered. Insertion of a Fogarty balloon into the internal iliac artery beyond a proximal tie on the side of the hemorrhage is followed by sequential advancement and inflation until the hemorrhage stops.[65] Another technique is to ligate the internal iliac arteries. Unfortunately, gluteal necrosis may occur after ligation of bilateral arteries and occasionally after ligation of a single internal iliac artery in patients with crush injuries (see Chapter 39).

Abdominal Veins (See Chapter 38)

Ligation is generally the treatment of choice in the context of major injuries to the common or external iliac veins, infrarenal inferior vena cava (IVC), superior mesenteric vein, or portal vein in a patient with profound shock.[66-70] After ligation of the infrarenal IVC, bilateral four-compartment below-knee fasciotomies should be performed immediately if the anterior compartment pressure is greater than 25 to 35 mm Hg, depending on the patient's hemodynamic stability. Bilateral thigh fasciotomies are also often necessary within 48 hours of ligation. When there are large defects in the sacrum or pelvic sidewall involving numerous pelvic veins or in the paravertebral area, a number of approaches are available to rapidly control hemorrhage. Packing the missile track with several vaginal packs, inserting fibrin glue, or placing a Foley catheter with a 30-mL balloon inflated at the site of hemorrhage may be effective. Placing packs outside of the blast cavity in the deep pelvis or paravertebral area often fails to control hemorrhage in the patient who develops a coagulopathy. Bleeding from presacral veins can be controlled by inserting sterile tacks directly into the visible defect or by suturing a free piece of omentum into the obvious area of perforation.

Extremity

Similar to other areas of the body, damage control operations on an extremity are appropriate when exsanguination has caused physiologic exhaustion, when multisystem injuries have occurred that require emergent treatment (skull, chest, abdomen), or when instability of an open fracture precludes formal repair of the associated vascular injury (as described earlier).[71]

After rapid control of hemorrhage, the best TIVSs for extremity injuries tend to be Argyle, Javid, or Pruitt-Inahara shunts, as previously noted.[72,73] The latter shunt possesses the added benefit of inflatable balloons on either end so that tying the shunt in place is not necessary. Its T-port also allows the infusion of heparin, vasodilators, or contrast for arteriography in the postoperative period.

Although ligation of major extremity venous injuries is often well tolerated in stable patients,[74,75] those requiring damage control may suffer severe sequelae.[71] These include compartment syndrome below the level of ligation in the lower extremity and excessive hemorrhage from soft tissue injuries and fasciotomy sites. Even if a compartment syndrome does not occur immediately, reperfusion injury during resuscitation will typically cause the syndrome to develop. This highlights the rationale for the rapid insertion of TIVS to ensure adequate venous outflow. Short 24F to 28F segments of thoracostomy tubes are excellent conduits for popliteal, femoral, or common femoral veins.

It should be reemphasized that if there has been any delay to restoration of venous flow (ie, long prehospital time, difficulty in controlling hemorrhage) or ligation of the major venous structures is required, ipsilateral four-compartment below-knee fasciotomies are recommended as part of the damage control procedure.

ABDOMINAL DAMAGE CONTROL TECHNQUES

Liver (See Chapter 33)

At rest, the liver has a blood supply approximating 1500 mL/min. In severe injuries, this can make stopping hemorrhage an extremely challenging task for not only a general surgeon, but also an experienced trauma surgeon.[76-81] As a fundamental philosophy of damage control, the techniques applied to major hepatic injuries with ongoing life-threatening hemorrhage should remain as limited and direct as possible.

Although the published history of hepatic trauma is replete with descriptions of various technical maneuvers ordered in a hierarchical scheme (extensive hepatorraphy, hepatotomy with selective vascular ligation, resectional debridement with

selective vascular ligation, rapid resectional debridement),[82-85] very few are commonly relevant in the context of modern trauma care and damage control. More specifically, damage control packing of hepatic hemorrhage controls the vast majority of ongoing bleeding in critically ill patients. The goal of packing is to reconstitute the liver as closely to its normal anatomic state as possible. It may be helpful to leave the falciform ligament intact to provide a medial wall against which to improve packing pressure (especially in blunt trauma to the right lobe). Although persistent perihepatic packing is required in less than 10% of operative liver injuries (ie, with an associated open abdomen), it remains an underappreciated skill. More specifically, it should be performed in an intentional and cautious manner to avoid further injury to the liver. The surgeon's nondominant hand is responsible for reconstituting the liver, followed by the placement of pads in strategic locations by the dominant hand. It should be noted that it is possible to pack the liver so tightly that it impedes venous return to the heart through the IVC and potentiates hypotension. Also, there has also been significant historical concern for interference from the radiopaque markers associated with laparotomy pads in subsequent angiography/angioembolization. Advances in digital subtraction technology and CT and the experience of interventional radiologists have made this less of a problem.

If hemorrhage continues in any scenario, an early Pringle maneuver (clamping of the porta hepatis with a vascular clamp) is mandated as both a diagnostic and potentially therapeutic technique. If bleeding continues despite application of a Pringle clamp, an injury to the retrohepatic vena cava or a hepatic vein is likely. It should be noted that not all critically injured patients in physiologic extremis tolerate extended Pringle maneuvers to the same extent as patients with hepatic tumors undergoing elective hepatic resection (40- to 60-minute upper limit). If the liver hemorrhage responds to packing but continues when unpacking is completed, the patient should be repacked and transferred to the intensive care unit with an open abdomen once damage control of concurrent injuries is complete. Covering the parenchymal or capsular injury with a plastic sheet or sterile x-ray cassette before inserting packs avoids adherence at the time of unpacking.

If control of the hepatic hemorrhage is dependent upon maintenance of a Pringle maneuver despite packing, the surgeon should call for an experienced assistant, mobilize the injured lobe, and see if there is an injury to the retrohepatic vena cava or a hepatic vein. On occasion, a patient with an injury to one of these structures may require total vascular exclusion (TVE) of the liver—that is, complete occlusion of the infrahepatic IVC, suprahepatic IVC, and porta hepatis (Pringle maneuver), as well as an infrarenal aortic cross-clamp within the abdomen. If TVE is pursued without concurrent clamping of the infrarenal abdominal aorta, the patient will often arrest due to a lack of coronary artery perfusion. Technically savvy surgeons prefer to obtain suprahepatic IVC control within the abdomen in patients with a normal length of IVC inferior to the diaphragm. Another option is to access the IVC as it enters the heart within the pericardium. This 2-cm length of IVC is easily accessible by opening the pericardial sac after dividing the diaphragm or after performing a median sternotomy. Veno-veno bypass is a damage control option that may require the assistance of a surgeon with experience in hepatic transplantation. If an atriocaval shunt is contemplated, two experienced surgical teams (one for the thorax and one for the abdomen) are essential. The decision to pursue this damage control shunt must be made early in the exploration process because they rarely result in patient salvage.

Similar to damage control for selected vascular injuries (see earlier discussion), ongoing hepatic hemorrhage that is not easily treated by direct repair and/or is challenging to control with external compression (eg, central hepatic gunshot wounds) may be controlled by intrahepatic balloon catheter tamponade.[85,86] Although techniques vary, a Foley, Fogarty, or inflated Penrose drain over a red rubber catheter is the most useful in controlling hemorrhage from a deep lobar stab or missile track. Inflation of the balloon is performed at different levels of the track until hemorrhage is controlled. Removal of the balloon catheter is performed at a reoperation when the patient's metabolic failure has been corrected. This technique is excellent at stopping hemorrhage and is associated with a reasonably high survival rate given the challenges of these injuries.

Pancreas (See Chapter 36)

Damage control for the pancreas itself is limited to packing of the injured gland if a coagulopathy is present. Ductal transections to the left of the mesenteric vessels that do not involve the splenic vessels are packed and drained, with the distal pancreatectomy delayed until reoperation (Fig. 42-1). Major parenchymal or ductal injuries in the head or neck of the pancreas are also packed or drained, once hemorrhage from the gland or underlying vasculature is controlled. Similar to a distal pancreatectomy, a required pancreatoduodenectomy is reserved for reoperation, as well.[87]

The dominant associated life-threatening scenario for peripancreatic injuries involves hemorrhage from the portal and superior mesenteric veins (and, occasionally, the IVC) (Fig. 42-1). Although these veins can be ligated as part of damage control, repair with 5-0 or 6-0 Prolene sutures is appropriate if rapid vascular control can be obtained. Another damage control option would be insertion of a small chest tube as a TIVS. Central injuries to the splenic vein are ligated, whereas those near the hilum mandate a splenectomy.

Spleen (See Chapter 34)

With American Association for the Surgery of Trauma (AAST) Organ Injury Scale (OIS) grade III, IV, or V injuries, splenectomy remains the safest choice when damage control is necessary.[88,89] Bulk ligation of the hilum via either suture ligature or a vascular stapler (linear or laparoscopic) is safe and rapid. Should an AAST OIS grade I or II injury be present,

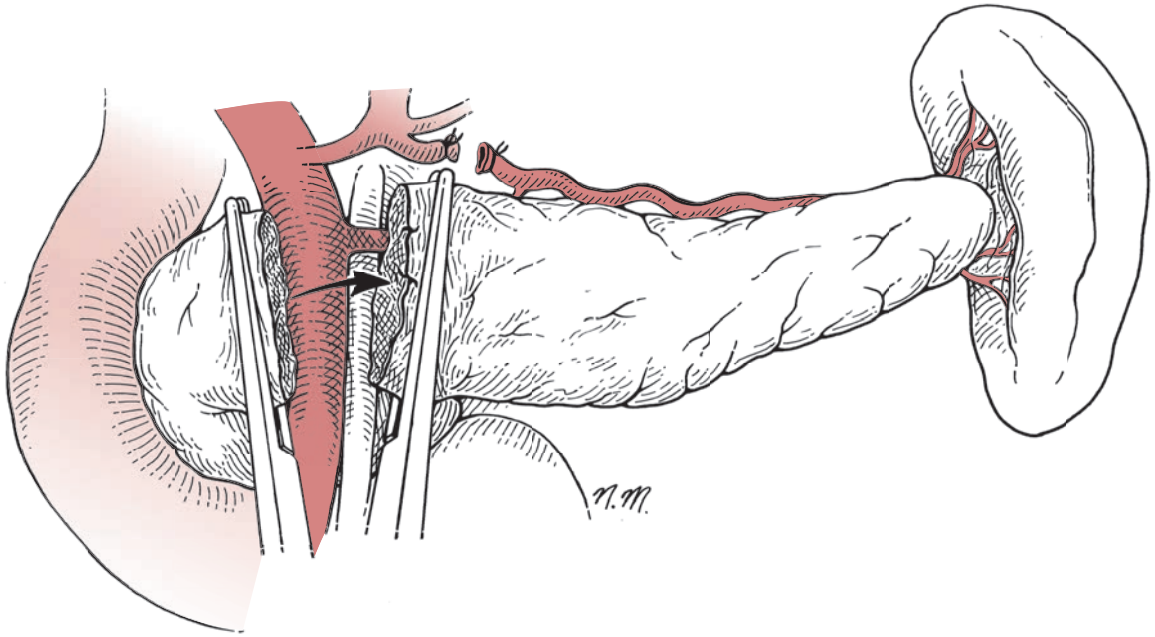

FIGURE 42-1 Distal pancreatectomy and splenectomy with exposure of the portal venous confluence. (Reprinted with permission from Cushman JG, Feliciano DV. Contemporary management of pancreatic trauma. In: Maull KI, Cleveland HC, Feliciano DV, et al, eds. *Advances in Trauma and Critical Care*. St. Louis, MO: Mosby; 1995, vol 10, pp 309-336.)

rapid mobilization and direct suture repair may be faster than splenectomy and will avoid a denuded retroperitoneal area that may be susceptible to hemorrhage in coagulopathic patients. With rupture of the splenic capsule, a multitude of commercially available topical hemostatic agents, as well as a bipolar sealing energy instrument, work well.[90,91]

Hollow Viscera (See Chapters 35–37)

Damage control techniques for hollow viscera include rapid excision for multiple adjacent injuries or temporary staple exclusion of injured segments. In the case of gastric division, the proximal stomach should be decompressed by a nasogastric tube. Near transections of the duodenum are stapled shut, whereas an associated injury to the head of the pancreas is packed. At the reoperation, once metabolic failure has been corrected, duodenal continuity can be restored with an end-to-end anastomosis. A pyloric exclusion with polypropylene suture and an antecolic gastrojejunostomy may be added in selected patients with severe duodenal contusion, narrowing after a suture repair, or a combined pancreatoduodenal injury.[92,93] Distal feeding access must also be considered in particularly ill patients.

If a limited number of enterotomies or colostomies from penetrating wound(s) are encountered, rapid one-layer, full-thickness closures using a continuous 4-0 monofilament suture is appropriate. Multiple large perforations within a short segment of small bowel or colon are treated with segmental resection, using metal clips or an energy ligation device for mesenteric hemostasis and staples to transect the bowel. The small bowel and colon can be left in discontinuity for up to 72 hours with minimal sequelae.[87] With shotgun wounds and multiple partial- and full-thickness perforations of the jejunum, a jejunectomy is appropriate because all of its absorptive capabilities are duplicated by the ileum. On occasion, large-blast or close-range shotgun injuries may cause 50 to 100 holes over the entire length of the small bowel. This particularly problematic scenario may lead to an enterocutaneous fistula after the reoperation due to a missed injury or failed repair. This will require treatment with drains, negative-suction devices, injections of somatostatin analog, nutritional support, and frequent returns to the operating room for control of intraperitoneal sepsis. A jejunectomy will lower the risk of this complication.

ABDOMINAL COMPARTMENT SYNDROME

Abdominal compartment syndrome (ACS) is defined as a sustained intra-abdominal pressure greater than 20 mm Hg that is associated with new organ dysfunction/failure (Fig. 42-2).[94-108] ACS differs from intra-abdominal hypertension (IAH), which is graded (I–IV) and defined as sustained pathologic elevation greater than 12 mm Hg. Symptoms of ACS are extensive and impact every major system within the human body. These include, but are not limited to, cardiovascular (hypotension), renal (acute kidney injury), and respiratory (failure) components. It is interesting to note that many of the dominant risk factors for developing ACS mirror the physiologic triggers for engaging in DCS/DCR. This observation supports the concept that physiologic variables (eg, core temperature, pH, base deficit) are clear markers for

FIGURE 42-2 Decompressive laparotomy and fasciotomies for a patient with severe burns and abdominal compartment syndrome.

the absolute sickest of the sick. Closing abdomens in patients manifesting physiologic extremis often leads to ACS, as well-described by Morris et al[97] in 1993. With closure, these authors described severe abdominal distension in concert with raised peak airway pressures, carbon dioxide retention, and oliguria. Their observed 63% mortality rate associated with reperfusion injury after unpacking was also dramatic. Recurrent or tertiary ACS is an important concept to consider in cases where ACS has already been treated previously but has recurred (ie, often in the setting of additional resuscitation for new hemorrhage or sepsis).[98] Quaternary ACS occurs once the abdominal wall has been closed, but the ACS recurs. Although the incidence of primary ACS has decreased dramatically over the past decade,[94] continued vigilance is crucial to guard against secondary and recurrent ACS. Despite the increased understanding surrounding this anatomic and physiologic complication, it is clear that many clinicians require more education with regard to both monitoring and treating ACS.[99] This concern has led to a recent evidence-based update of the definitions of primary, secondary, and recurrent ACS, as well as of an expert society's therapeutic recommendations.[95] More specifically, in addition to multiple suggestions (Tables 42-4 and 42-5), the World Society of the Abdominal Compartment Syndrome strongly recommends the following: (1) measuring intra-abdominal pressure when any known risk factor for IAH/ACS is present in a critically ill or injured patient using a transbladder technique (grade 1C); (2) using protocolized monitoring and management of intra-abdominal pressure (grade 1C); (3) engaging in a decompressive laparotomy for cases of overt ACS (grade 1D) (Fig. 42-2); (4) attempting to ensure same-hospital-stay abdominal fascial closure (grade 1D); and (5) using negative-suction therapy in patients with open abdominal cavities (grade 1D).[95] It should also be noted that some patients may adequately respond to decompression (nasogastric, colonic, intraperitoneal, increased sedation, and/or paralysis) as primary therapeutic maneuvers. Failure to resolve ACS with these medical therapies, however, should lead to rapid surgical decompression. Measuring intra-abdominal pressures can be easily performed at the bedside with a three-way Foley catheter, pressure transducer, and intravenous tubing.[108,109] The probe should be zeroed at the patient's hip in the supine position.

TABLE 42-4: Consensus Definitions of the World Society of the Abdominal Compartment Syndrome (ACS)

IAP is the steady-state pressure concealed within the abdominal cavity.

APP = MAP – IAP

IAH is graded as follows:

- Grade I, IAP 12–15 mm Hg
- Grade II, IAP 16–20 mm Hg
- Grade III, IAP 21–25 mm Hg
- Grade IV, IAP >25 mm Hg

ACS is defined as a sustained IAP >20 mm Hg (with or without an APP <60 mm Hg) that is associated with new organ dysfunction/failure.

Primary ACS is a condition associated with injury or disease in the abdominopelvic region that frequently requires early surgical or interventional radiologic intervention.

Secondary ACS refers to conditions that do not originate from the abdominopelvic region.

The reference standard for intermittent IAP measurement is via the bladder with a maximal instillation volume of 25 mL of sterile saline.

IAP should be expressed in mm Hg and measured at end-expiration in the complete supine position after ensuring that abdominal muscle contractions are absent and with the transducer zeroed at the level of the midaxillary line.

Normal IAP is approximately 5–7 mm Hg in critically ill adults.

IAH is defined by a sustained or repeated pathologic elevation in IAP ≥12 mm Hg.

Recurrent ACS refers to the condition in which ACS redevelops following previous surgical or medical treatment of primary or secondary ACS.

Polycompartment syndrome is a condition where two or more compartments have elevated compartmental pressures.

An open abdomen is one in which the abdominal viscera are exposed to the outside environment or retained by a nonautologous artificial barrier.

Pathophysiologic classification of the open abdomen

1A = clean, no fixation

1B = contaminated, no fixation

2A = clean, developing fixation

2b = contaminated, developing adhesions

3 = "frozen abdomen" with complete fixation

4 = "frozen abdomen" with enterocutaneous fistula

Abdominal wall compliance defines a concept regarding the ease of expansion of the abdominal wall and its contents, which is determined by the overall intra-abdominal volume and elasticity of the abdominal wall.

APP, abdominal perfusion pressure; IAH, intra-abdominal hypertension; IAP, intra-abdominal pressure; MAP, mean arterial pressure.

TABLE 42-5: Summarized World Society of the Abdominal Compartment Syndrome Consensus Management Statements

Recommendations

1. Measure IAP when any known risk factor is present in a critically ill/injured patient.
2. Studies adopt the current and accepted standard IAP measurement technique.
3. Protocolized monitoring and management of intra-abdominal pressure should be used when caring for the critically ill/injured.
4. Efforts and/or protocols should be used to avoid sustained IAH.
5. Use DCL to reduce IAP in cases of overt ACS.
6. Negative-pressure therapy should be used to faciltate earlier fascial closure.

Suggestions

1. Critically ill/injured should receive optimal pain and anxiety relief.
2. Brief trials of neuromuscular blockade may temporize the treatment of IAH.
3. The potential contribution of body position in elevating IAP should be considered in patients with moderate to severe IAH or ACS.
4. Use a protocol to try to avoid a positive cumulative fluid balance in the critically ill with or at risk of IAH.
5. Use an enhanced ratio of plasma to packed red blood cells during resuscitation from massive hemorrhage.
6. Use percutaneous drainage to remove fluid in those with IAH/ACS when this is technically possible whether the alternative is doing nothing *or* a decompressive laparotomy.
7. Physiologicaly exhausted posttrauma laparotomy patients should use a prophylactic open abdomen strategy.
8. Intraperitoneal contamination (even if severe) is **NOT** an indication for the routine or prophylactic use of the OA technique.
9. Biological meshes should **NOT** be routinely used to faciltate early acute fascial closure.

No recommendations

1. No recommendation was made regarding the use of the abdominal perfusion pressure as a resuscitation marker.
2. No recommendation was made regarding the use of diuretics to mobilize fluid in hemodynamicaly stable patients with IAH.
3. No recommendation was made regarding the use of renal replacement therapies to mobilize fluids in hemodynamically stable patients with IAH.
4. No recommendation was made regarding the administration of albumin to mobilize fluids in hemodynamically stable patients with IAH
5. No recommendation could be made to use the component separation technique to facilitate earlier acute fascial closure.
6. No recommendation was made regarding the use of the OA technique in emergency surgery in patients with physiologic exhaustion.

ACS, abdominal compartment syndrome; DCL, decompressive laparotomy; IAH, intra-abdominal hypertension; IAP, intra-abdominal pressure; OA, open abdomen.

In addition to raised pressures within the abdominal compartment, similar manifestations may also occur in closed compartments of the extremities. Akin to secondary abdominal compartment syndrome, secondary extremity compartment syndrome is a result of a massive resuscitation.[110] It is also associated with extremely high morbidity and mortality (35%–70%). Serial measurements of creatine phosphokinase (CPK) and urine myoglobin may be appropriate in high-risk patients as a screening tool. Any individual with persistently high CPK levels or the unexplained development of myoglobinuria may benefit from measurement of extremity compartment pressures and fascial releases as appropriate.

MANAGEMENT OF THE OPEN ABDOMEN (SEE ATLAS FIGURE 67)

The concept of delaying abdominal wall closure is credited to Dr. H. Harlan Stone at Grady Memorial Hospital in Atlanta, Georgia, in 1981.[100] Among 167 patients, mortality approximated 85% in those whose abdomens were closed under tension, compared to only 22% in patients who underwent delayed fascial closure. This truly remarkable report altered the DCS landscape dramatically. Unfortunately, the open abdomen is also responsible for significant short-term (fluid and protein loss, sepsis, intestinal fistulas, nursing care challenges, economic costs) and long-term (chronic physical discomfort, physique embarrassment, delayed return to work, poor quality of life) morbidity.[103,104]

Management of the open abdomen can be divided into two phases. In the acute phase, the goal is to provide some variant of temporary coverage to allow the patient to be taken from the operating room to the intensive care unit for additional resuscitation and stabilization with the intent of returning to the operating room when normal physiology has been restored. In the second phase, which follows reoperation, the ultimate goal is a delayed fascial closure. On occasion, this is not technically possible, and a planned ventral hernia will be required.

Multiple techniques for covering the open abdomen at the index operation are available. These range from simple techniques such as covering the viscera with nylon cloth material followed by "generous gauze packs" (Detroit Receiving Hospital) to commercially available negative-suction devices.[111,112] Because no single technique has been shown to be far superior to others, a given trauma center should employ a single consistent option that ensures familiarity by all surgeons, house staff, and nurses. This allows accurate assessment of fluid losses, as well as intermittent troubleshooting. A simple and

cost-effective choice remains a large sterile x-ray cassette drape with two closed suction drains and a covering plastic adhesive drape. This temporary silo technique was initially described by Oswaldo Borraez G. at the San Juan de Dios Hospital in Bogota, Columbia, in 1984. Alternative materials for coverage include a 3-L plastic irrigation bag that is opened up into a single sheet of plastic, a Silastic sheet, or a PTFE sheet. The use of vacuum-assisted wound closure devices is also now common throughout much of the world. The initial "homegrown" description of this concept was reported by Barker et al[113] in 112 patients. The principal goals of this technique remain coverage of the viscera, rapid removal of peritoneal fluid, and maintenance of some midline traction. In much of the developed world, low-technology versions of commercial products have provided clinicians with an excellent alternative. It is critical to mention, however, that avoiding commercial negative-suction devices during the initial critical phase (ie, following the first laparotomy) may be helpful in the prevention of recurrent ACS.[105] Alternatively, if recurrent ACS does occur, simply turning off the suction pump and therefore converting the negative-suction device into a simple silo often relieves recurrent IAH.

Other options for covering the open abdomen include towel clip or suture closure of the skin. The advantage of these techniques is that they are simple, rapid, and readily available in almost all settings.[114] They can also be employed for closure of chest, abdomen, and groin incisions. Depending on the length of the incision, up to 30 standard towel clips may be necessary to complete the closure. To prevent manipulation of the towel clips and minimize secondary contamination of the chest, abdomen, or groin through the spaces between the towel clips, a large plastic adherent drape is also placed over the towel clips in combination with a closed suction drain lying lateral to the incision. When suture closure of the skin is selected, 2-0 nylon or thicker suture material is selected, depending on the tension. It should also be noted that these skin-only closures are used much less commonly now given their propensity to increase intra-abdominal pressure.

It is clear that as the patient is exposed to multiple subsequent operative interventions, intestinal coverage (via endogenous abdominal wall or skin or split-thickness skin graft) must be achieved as soon as possible to limit the development of enteroatmospheric fistulas. It is also evident that, regardless of technique, severely injured patients more commonly achieve fascial closure during their initial hospital stay than their nontrauma, acute care surgery counterparts. If closed too early, ACS, fascial dehiscence, necrotizing fasciitis, and ventilation challenges are notable complications. Despite the poor methodology inherent in the open abdomen literature (ie, mixed patient cohorts, lack of complete inclusion, ignorance of nonsurvivors, variable individual surgeon effort and interest), it is evident that the application of negative-suction dressings at subsequent operations has improved closure rates and shortened time to closure. The two dominant principles when using negative-suction therapy are maintenance of the peritoneal/abdominal domain and continuous and progressive tension on the midline abdominal wall. These goals are achieved first by insertion of a plastic barrier deep into the paracolic gutters (maximally lateral to prevent adhesions between the colon and abdominal wall) and, second, by generation of midline abdominal wall tension using nonfascial retention sutures or commercial systems. It should also be noted that intra-abdominal pressures often exceed "normal" (>20 mm Hg) immediately after progressive increases in tension at the midline during repeat laparotomy and attempted closure.[107] This typically abates over the subsequent few hours and is considered acceptable in the absence of end-organ ischemia (decreased urine output, increased airway pressures). As a result, it is considered fundamentally different from the acute phase of ACS. If the intra-abdominal pressure does not normalize, however, the abdomen must be reopened to prevent recurrent ACS.

In conclusion, an individual patient with an open abdomen will either continue to improve, mobilize fluid, and allow gradual abdominal closure via repeat laparotomies, or will continue to be challenged with sepsis and multiorgan failure, will not mobilize fluid, and will eventually require coverage with a split-thickness skin graft (Fig. 42-3). Enteroatmospheric fistulas must also be prevented at all costs. This complicates short-term management, as well as eventual reconstruction of the abdominal wall (component separation, modified component separation, retrorectus mesh procedures, indications for the use of biologic mesh implants). If present, these fistulas are best intubated by soft rubber catheters placed within the sponge material of a negative-pressure suction dressing.[115] Over time, this will allow the patient to develop a granulation plate around the fistulas appropriate for a skin graft (ie, conversion into a stoma).

A detailed discussion of the tiered algorithm for abdominal wall reconstruction, as well as the indications for occasional use of biologic materials, is beyond the goals of this review. Clearly, the appropriate timing of reconstruction (6–12 months) is vital to the success of the repair (adhesions vs lateral retraction of the rectus muscle). Extensive experience in reconstructive techniques is also crucial to ensure

FIGURE 42-3 Split-thickness skin graft on an open abdomen.

acceptable outcomes. These principles include, but are not limited to, timing, sequencing (stoma reversal or fistula closure), ensuring adequate skin coverage, sparing of periumbilical perforators, minimally invasive lateral releases, and management of wound complications. In particular, reconstruction of the gastrointestinal tract (eg, stoma takedown, resection of fistulas) can be undertaken by partial elevation of a healed split-thickness skin graft as a first separate procedure. Three or more months later, a separate reconstruction of the abdominal wall can be safely performed without the risk of gastrointestinal contamination.[116] Consideration may also be given to the use of expensive, but effective, biologic mesh inserts in fields of mild to moderate contamination as a one-stage procedure.

REOPERATION

Following control of surgical bleeding and contamination, patients are transferred to the intensive care unit for ongoing resuscitation and stabilization. The immediate goals are to both provide adequate oxygenation and reverse the effects of inadequate tissue perfusion and resultant metabolic failure. Correction of hypothermia, coagulopathy, and acidosis must be at the forefront. Hypothermia can be treated by external rewarming or, in extreme cases, cardiopulmonary bypass. Our increasingly nuanced understanding of the state of coagulopathy has also ushered in new tests such as thromboelastography.[117] Although significant excitement surrounds these techniques, our true understanding of their clinical role continues to evolve (see Chapter 16).

Reoperations can be divided into emergency or planned. Failure to attain the desired end points of resuscitation in the immediate postoperative period of damage control may reflect continued hemorrhage.[97,118] An early return to the operating room is a difficult decision because physiologic and biochemical stabilization is typically incomplete at this point (Table 42-6). Therefore, the surgeon must postulate whether mechanical or surgical hemorrhage is occurring versus diffuse oozing from a coagulopathy in which an early reoperation may not be indicated. As mentioned, an obvious indication for an early reoperation is the development of ACS (ie, with failure of a decrease in pressure once the negative-suction pump has been turned off).

A planned reoperation typically occurs when postoperative bleeding is not a dominant concern and the patient has achieved normalization of cardiovascular, pulmonary, and metabolic parameters (Table 42-7).[119] Although the specific timing of a return to the operating room remains a source of debate, a patient who is normotensive, without a coagulopathy, and is in the diuretic phase of recovery after resuscitation from shock is the ideal candidate. The more important concept remains returning the patient to the operating room as soon as the patient has stabilized, rather than based on a given surgeon's schedule.

In patients who cannot achieve fascial closure at the initial reoperation (due to incomplete reconstructions, persistent intraperitoneal sepsis, or visceral/abdominal wall edema secondary to the initial resuscitation), a repeat temporary abdominal closure must be applied. Choices remain identical to the initial operation, with the exception of a much lower risk of recurrent ACS with a negative-suction device.[105] Although the literature is composed of a long list of evolving techniques to address the recurrent open abdomen (vacuum-assisted,[120-123] zippers,[124] Wittmann Patch [Starsurgical, Inc., Burlington, WI],[125-128] absorbable meshes,[129-132] or permanent meshes[100,133-136]), the majority of centers use a commercially available negative-suction device. As previously mentioned, maintenance of the peritoneal domain and prevention of adherence of the viscera to the underside of the abdominal wall are critical to allow progressive closure of the fascia with repeated operations. Other nuanced technical concerns include the following: avoidance of injuring the fascia at all operations preceding the final closure irrespective of the technique selected; maintaining progressive midline traction with each successive operation (ie, beyond simply applying a negative-suction device); and avoiding converting the geometry of the wound from an ellipse into a circle (ie, by closing the top and bottom but leaving the middle of the wound open). By following these principles and applying a negative-suction device at reoperation as an adjunctive tool, it is clear that patients have fewer wound issues, better management of peritoneal fluid and contamination, and fewer planned ventral hernias.

TABLE 42-6: Indications for Emergent Return to the Operating Room After a Damage Control Laparotomy

Blunt trauma	Penetrating trauma
Normothermic but bleeding >2 U/h	Normothermic but bleeding >2 U/h
Abdominal compartment syndrome with ongoing blood loss	

TABLE 42-7: Indications for Elective/Planned Return to the Operating Room After a Damage Control Laparotomy

Temperature >36°C (96.8°F)
Acid-base balance
Base deficit corrected to greater than –5 mmol/L if originally less than –15 mmol/L
Serum lactate normal or correcting gradually
Coagulation
Prothrombin time <15 seconds
Partial thromboplastin time <35 seconds
Platelets >50,000/mm^3
Cardiovascular
Cardiac index >3 L/min/m^2, with or without low-dose inotrope
Pulmonary
Fraction of inspired oxygen <0.50
Oxygen saturation >95%

FIGURE 42-4 Resuscitation with Angiography, Percutaneous Techniques, and Operative Repair (RAPTOR) environment.

HYBRID CARE SUITES

Given that DCR is dedicated to our most critically injured patients, it is not surprising that the development of a single location (ie, RAPTOR—Resuscitation with Angiography, Percutaneous Techniques, and Operative Repair) where percutaneous therapies, operative interventions, cross-sectional imaging, and critical care can all be delivered holds significant promise (Fig. 42-4).[137-140] This concept transitions care from a location-based approach to a truly disease- and urgency-based algorithm. The best example remains a patient with ongoing hemorrhage from an unstable pelvic fracture in the context of associated injuries that may or may not require emergent operative intervention. In recent reports, the use of a hybrid suite in severely injured patients with ongoing hemorrhage was shown to reduce both the time to intervention and the overall procedure duration.[139,140] Further, a large survival benefit was also noted in the most critically ill patients.[140] The significant concerns with this technology remain the tremendous cost of building hybrid suites, as well as the training requirement for clinicians to safely perform hybrid procedures.[137,138]

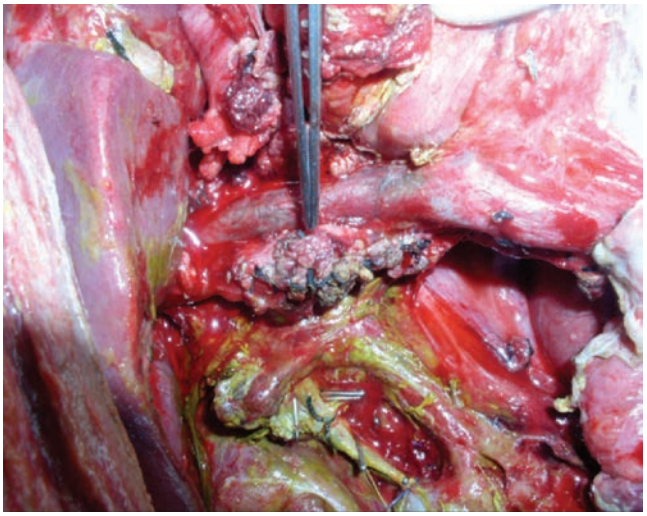

FIGURE 42-5 Resection of the pancreatic head following ligation of the inferior vena cava with synchronous right nephrectomy as an initial damage control procedure.

CONCLUSION

In conclusion, DCR currently includes simultaneous early transfusion of blood products and arrest and/or temporization (ie, balloon tamponade and TIVS) of ongoing hemorrhage in the most challenging patients (Fig. 42-5). As a result, DCR addresses the early coagulopathy of trauma, avoids massive crystalloid resuscitation, and leaves the peritoneal cavity open when a patient approaches physiologic exhaustion without improvement. Although the precise indications for DCS remain debated,[141,142] the future evolution of the DCR concept will include further elucidation of personalized resuscitations (individual blood product ratios based on point-of-care testing), as well as introduction of hybrid angiography-operating suites in centers with resources.

Upper Extremity

Raymond Pensy

KEY POINTS

- The field of hand surgery has evolved via the integration of surgical disciplines specific to bone, tendon, nerve, vessel, and skin.
- A careful inventory of each of these components must be made in every patient to plan treatment and anticipate expected functional recovery of the traumatized hand and upper extremity.
- Assessment of tissue viability should occur through a careful vascular and neurologic examination, both pre- and intraoperatively.
- The skeleton represents the foundation of any reconstruction of the upper limb; a plan for temporizing and/or definitive fixation in every fracture must be established prior to finalizing any other repair.
- A plan for soft tissue coverage should be made early when the skin envelope is compromised.

INTRODUCTION

The origins of hand and upper extremity surgery in the United States as a surgical specialty can be largely attributed to Major General Norman Kirk, MD (Fig. 43-1), the first orthopedic surgeon to be appointed as surgeon general of the armed forces.[1] With his significant experience in treating veterans of World War I and World War II,[2] he appreciated that injuries of the hand and upper extremity commonly involve joint, bone, vessel, tendon, and nerve, and optimal treatment required familiarity with each.

In an effort to improve the outcomes related to the care of the hand and upper extremity, Sterling Bunnell[3] (Fig. 43-2), a friend and contemporary of Norman Kirk, was charged with founding the first group of specialized military training centers for hand surgery.[3] These programs have evolved into the current modern hand fellowships.

In 1989, recognizing that surgery of the hand requires a specific skill set for optimal outcomes, the American Boards of Surgery, Orthopaedic Surgery, and Plastic Surgery[4] initiated a specialty examination process culminating in a Certificate for Additional Qualifications for Surgery for the Hand, now called Subspecialty Certificate in Surgery of the Hand. This certification represents the pinnacle of training and aspirations of clinicians committed to caring for those afflicted with trauma or malady of the hand and upper extremity. This chapter is a reflection of the basic tenets and a brief overview of the current state of this specialty.

THE HAND AND UPPER EXTREMITY AS PART OF THE WHOLE

The approach to the treatment of the trauma victim must follow the standardized, thoroughly investigated, and well-established protocols of basic and advanced life support in the field, as well as Advanced Trauma Life Support (ATLS). Many would agree that the severed or mangled hand, forearm, or arm can be a disturbing sight, but the experienced traumatologist recognizes the importance of first assessing the airway, breathing, and circulatory system, as well as the potential for injuries to the brain, chest, or abdomen. Because these injuries are frequently life-threatening, timely and thorough evaluation of these systems must be completed first, even in those cases where the most obvious injury is that of the extremity and even in cases of amputation.

When considering severe trauma to the upper extremity, assessment of the perfusion status is paramount.[5] In instances where absolute ischemia exists due to a tourniquet or as the result of an incomplete amputation, all appropriate haste must be made to ensure that ischemic time is minimized. The time of injury or tourniquet application time

FIGURE 43-1 Major General Norman Kirk, MD. (From U.S. National Library of Medicine. http://resource.nlm.gov/101420484.)

FIGURE 43-2 Sterling Bunnell, MD.

must be documented, and efforts to minimize this time are paramount.

In all other cases, injuries of the hand and upper extremity can be evaluated with a careful physical examination, thorough radiography, splinting, and, finally, operative treatment as necessary. With these careful assessments, the status of the constituent nerves, bone, tendon, and skin will be determined.

In planning appropriate treatment of the hand or arm of the polytrauma victim, one must consider the influence this injury will have on the patient and his or her recovery as a whole. The experienced reconstructive surgeon will recognize the impact that early functional rehabilitation of the hand and arm will have for the overall care of the patient.[6] The differences in treatment rendered for an isolated injury to the upper extremity, compared to that in a patient with concomitant injuries, can be significant. For example, a patient with a humerus fracture in isolation will do well with splinting, but if a non–weight-bearing injury in a lower extremity is present also, the patient will do better with rigid fixation permitting unrestricted weight bearing of the upper extremity.

In an effort to simplify the approach to examination, diagnosis, and treatment to the injured hand and upper extremity, the author finds it reasonable to consider the upper extremity as a collection of skeletal, joint, vascular, artery, muscle, tendon, nerve, and skin tissues. Each of these requires its own set of independent diagnostic modalities and treatments, and the sections that follow are organized as such.

SKELETON AND JOINT—GENERAL EVALUATION AND TREATMENT

Physical Examination

None would argue that, in the absence of a sturdy, robust, and well-formed foundation, efforts at subsequent reconstruction are fruitless. The first responders will relay a history of deformity if present, as well as other crucial information. Simple inspection will reveal asymmetric posture and malangulation. The awake patient will guard the fractured upper limb and avoid movement, often keeping the limb motionless. The surgeon must examine the patient's extremities for deformity, crepitance, "clunking," and pain to assess for gross signs of fracture or dislocation of a joint.[7] The movements of the upper extremity at all joints and planes should be supple and painless and assessed in every degree of motion, both passive and active. Joints should be examined for swelling, and the skin checked carefully for ecchymoses, lacerations, and abrasions, with particular attention paid to the possibility of an open fracture. Finally, careful and deliberate palpation of each region of the upper limb should be performed and documented. Not infrequently, the polytrauma patient will have concomitant injury to the spine, trunk, or lower extremity, which may distract the examiner from the smaller bones of the hand and feet. Thus, in some instances, a repeat secondary survey with focal radiography is advised.[8]

TABLE 43-1: Imaging Examinations for Shoulder Girdle Region

Conditions	X-ray	Advanced imaging
Sternoclavicular dislocations	AP, serendipity view	CT
Clavicle fracture	AP, apical/oblique views	
Acromioclavicular dislocations	AP, apical/oblique views	
Scapular fracture	True AP, scapular Y, and axillary lateral views	CT
Acromion fracture	True AP, scapular Y, and axillary lateral views	
Glenoid neck fracture	True AP, scapular Y, and axillary lateral views	
Glenoid fracture	True AP, scapular Y, and axillary lateral views	
Scapular body fracture	True AP, scapular Y, and axillary lateral views	
Floating shoulder without associated clavicle fracture	True AP, scapular Y, and axillary lateral views	
Scapulothoracic dissociation	True AP, scapular Y, and axillary lateral views	CT/MRI/angiography
Glenohumeral dislocation	AP/Bloom–Obata modified	Axillary view
	Scapular Y view	CT/MRI

AP, anteroposterior; CT, computed tomography; MRI, magnetic resonance imaging.

Diagnostic Modalities

ORTHOGONAL RADIOGRAPHY

In the trauma patient, plain radiography will reveal the majority of skeletal injuries requiring intervention (Tables 43-1, 43-2, and 43-3). In many cases, the nature of the fracture's appearance on plain films will alert the provider to possible significant injury related to the other components of the upper extremity (Figs. 43-3A and B and 43-4).

In general, any part of the upper limb that demonstrates deformity, lack of suppleness, crepitance, or pain upon palpation should be imaged, as should the joint above and below. Many fractures of the upper extremity will involve dislocation of the joint distal or proximal to the level of an obvious fracture and result in significant morbidity if unrecognized, such as Monteggia and Galeazzi injuries[9] (Fig. 43-5).

Orthogonal radiographs should be acquired in a standardized manner. The fractured arm (humerus) or forearm (radius and/or ulna) is imaged in the anteroposterior (AP) plane, replicating the anatomic position, and then a lateral plane, obtained without rotating the limb. This is accomplished by positioning the cassette and beam 90° from the initial exam and with a provider or assistant carefully lifting the limb and holding the cassette to achieve this orthogonal view. It is generally contraindicated to "twist" or rotate the limb in order to achieve this orthogonal view, as it will cause undue pain,

TABLE 43-2: Imaging Examinations for the Arm, Elbow, Forearm, and Wrist

Conditions	X-ray	Advanced imaging
Proximal humerus fracture	AP, transscapular lateral, Bloom–Obata modified	CT
Humeral shaft fracture	axillary view	
Elbow trauma	AP, lateral	
Distal humeral fracture	AP, lateral	CT

Elbow dislocations/fracture-dislocations	AP, lateral	CT
Fracture of proximal ulna	AP, lateral	CT
Radial head fracture	AP, lateral	
The floating elbow	AP, lateral	
Monteggia fracture-dislocations	AP, lateral	
Ulna shaft fracture	AP, lateral of elbow and forearm	
Radial shaft fracture	AP, lateral	
Distal radius injury/fracture	AP, lateral	
Radius/ulna fractures	AP, lateral	
Scaphoid fractures	AP, lateral	
	PA, lateral, oblique, scaphoid	MRI

AP, anteroposterior; CT, computed tomography; MRI, magnetic resonance imaging.

TABLE 43-3: Imaging Examinations for Wrist and Hand

Conditions	X-ray	Advanced imaging
Triquetrum fractures	PA, lateral, oblique	CT/MRI
Pisiform fractures	Carpal tunnel view and/or supinated oblique view	CT
Trapezium fractures	Hyperpronated Roberts view, Bett's view, carpal tunnel view	CT
Trapezoid fractures	PA, lateral, oblique	CT
Capitate fractures	PA, lateral, oblique, and scaphoid view	CT
Hamate fractures	Carpal tunnel view and/or supinated oblique view	CT
Hook fractures	Carpal tunnel view and/or supinated oblique view	CT/MRI
Lunate fractures	PA, lateral, oblique	
Carpal dislocations	PA, lateral, oblique	
Metacarpal fractures	PA, lateral, oblique	
Phalangeal fractures	PA, lateral, oblique	
Metacarpophalangeal dislocations	PA, lateral, oblique	
Interphalangeal joint dislocations	PA, lateral, oblique	

CT, computed tomography; MRI, magnetic resonance imaging; PA, posteroanterior.

result in poor image quality, and, in some cases, further displace the fracture or dislocation.

Static injury films of the limb are acquired in its injured state prior to realignment, splinting, or traction, and provide useful information regarding the force vector that resulted in a given injury pattern. This will often dictate the method of treatment, whether it be in regard to an initial reduction maneuver, application of a three-point mold with splinting or casting, or the application of plates to "buttress" or "neutralize" the deforming forces. Further, injury films document the severity of the injury. To the experienced eye, even these plain radiographs will yield valuable information regarding the possibility of significant compromise of soft tissue above and beyond that which is obvious to the skeleton. In any trauma center with the availability of a physician or other medical personnel capable and trained in performing reductions, injury films should, in most instances, be performed prior to the reduction attempt. Although tempting to reduce the injured part out of a perceived benefit to the patient (to restore blood flow; limit desiccation to exposed cartilage, tendon, or bone; lessen skin tension and ischemia), the few minutes required for radiography will not significantly add to morbidity, as the time from injury to reduction is only modestly lengthened by radiographs that almost always assist in treatment.

Traction views will provide the astute extremity surgeon with additional information, particularly for injuries of the distal humerus, radius, and phalanges.[10,11] In many cases, traction alone can realign fractures of the distal radius and phalanges to acceptable parameters. This may demonstrate fractures that can be treated with less invasive external fixation or other closed techniques. Additionally, traction views will clarify the "reducibility" of fracture elements through ligamentotaxis, which will further delineate treatment parameters such as the surgical approach, choice of surgical implants, and the likely duration of the surgical effort (Fig. 43-6).

COMPUTED TOMOGRAPHY

Computed tomography (CT) has revolutionized imaging and care of the trauma patient, especially in the precise delineation of skeletal injury patterns and particularly in those in periarticular regions.[12]

Specific to the upper extremity, CT is recommended for the following: fractures involving the scapula, particularly those involving the glenohumeral joint; fracture-dislocation of the elbow (fractures involving the primary stabilizers including the coronoid, radial head, and trochlea, associated with dislocation); distal radius fracture in some instances; carpometacarpal joint fractures; and intra-articular injuries of the fingers and those of the carpus, particularly scaphoid fractures.[13-15]

Treatment

The rationale behind skeletal stabilization is simple, yet its effects are profound. First, stabilization of the injured/fractured long bone will substantially mitigate pain.[16] The stabilization of a long bone (femur, tibia, and humerus) limits additional microtrauma to the surrounding muscle, vessels, and nerves, and immediately improves pain. Effective pain control is important in mitigating its effects on the cardiopulmonary and neurologic systems.[17,18]

Continued instability of the injured limb often promotes vasospasm and arterial thrombosis. Finally, in circumstances of severely displaced fractures or malaligned joints, the skin will become tented, resulting in localized ischemia and, in severe cases, necrosis. This will further complicate treatment because of unwanted exposure of neurovascular structures, tendons, or joints.

Stabilization of the fractured or dislocated skeleton is performed with a variety of nonoperative and operative techniques. The orthopedist has a broad array of techniques available (Table 43-4). These techniques have roles specific to

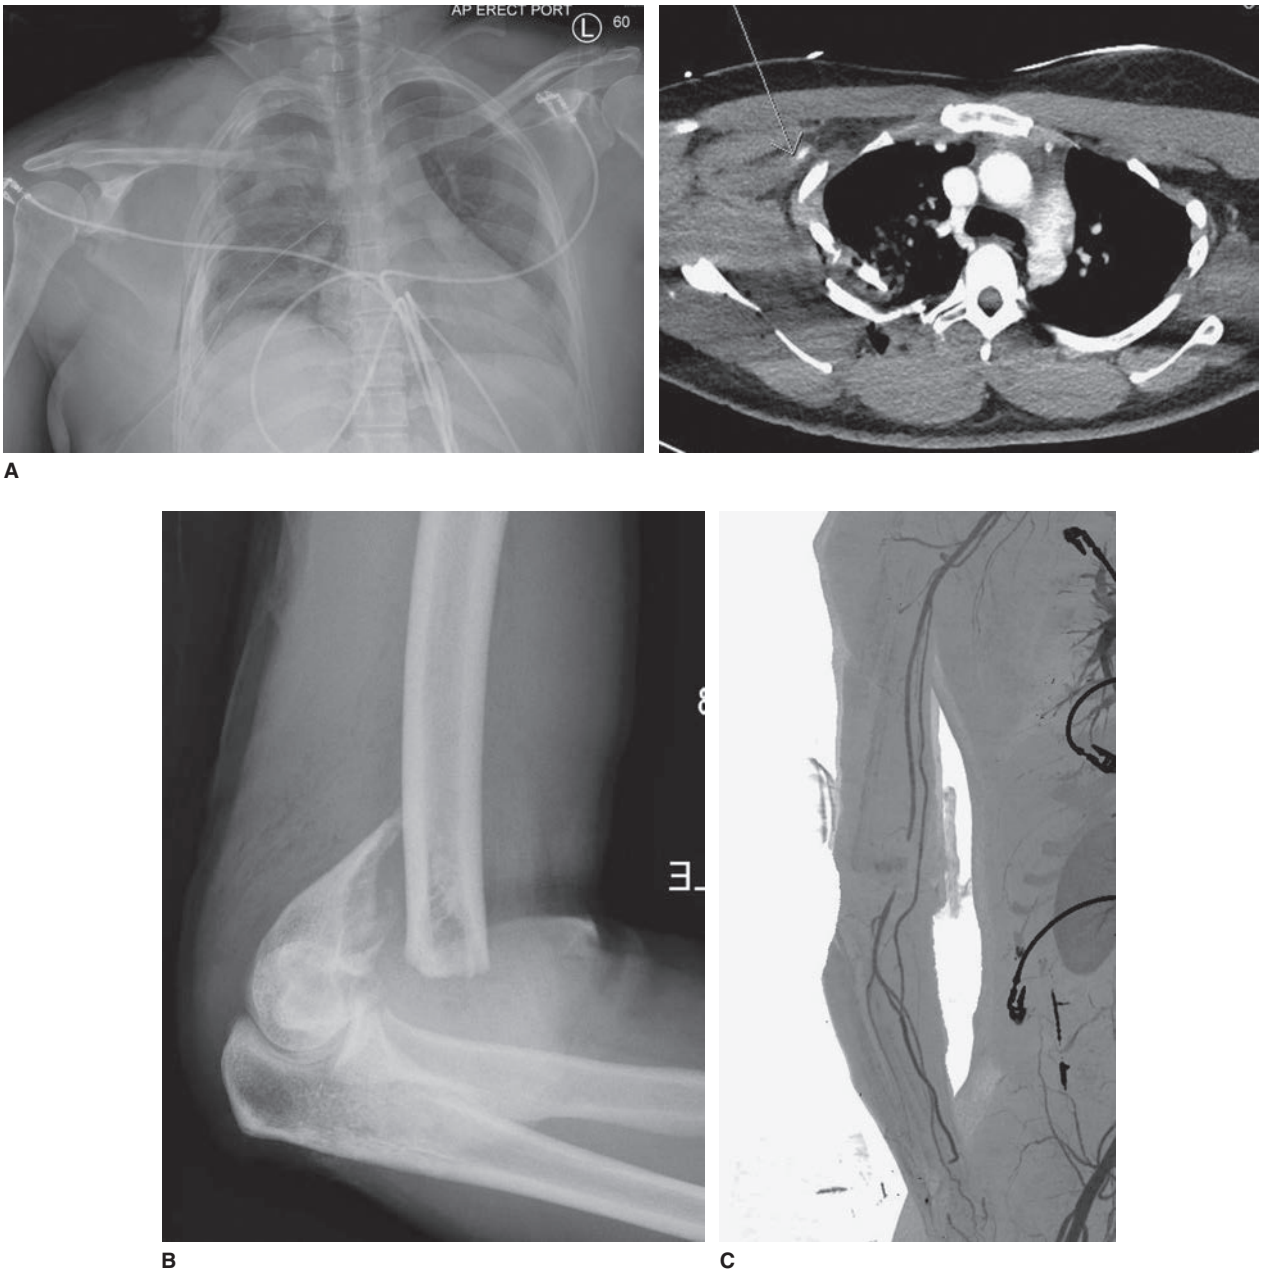

FIGURE 43-3 (**A**) Axillary artery injury with scapulothoracic dissociation. (**B**) Brachial artery injury with extension-type supracondylar humerus fracture. (**C**) Brachial artery injury following ballistic trauma, with maintained perfusion via high/proximal radial artery origin.

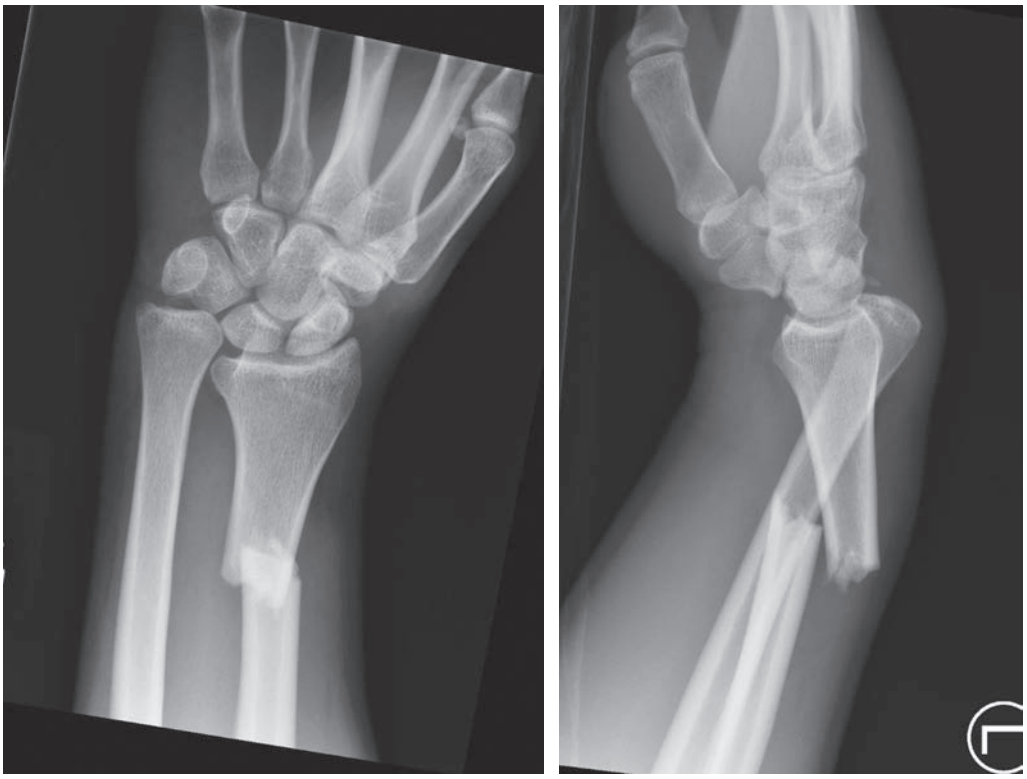
FIGURE 43-4 Brachial artery injury with elbow dislocation.

the bones that require stabilization and have different properties of mechanical rigidity, different amounts of requisite surgical dissection and trauma, different risk profiles, and, of course, differences in the time required to achieve application.

SPLINTING/CASTING

The efficacy of a well-molded splint or cast cannot be overstated. Current widely employed splints of plaster of Paris and moldable fiberglass provide efficient and effective means of stabilizing the injured limb.[19] They provide effective pain control, decrease risk to the overlying skin and the underlying vascular tree, and facilitate patient transport and transfer. In



A

B

FIGURE 43-5 (**A**) Galeazzi fracture dislocation. (**B**) Monteggia fracture dislocation.

many cases, splinting with conversion to casting will provide definitive treatment in the closed management of fractures and dislocations. In other cases, splints provide optimal initial treatment until surgical stabilization occurs.[20]

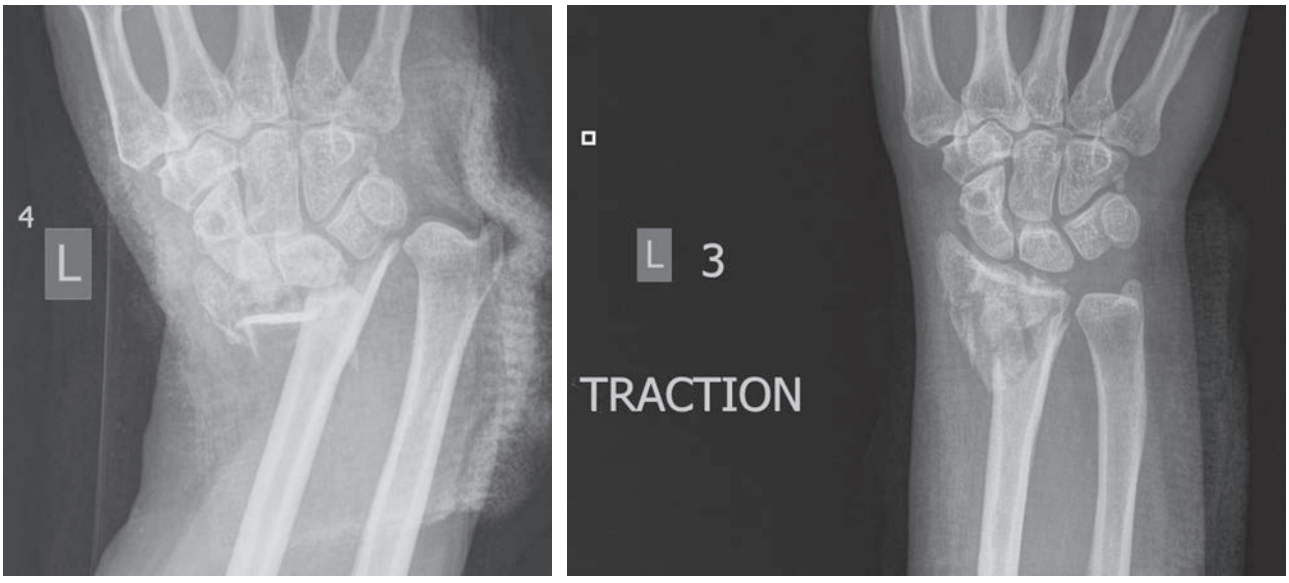
Splinting materials should be readily available in any emergency department. Typically, a dedicated work station, platform, or cart should be maintained and well-stocked with undercast padding, differing widths of material, finger traps, and conforming and nonconforming overwrap.

The application of these splints should be performed by those with specific training, as improperly molded splints that are insufficiently padded or without appreciation for the underlying anatomy can be deleterious to both the skin (resulting in pressure sores or decubiti) and vascular tree (compromise secondary to an overly compressive wrap).

TRACTION

The application of traction, particularly to injuries of the lower limb, can also be extremely effective in mitigating pain. In addition, traction will counteract the shortening of the limb, resulting from the reflexive contraction of opposing muscle groups. In the upper extremity, traction is not commonly employed in the developed world, as appropriate splinting will yield to operative treatment for those fractures where anticipated shortening is expected.

A



B

FIGURE 43-6 (**A**) Traction view of distal humerus. (**B**) Traction view of distal radius.

EXTERNAL FIXATION

The application of percutaneous wires and pins, tensioned with bridging bars and struts, has been an important component of fracture care for nearly 200 years. More modern techniques of external fixation were implemented by Hoffman.[21] In most patients, the external fixator is used to align fractures, whether as a temporizing or definitive method.[22] In other instances, external fixators are used as an extremely effective method of providing elevation to limit edema or controlling unstable joints to prevent recurrent dislocation and/or preventing disruption of surgical repairs of an artery, nerve, or the skin.

As temporizing treatment, fixators permit operative disassembly and re-creation of the traumatic deformity, allowing

TABLE 43-4: Skeletal Fixation Methods

Technique	Common	Pros	Cons
Plate fixation	Humerus	Anatomic fixation	Operative time
	Radius	Rigid	Blood loss
	Ulna	Immediate range of motion	Technique dependent
	Clavicle	Possible weight bearing	Dissection and soft tissue disruption
	Metacarpals	Low dependence on radiography	
	Metatarsals	No external orthosis required	
Intramedullary fixation	Femur	Strong	Malrotation possible
	Tibia	Early weight bearing typically permitted	Large radiography dependence
	Humerus	Immediate range of motion	Embolization of marrow contents
External fixation	Tibia	Limited blood loss	Pin tract infections
	Femur	Simple technique	Pin loosening
	Humerus	Fast	Expensive
			Bulky
Splint	Any appendicular bone	Cheap	Obscures soft tissue
		Easy to apply	Possible decubiti
		Fast	Immobilizes joint
		No operating room requirement	Least rigid
Cast	Any appendicular bone	Cheap	Obscures soft tissue
		Easy to apply	Decubiti
		Fast	Immobilizes joints

for thorough repeat debridement. For the patient who is critically ill, external fixation provides a means of damage control orthopedics to mitigate the adverse consequences of instability of a long bone (pain, extravasation of marrow contents, inflammatory cascade).[22]

In the upper extremity, external fixation is most commonly employed for fractures of the humeral shaft and distal radius and unstable fractures and dislocations of the elbow.[23]

INTERNAL FIXATION

The modern orthopedic surgeon is trained to incorporate a knowledge of extremity anatomy and biomechanical properties of implants to achieve fixation in the least disruptive means possible. Routine instruction in cadaveric anatomy, formal and informal didactics, and "saw bones" courses provide the orthopedic trainee the opportunity to learn the rapidly evolving techniques of skeletal fixation.

Plating. Although more disruptive to the soft tissues, plating fractures of the long bones of the upper extremity (humerus, radius, and ulna) results in high union rates.[24] Additionally, this technique facilitates early rehabilitation and nursing care. Intramedullary implants, although biomechanically superior in fatigue and load (failure strength) compared to plates, have not become quite as popular. The skeletal structure of the upper extremity does not favor intramedullary implants, because they are less likely to provide adequate rotational or longitudinal stability to permit immediate and unrestricted weight bearing.

Intramedullary Fixation. Intramedullary fixation for almost any tubular bone of the upper extremity is "friendly" to soft tissue. In ballistic injuries of the humerus and in some mangling injuries of the forearm, especially those involving the ulna, intramedullary fixation is preferred. As noted earlier, rotational stability is comparatively difficult to provide to the upper extremity, however, because the intramedullary diameters of the forearm bones do not permit implant sizes amenable to stout locking bolts and targeting guides. Yet, blood loss and surgical time are decreased compared to plating techniques.

Tension Band and Interosseous Cerclage. Interosseous cerclage provides an effective means of restoring skeletal anatomy in certain fracture patterns, particularly those with comminution, small fragments, or ligamentous avulsion injury.[25]

MANAGEMENT OF SPECIFIC FRACTURES AND DISLOCATIONS

A review of the diagnosis and management of fractures and dislocations in the upper extremity is provided in the following sections, and a summary of operative indications is provided in Table 43-5.

Sternoclavicular Dislocation

Injuries of the sternoclavicular (SC) joint occur with high-energy trauma. Notoriously difficult to diagnose with physical examination and plain radiography, posterior dislocations of this joint can result in significant morbidity. For example, reports of injuries to the trachea, esophagus, and brachial plexus are common in patients with untreated posterior SC dislocations.[26]

TABLE 43-5: Important Clinical Presentations and Their Associated Findings: What Not to Miss

Condition	Do not miss!!!	Comment	Treatment
Sternoclavicular dislocation	Posterior displacement into the mediastinum	Thoracic surgeon recommended for reduction	Reduction (closed if possible)
Scapular fractures	High index of suspicion for other serious, possibly life-threatening problems	Rule out injury to the chest, cervical spine, or neurovascular structures	Workup for other associated injuries
Proximal humeral fractures	Nerve injuries are common, especially involving the axillary nerve	A vascular injury may be present even if a radial pulse is palpable, due to the presence of multiple collateral vessels around the shoulder	
Proximal humeral fractures	Open fractures into the armpit may be small and overlooked	Small puncture lacerations are at high risk for severe infections of the chest wall (such as necrotizing fasciitis)	Early recognition of aggressive irrigation and debridement in OR and broad-spectrum IV antibiotic treatment
Humeral shaft fractures		The radial nerve is at highest risk, particularly in the distal third of the shaft	Coaptation splint is effective for most humeral shaft fractures
Elbow trauma	Care should be taken to identify associated injuries, which may include trauma to the median, ulnar, and radial nerves, as well as the brachial artery	Note this is a complex set of articulations including the ulnohumeral, radiocapitellar, and proximal radioulnar joints	
Elbow dislocations	Nerve and vascular injuries	Always assess and note stability during range of motion after reduction	
Elbow dislocation, complex type	The "terrible triad of the elbow"	Fracture-dislocation of the radial head, coronoid, and injury to the collateral ligaments	Surgical treatment is required with reconstruction to restore stability to the elbow
Supracondylar elbow fractures	Nerve injuries most commonly involve the median nerve or its anterior interosseous branch; rule out brachial artery injuries	Nerve injuries often recover with expectant management	
Distal radius fracture	Acute carpal tunnel syndrome	This is a "compartment" syndrome involving the median nerve	Urgent surgical decompression
Proximal radial head fractures	Associated injuries to the distal radioulnar joint with proximal migration of radius and injury to interosseous membrane	This is termed *Essex-Lopresti* fracture-dislocation	Check for elbow and wrist stability and range of motion
Distal radial shaft fractures	Associated distal radioulnar joint dislocation	This is termed *Galeazzi fracture-dislocation* and is more common in children	
Radius and ulna shaft fractures	Associated risk of compartment syndrome has been reported		
Wrist pain	Scaphoid fractures	These can be difficult to see radiographically on presentation	Conventional wisdom is to follow the clinical exam and picture more than initial radiographs
Hook of hamate fractures	Both ulnar and median nerve injuries may be associated with hook fractures	A thorough examination of motor and sensory function should be documented	
Perilunate and carpal dislocations	Associated median nerve injury is common		
"Fight bite" or clenched fist injuries	Septic arthritis of metacarpophalangeal joint	Always assume that the tooth entered deep into the joint	Systemic antibiotic and surgical arthrotomy and irrigation in the OR are the rule

(*continued*)

TABLE 43-5: Important Clinical Presentations and Their Associated Findings: What Not to Miss (*Continued*)

Condition	Do not miss!!!	Comment	Treatment
Felon	Direct extension of infection to periosteum	Associated bone involvement of this deep infection	Deep incisions and drainage
Compartment syndrome	Do not wait for paresthesia, pallor, or pulselessness	Pain out of proportion should be enough to raise suspicion	Fasciotomies should be performed emergently
High-pressure injection injuries	Small puncture wound but these injuries travel proximally down the fascial planes	Verify the type of solution injected because oil-based paints create chemical burns	Wide incision and drainage with debridement of all paint material

IV, intravenous; OR, operating room.

In the patient with tenderness about the SC joint or asymmetry on plain radiography, a CT examination is warranted. In addition, CT angiography provides opacification of the large, proximal arterial and venous structures adjacent to the SC joint (Fig. 43-7).

Reduction of posterior SC dislocations is mandatory, preferably at a center with cardiothoracic surgery available in the unusual event that a major vascular injury is present as well. Suture, transarticular plating, and ligament reconstruction are all reasonable methods of treatment. With closed treatment, recurrent dislocation is possible. Additionally, recurrent instability is difficult to detect and requires follow-up CT, further supporting open reduction and fixation.[27]

Anterior dislocations carry less morbidity and are generally treated with closed reduction. Although recurrent instability can be common, this does not carry the same danger as unreduced or recurrent posterior dislocations.[28]

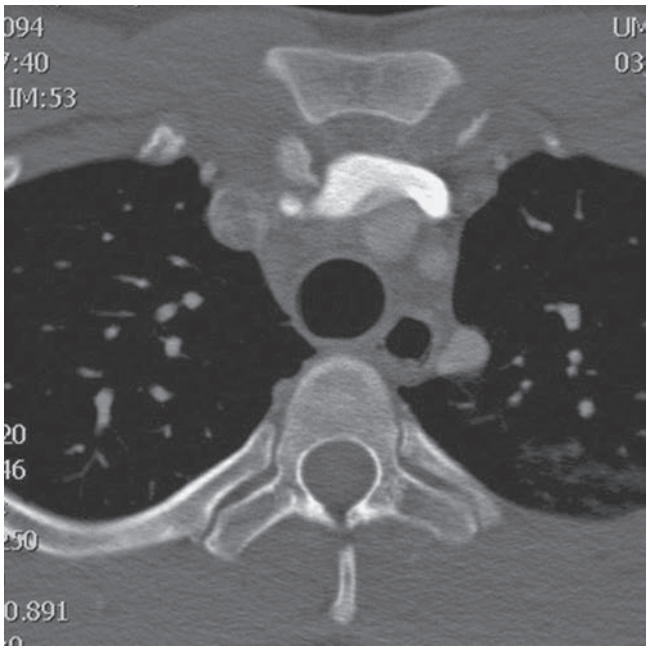


FIGURE 43-7 Axial computed tomography image of posterior sternoclavicular dislocation.

Fracture of the Clavicle

Fractures of the clavicle are extremely common, particularly in the polytrauma patient. Diaphyseal fractures of the clavicle are much discussed and have been the subject of quality randomized controlled trials (RCTs). A recent meta-analysis of these studies suggests that, although functional outcomes are modestly improved with surgical treatment, secondary operations are common, particularly as they relate to symptomatic hardware.[29]

Recent studies suggest that mid-shaft fractures displaced more than 100% may benefit from operative treatment, citing improved shoulder outcome scores. In many surgeons' opinions, this potential benefit is often outweighed by the possible risks of operation, including significant hemorrhage, need for removal of symptomatic hardware, anterior chest wall numbness, and unsightly scarring.[30,31]

No study to date has validated early operative fixation to facilitate rehabilitation. In the author's experience, patients with diaphyseal clavicle factures who are permitted unrestricted weight bearing on the upper limb for transfers, gait training, and activities of daily living (ADLs) do so quickly and without an apparent increased risk of nonunion. At the Shock Trauma Center at the University of Maryland, operative treatment for clavicle fractures is reserved for open injuries, evolving neurologic deficit, and in rare patients, injuries requiring vascular access or stabilization for vascular reconstruction.

Fractures of the lateral third of the clavicle, particularly those that are displaced and involve disruption of the coracoclavicular ligament complex, will often progress to symptomatic nonunion and the case for operative intervention is more substantial.[32]

Fracture of the Proximal Humerus

Neer's original description of proximal fractures of the humerus describes the following four parts: greater and lesser tuberosities, head, and shaft fragments.[33] The fragment qualifies as a "part" if displaced more than 1 cm or angulated more than 45°. Quality research has added to our understanding of the management of these injures, particularly in the elderly, where nonoperative and operative outcomes are similar.

In open injuries (commonly two-part fractures), careful assessment is indicated. Injury to the axillary nerve, brachial

plexus, and axillary or brachial vessels can occur. For two-part fractures in the young polytrauma patient, rigid fixation with either an intramedullary implant or a locking plate permits early functional return and facilitates rehabilitation. The results between these two techniques have been widely studied with similar long-term functional outcomes.[34]

In three- and four-part fractures, increased complications are noted, both in young and aging patients. A recent RCT comparing open versus closed treatment in elderly patients found such an outcome.[35] This study excluded patients who "required" operative treatment. Thus, significant debate remains regarding whether displaced fractures of the proximal humerus are better served with operative versus nonoperative treatment,[36] particularly in those age 60 years or older. In general, fractures in the young patient with displacement more than 1 cm or 45° of angulation are generally deemed operative with careful consideration of comorbidities.

In the elderly patient, fractures of the proximal humerus represent an area of significant controversy. Open reduction results in not uncommon hardware complications, whereas hemiarthroplasty often results in residual pain and inferior shoulder scores. More favorable results have been achieved with reverse arthroplasty, balanced at the expense of significant bone resection and lack of a good option for revision. Operative treatment is indicated for nearly all glenohumeral fracture-dislocations. In fracture-dislocations in young patients, open reduction and fixation is recommended because it preserves the skeleton and associated muscle units. In the elderly patient, good results have been achieved with arthroplasty.[37]

Fractures of the Shaft of the Humerus

In isolation, fractures of the shaft of the humerus are successfully and reliably treated with bracing.[38] Bracing depends on the coactivation of the biceps and triceps muscles, gravity, appropriate careful molding, and routine clinical follow-up. A mild varus deformity can be expected, without significant functional or cosmetic detriment. Although some studies suggest earlier return to function with an open operation, splinting results in acceptable alignment and functional outcomes in the majority of patients.[39]

In the polytrauma patient, treatment of the fractured humerus warrants more careful consideration. In a patient with an injury to the contralateral upper extremity, rigid internal fixation provides immediate functional benefit, as previously noted. Feeding, hygiene, and other routine ADLs are permitted immediately. With robust fixation, the patient with a fractured humerus is also permitted immediate and unrestricted weight bearing, allowing for crutch training, transfers, wheelchair propulsion, and so on.[40] In a patient with an associated injury to a lower extremity, it has been found that plate fixation of the humeral fracture reduces length of hospital stay, allows for discharge to lower level of care facilities with improved access to therapists, and leads to overall decreased inpatient rehabilitation stays.

In certain instances, intramedullary nail fixation of the humerus is preferred, as it generally requires less surgical time and less blood loss. External fixation is also an effective means of treatment. Union rates, functional outcomes, and complication risks are similar across these treatment methods.[41,42]

Fracture of the Distal Humerus

Fractures of the supracondylar humerus, without intra-articular extension, are also amenable to closed treatment. Careful bracing and prescribed therapy are important in achieving satisfactory outcomes. Similar to the humeral shaft, patients who have sustained injuries to both an upper and lower extremity will benefit from operative treatment and rigid internal fixation, in order to permit ADLs.[43] Weight bearing is generally prohibited because fractures in the periarticular region are not as amenable to fixation that provides an adequate biochemical milieu for early healing.

Extension of the distal fracture into the intercondylar area generally requires operative treatment to obtain the best clinical result. Fixation of the components of the joint permits immediate range of motion (ROM), and in many cases, splinting can be avoided and ADLs encouraged.[44]

Dislocation and Fracture of the Elbow

Simple elbow dislocations, which concentrically reduce, are treated closed. Assessment of stability is necessary, in order for a guided rehabilitation program. Typically, in the awake, alert, and cooperative patient, the dynamic stabilizing muscles (biceps, triceps, brachialis) permit immediate ROM to tolerance and ADLs. In the obtunded patient or one lacking in muscle stabilizers, splinting at 90° and assisted ROM are prescribed. Limits are set by the provider assessing the stability of the elbow after reduction, increasing the prescribed ROM over a period of several weeks.

In dislocations involving the key stabilizers of the elbow (radial head, coronoid, trochlea, and capitellum), operative treatment is generally indicated. Restoring anatomic joint relationships is critical in achieving stability and a satisfactory outcome. Mini-plate fixation, intramedullary implants, radial head arthroplasty, and precontoured plates are currently available options.[45]

Patients in whom the elbow will require additional stabilization (external fixation) have undergone ligamentous repair or fixation of small but critical components such as the coronoid or radial head. This is especially true in patients who have a concomitant injury to a lower extremity or are obese. These fixators can be unlocked by the therapist, permitting supervised ROM, and then locked again. This will prevent recurrent dislocation in the patient whose arm is not satisfactorily braceable or in the patient who assumes a functional quadruped status secondary to their other injuries.[46] Methods of external and internal hinged fixation are now available as well.

Fracture of the Shaft of the Radius

Displaced fractures of the diaphyseal radius in adults are fractures "of necessity." The actions of the brachioradialis, supinator,

and pronator muscles act upon the radius to cause a predictable deformity. The resulting malunion and associated disability are not prevented with closed, nonoperative treatment.[47] Therefore, rigid internal plate fixation is required for this fracture.[48]

In certain patients, a fracture of the radial shaft will result in dislocation of the distal radioulnar joint. This is commonly referred to as a Galeazzi fracture (Fig. 43-5A). Anatomic plate fixation of the radius fracture will typically result in reduction of the distal radioulnar joint. The injury is then splinted for a period of several weeks, with gradual resumption of prosupination to allow satisfactory healing of the disrupted distal radioulnar joint.[49]

Fracture of the Shaft of the Ulna

An isolated fracture of the ulna shaft does not usually result in malalignment if appropriate splinting is performed; thus, closed treatment is often satisfactory. In patients with bilateral upper extremity fractures, an argument can be made for operative fixation to permit unrestricted range, weight bearing, and ADLs.[50]

Monteggia Fracture

A fracture of the proximal ulna requires a careful radiographic examination of the proximal radioulnar joint. An associated dislocation of the radial head is termed *Monteggia fracture* (Fig. 43-5B). Difficulty in maintaining reduction of the radial head with closed treatment of the ulnar fracture has led to the wide adoption of anatomic and rigid fixation of the shaft of the ulna. In patients in whom the radial head fails to reduce, open reduction of the proximal radioulnar joint is accomplished by extraction of the entrapped annular ligament.[51]

Combined Fractures of the Shafts of the Radius and Ulna

Displaced fractures of the shafts of the radius and ulna, commonly referred to as *both bones* fractures, are treated with rigid plate fixation. Accounting for the anatomic contours of each bone, plate fixation results in union rates of better than 98%. In many patients, plate fixation will permit unrestricted activities immediately postoperatively, including ADLs and full weight bearing.[52]

Fracture of the Distal Radius

Fractures of the distal radius are grouped into extra- and intra-articular injuries. Restoration of the distal anatomy of the radius, accounting for the relationship of length to the ulna, palmar tilt, radial inclination, and articular congruity, is required for an optimal result in young patients. In sedentary patients, malalignment is felt to be more tolerated. Consensus opinion regarding exact age cut-offs over 50 and the degree of acceptable malalignment that will still permit satisfactory outcome does not exist.[53]

Partial articular fractures generally warrant operative treatment regardless of patient age or activity level. These fractures have a propensity to shorten significantly with resultant "point loading" and rapid degenerative arthritic changes.

High-energy articular fractures with multiple joint fragments are typically treated operatively. In the young patient, optimal outcomes require anatomic restoration of alignment and joint congruity. Current techniques favor neutralization of the forces that lead to shortening and impaction, typically by either external fixation or internal fixation with a spanning bridge plate, followed by anatomic restoration of critical joint fragments using mini-locked plates.[54]

Fracture-Dislocation and Fracture of the Carpal Bones

Perilunate dislocations are common in patients after high-energy trauma. Lunate dislocations are common and frequently misdiagnosed, leading to significant morbidity. A compressive median neuropathy results from complete lunate dislocation, and urgent reduction is required for an optimal result.[55]

Careful examination of wrist radiographs is paramount. Fractures of the other carpal bones in high-energy trauma may be present, and careful inspection of Gilula's lines is mandatory (Fig. 43-8). Disruption of these arcs represents an intrinsic carpal ligament injury. Disruption of other carpal relationships may also represent longitudinal axial disruptions. In patients in whom an abnormality is suspected, contralateral wrist views can aid in the diagnosis of intercarpal instability.[56]

Fractures of the scaphoid can lead to significant disability if not recognized and treated appropriately at presentation. Displaced fractures of the scaphoid (>1 mm) require operative treatment, as union is delayed and nonunion is common with attempts at closed management. Nondisplaced fractures are effectively treated with immobilization of the thumb in a Spica cast for a period of 6 to 8 weeks.[57]

In patients with tenderness in the anatomic snuffbox, a CT scan or magnetic resonance imaging (MRI) can be an effective method for diagnosis, with sensitivity of more than 95%.[58] If any question regarding the diagnosis remains, immobilization with a thumb Spica splint for 3 weeks is appropriate until repeat x-rays are obtained. Delay in immobilization will frequently result in further displacement of the fracture, prolonging the time to union, altering carpal kinematics, and causing a possible nonunion.

Fractures of the carpometacarpal joints, particularly in patients after a motorcycle crash, can represent fracture-dislocations and other complex injuries. The base of the thumb is frequently dislocated by a hyperextension force, resulting in rupture of the palmar oblique and dorsal radial ligaments and chronic instability.[59] Thus, avulsion injuries in the hand require careful assessment for stability.

Fractures of the Metacarpal Bones

Nondisplaced fractures of the metacarpal bones are generally treated with splinting and early mobilization of the

FIGURE 43-8 Anteroposterior radiograph of perilunate dislocation with disruption of Gilula's lines.

interphalangeal joints. These fractures will heal in 3 to 4 weeks, permitting relatively early rehabilitation.[60]

Metacarpal fractures that are displaced and result in significant malangulation or shortening, particularly when multiple, require operative treatment. Restoration of the rotational malalignment is critical. As the patient regains flexion at the metacarpophalangeal joint, malrotation can manifest in disabling "scissoring." Sagittal malangulation of the metacarpal necks (15° for index, 25° for middle, 35° for ring, and up to 45° for the small finger) is accepted as the motion at the proximal carpometacarpal articulations permits compensatory motion in the sagittal plane.[61] Greater malangulations are an indication for operative treatment. Fixation techniques for the metacarpal bones include transmetacarpal pinning, intramedullary "bouquet" pinning, plate fixation, and external fixation.

Fracture of the Phalanges

Nondisplaced fractures of the phalanges are treated closed, also. Stiffness of the proximal phalangeal joints after trauma or surgical dissection is frequent and may take many months to resolve.

Slight malalignment in any plane results in an obvious and disabling clinical deformity. Displaced fractures of the phalanges are typically treated with K wire fixation, although the proximal phalanx is amenable to plate fixation as well.[62]

Displaced fractures involving the metacarpophalangeal joint typically represent ligamentous avulsion or impaction. Displacement of more than 1 mm requires operative treatment. Fractures involving the proximal interphalangeal joint are notoriously difficult to treat. Small (1.0 mm) screws are often required, as are thin Kirschner wires (0.035/0.028). External fixation for fracture-dislocations of the proximal interphalangeal joint can be an option.

VASCULAR INJURIES IN THE UPPER EXTREMITY (SEE CHAPTER 45)

Physical Examination

Assessment of a presumptive vascular injury should be rapid. Patients presenting with a tourniquet in place represent one of the few true limb-threatening emergencies. A thorough history should be obtained from the emergency medical service personnel to include mechanism of injury, presence of pulsatile bleeding, presence or absence of movement of the hand or arm prior to placement of the tourniquet, and exact time of placement. Typically, the upper extremity with an appropriately applied tourniquet will lose motor function approximately a half-hour after application. Field tourniquets are applied as a lifesaving intervention but do not afford controlled application of pressure. In the setting of the appropriately applied tourniquet, one must remember that the limb that was frequently *relatively* ischemic with only collateral flow is now rendered *absolutely* ischemic. Thus, the ongoing muscle ischemia represents an emergent condition. Within 4 hours of ischemia, skeletal muscle cells begin to undergo irreversible cell death, with deleterious increases in serum lactate, potassium, and myoglobin.[63,64]

Once a primary assessment and ATLS protocols have been completed, removal of the tourniquet should be completed in a controlled fashion. If pulsatile bleeding occurs, replacing the field tourniquet with a standard pneumatic tourniquet is necessary. This permits hemostasis with a known pressure over a broader and safer area. If pulsatile bleeding is anticipated by the obvious nature of the wound, immediate operative intervention is required. The tourniquet should be left in place until the patient is positioned on the operating room table and

anesthetized. Then, under appropriate conditions with excellent lighting, the surgical team removes the tourniquet while providing direct pressure, rapid exploration, and vascular control.

In patients in whom the bleeding can be effectively controlled with a compressive dressing, the tourniquet should be removed to permit collateral flow, even in patients with a presumed injury to the brachial artery.[65] In the upper extremity, the presence of collateral flow will permit adequate perfusion to prevent irreversible muscle damage during an appropriate secondary survey and diagnostic testing.[66]

A palpable pulse in the normotensive patient nearly eliminates the possibility of a vascular insult requiring operative intervention. In the patient without a palpable pulse, adequate assessment of the color of the limb under appropriate lighting is valuable. Assessment with an incandescent light source or flashlight to assess capillary refill, turgor, and color of the digits can be very helpful.

In addition to the "hard signs" of vascular injury (eg, pulselessness, pale limb, pulsatile bleeding, expanding hematoma), "soft signs" may alert the clinician to a vascular injury. A penetrating injury immediately adjacent to the course of a major vessel, widely displaced fractures or dislocations, a peripheral nerve deficit, or nonpulsatile hemorrhage should be taken into account and may warrant angiography.[67]

Diagnostic Modalities

PENCIL DOPPLER

In a patient with an absent pulse and color difficult to assess, a pencil Doppler can provide important data. First, one must ensure the Doppler is functional. Using the examiner's own finger as a baseline exam, the pencil Doppler is placed at the "swirl" of the fingerprint. A properly functioning Doppler will easily provide biphasic signal of the small digital arteries in the normotensive healthy examiner and then can be used to verify arterial patency for the injured patient. Once confirmed, a Doppler examination of the brachial artery medial to the biceps tendon, the radial and ulnar arteries, and the palmar arch is completed. A Doppler Allen test, completed by sequential and independent compression of the radial and ulnar arteries at the wrist, can provide data as to the patency of each. A Doppler examination of the fingers can also be completed to assess the perfusion of the digits. The patient who is hypotensive or peripherally vasoconstricted will have altered perfusion of the distal extremities, complicating the examination.

CT ANGIOGRAPHY

CT angiography has generally replaced formal angiography in the initial assessment of the vascular tree. This modality permits rapid and accurate assessment with sensitivities and specificities above 95%.[68,69] In the limb with a well-defined zone of injury, CT angiography is not required for diagnosis.

Treatment

PRIMARY REPAIR

Well-localized vascular disruptions are suitable to primary repair.[70] Commonly, the mechanism of injury alone will provide the surgeon a reasonable plan of action. Injuries that result from a penetrating focal laceration (eg, knife, glass, metal, shrapnel, or iatrogenic transection) are generally amenable to resection of a small portion of the injured vessel and a lateral repair or an end-to-end anastomosis.[71]

SHUNT (TEMPORARY INTRAVASCULAR SHUNT)

Temporary urgent intraluminal shunting as the initial maneuver can often be predicted by the mechanism of injury. An injury to the brachial artery after a rollover motor vehicle crash, shotgun blast, or any crush injury implies a lack of collateral flow, as the resultant zone of injury can be large. In such a patient, insertion of a shunt to expeditiously restore flow is appropriate[72] (Fig. 43-9).

The shunt allows the surgical team adequate time for the critical steps of a tumor-like debridement. In many patients in whom a shunt is required, the zone of injury is significant, as is the potential for contamination and muscle necrosis. A debridement beginning through a zone of normal, uninjured tissue is recommended. Similar to that of resection of a sarcoma, the dissection is begun in normal, noncancerous tissue, respecting neurovascular planes and intervals. In this manner, a complete debridement is ensured. The debridement is often the longest and most critical part of limb salvage and can be completed in a thorough and nonrushed manner through restoration of arterial inflow (and/or venous outflow) by the shunts.

Temporary intravascular shunts are also extremely helpful in the setting of a vascular injury with concurrent fracture of a long bone (ie, Gustilo 3C). By rapidly inserting a temporary intravascular shunt, the orthopedic team can then bring the bone out to length and fixate it at this position in a controlled manner. Once fixed, the trauma/vascular surgeon is then able to reconstruct the vascular injury in a limb that will not stress the subsequent repair.[72]

INTERPOSITION VEIN GRAFT

In instances where injury of the vessel involves more than 2 to 3 cm, vascular reconstruction with an interposition vein graft is recommended. In the upper extremity, the cephalic, basilic, and associated brachial veins are suitable graft sources and rapidly employed. These veins are frequently dissected during the initial

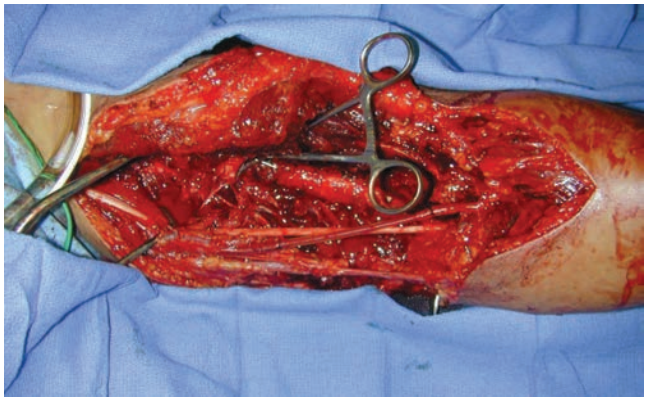

FIGURE 43-9 Shunt of brachial artery.

exposure, and care should be taken to preserve them.[73] Inspection of these veins during the approach will identify obvious trauma. If the local veins are traumatized, a greater saphenous vein from the thigh or ankle is preferred. In order to facilitate a two-team surgical approach, the contralateral greater saphenous vein is harvested, as the vein harvest team will be positioned on the opposite side of the operating table from the injured upper limb. This also highlights the need to prepare and drape the entirety of a lower limb (ie, even with an isolated injury to an upper extremity) in cases that may require a vein graft.

Management of Specific Vascular Injuries

SUBCLAVIAN AND AXILLARY ARTERIES

Traction injuries to the vessels are often devastating because they are frequently associated with severe injuries to the brachial plexus. Fortunately, significant progress has been made with endovascular stenting of proximal arterial lesions.[74]

Injuries that require exploration for repair or grafting will require familiarity with the brachial plexus. As the primary determinant of outcome, an associated injury to the brachial plexus warrants special attention. A perfused but inanimate hand is of little, if any, use to the patient. Therefore, identification and preservation of the brachial plexus are mandatory during open exposure of either the subclavian or axillary artery. Observation of a transection or avulsion should be communicated early to the "peripheral nerve" surgeon, preferably for intraoperative consultation. Generally speaking, the functional outcome of an injured upper extremity is tied to the integrity of major peripheral nerves. Therefore, the most appropriate time for proper identification and inventory is during the initial exposure for arterial repair. In cases of sharp transection of a trunk, division, or cord of the plexus, immediate repair will often result in a reasonable functional outcome. In those instances where repair is not possible, insertion of a nerve graft similarly can provide a good, if not excellent, result. If neither grafting nor repair is possible, identification of the injured nerves is critical. Nerve transfers are now recognized as a valuable tool in providing recovery and can be implemented early, provided the surgeon has an accurate understanding and identification of the nerves that are deemed unreconstructible.[75] Nerve transfers, when performed early, facilitate expeditious recovery.[76]

BRACHIAL ARTERY

For injuries of the brachial artery, shunting is performed when critical ischemia is present. Fortunately, the mechanism of injury will often predict the degree of ischemia, as previously noted.[77] A shotgun blast at the humeral level, crush injury, or entrapment will frequently result in disruption of the profunda brachii artery, as well as the ulnar and radial collateral systems. With disruption of these collaterals, shunting provides immediate reperfusion of the forearm muscles.

Fortunately, the upper extremity maintains a robust collateral system about the elbow (Fig. 43-10A). The superior and inferior collateral systems medially, as well as the profunda brachii and associated radial collateral systems, will maintain perfusion sufficient for at least short-term viability in many cases. Intraoperatively, assessment of perfusion will occur based on the color of the hand, the contractility of the forearm muscles, and back-bleeding from the surgically identified and isolated distal arterial stump.

RADIAL AND ULNAR ARTERIES

An injury to either the radial or ulnar artery, in isolation, will typically not result in ischemia of the hand or forearm (Fig. 43-10B). Standard clinical examination to include assessment of color, capillary refill, palpation of pulses, and an Allen test should be a routine part of every examination of the hand and upper extremity with significant trauma, as previously noted.

Importantly, an innocuous low-velocity gunshot wound or penetrating sharp injury to the forearm can result in a significant hematoma and a possible compartment syndrome. Injury to the anterior interosseous artery, in particular, can result in significant bleeding within the deep compartment of the forearm, resulting in the compartment syndrome cascade of swelling, ischemia, nerve dysfunction, and muscle necrosis.

In instances where either the radial or ulnar artery is injured and subsequently repaired, only 47% are found to be patent at 1 year.[78] In the same study, if both vessels are injured and only one repaired, patency rates approach 100%. In those cases where both were repaired, both remained patent in 41% of patients. This is an obvious demonstration of the robust collateral retrograde supply that the patent vessel maintains through a healthy palmar arch.

In patients in whom the surgeon chooses to maintain perfusion via repair of only one vessel (other vessel thrombosed or ligated), the author will confirm perfusion to each digit with capillary refill, a Doppler signal, and, if exposed, back-bleeding in the unrepaired vessel. Consideration is also given to achieving soft tissue coverage over any vascular repair. Additional consideration is given to the possible need for subsequent microvascular reconstructions (Fig. 43-11).

PALMAR ARCH AND DIGITAL ARTERY

The hand enjoys a robust collateral system, composed of the dual contribution of both the radial and ulnar arteries to both the deep and superficial palmar arches.[79] Each digit receives flow from two digital arteries, either of which is sufficient to maintain viability. In some cases, digital viability is maintained with the dorsal circulation alone.

The common digital and palmar metacarpal arteries provide additional redundancy, such that an isolated lesion of either the deep or superficial palmar arch will not cause critical ischemia (Fig. 43-12).

Again, assessment of color, capillary refill, and Doppler examination are the mainstays of evaluation when determining whether or not to undertake microvascular reconstruction in the hand or digits.

In any patient in whom there is question about the perfusion of the hand, there are many relatively conservative measures that can be taken. Warming the patient, adequate resuscitation to limit hypotension, warming the extremity with a warming blanket, ensuring skeletal stability (either

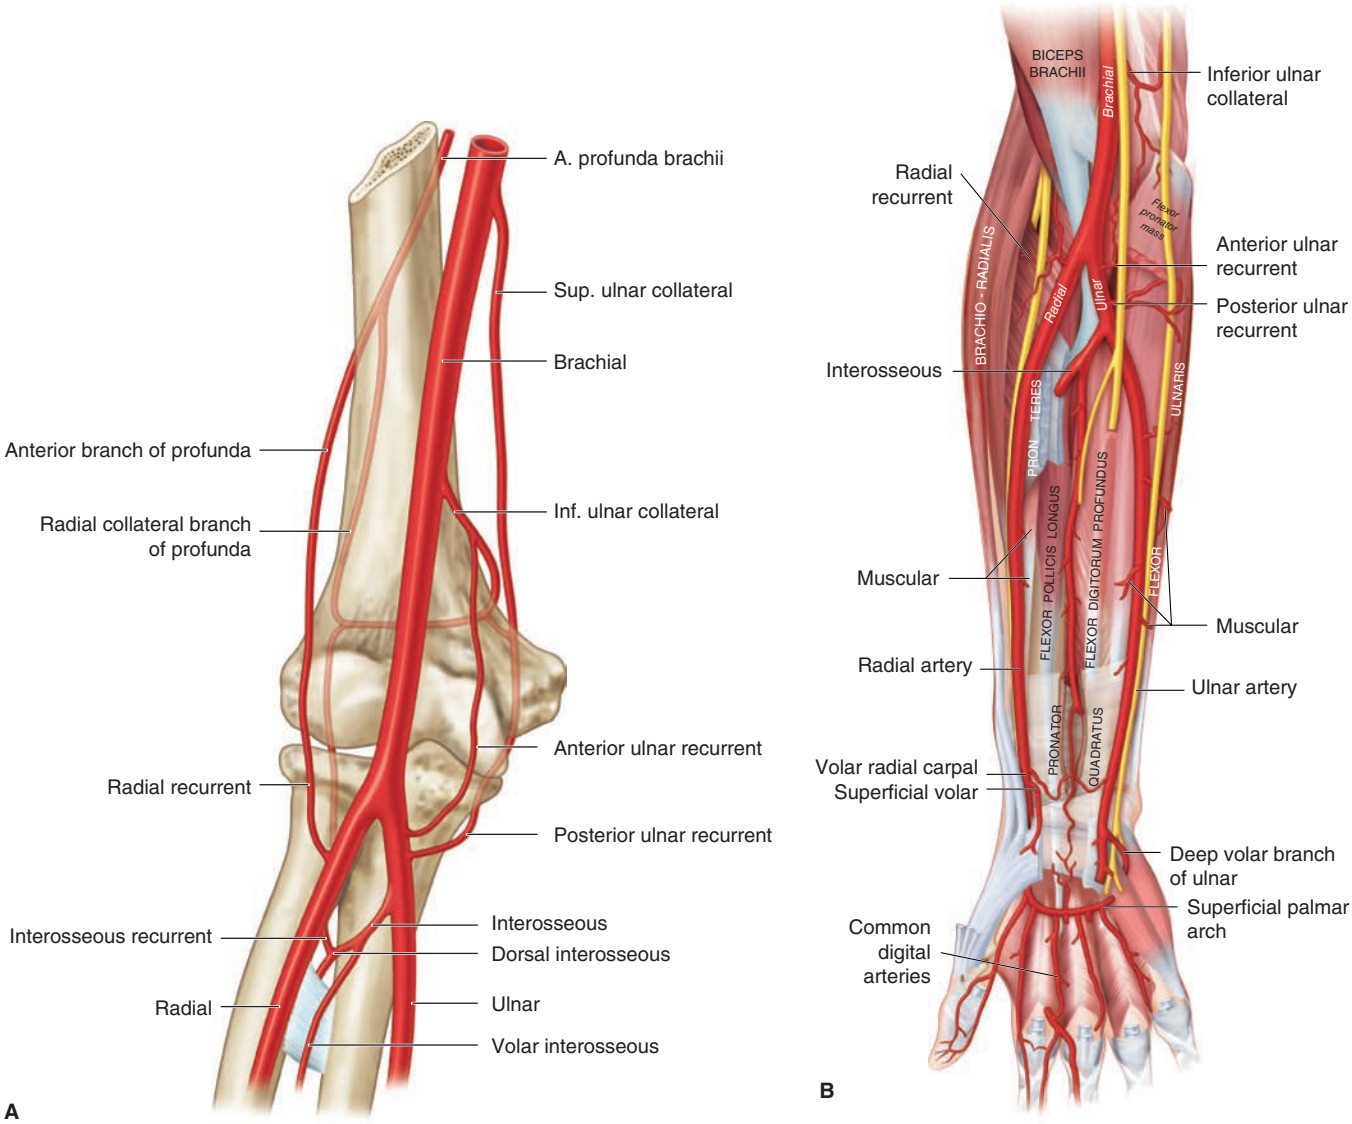

FIGURE 43-10 (**A**) Vascular tree of the arm. (**B**) Vascular tree of the forearm.

through operative fixation or splinting), and providing a regional anesthetic (infraclavicular, axillary, or wrist block) have all been shown to increase perfusion.[80,81]

In cases requiring repair, it is not uncommon to require suture of 8-0 caliber or smaller and the use of an operating microscope or high-power loupes (3.5× or more). In cases of significant trauma, vein grafts from the palmar wrist or dorsal foot are suitable for reconstruction.

NERVE INJURIES IN THE UPPER EXTREMITY

Physical Examination

To provide an accurate assessment of trauma to a peripheral nerve in the upper extremity, a thorough knowledge of anatomy beginning with the brachial plexus and each of its branches is required[82] (Table 43-6). Ideally, a complete examination requires a fully awake and compliant patient; however, even in a patient who cannot follow commands, simple observation of the upper extremity can provide the astute examiner a basic status of the integrity of peripheral nerves. Gross movement of the shoulder, biceps muscle, and wrist and finger motion will give the surgeon a reasonable indication of significant nerve trauma, important to rendering initial care and planning (Table 43-6).

Although the anatomy of the brachial plexus is complex, general injury patterns help the clinician understand the anatomy and pathoanatomy. In general, the plexus can be thought of in three main components corresponding to the trunks: those for shoulder function, elbow function, and wrist/hand function. The upper trunk and respective roots provide motor function via the suprascapular, axillary, and musculocutaneous nerves to the rotator cuff and deltoid,

FIGURE 43-11 (**A–C**) Nearly amputated hand, repair of radial artery, and subsequent utilization of the ulnar artery for end-to-end microanastomosis of the osteocutaneous free fibula graft.

biceps, and brachial muscles, respectively. The C7 root and middle trunk are important to elbow and wrist extension through activity of the radial nerve, and the C8 and T1 (lower trunk) roots are important in the grip and fine motor function of the hand.[83]

Injuries to the adult brachial plexus and peripheral nerves can be the result of a variety of mechanisms.[84,85] Therefore, the author finds it helpful to consider the resultant zone of injury in planning and rendering treatment.

An initial part of triage always should include a description of the injury from the patient if possible. In high-energy trauma, however, this is often obtained from the first responder. Traction injuries are common to motorcyclists, and a detailed history from emergency medical service personnel regarding the accident can be helpful. For example, a motorcyclist with abrasions on his or her helmet or head suggest that the head and cervical spine have been forcibly deviated from the shoulder and plexus. This will commonly result

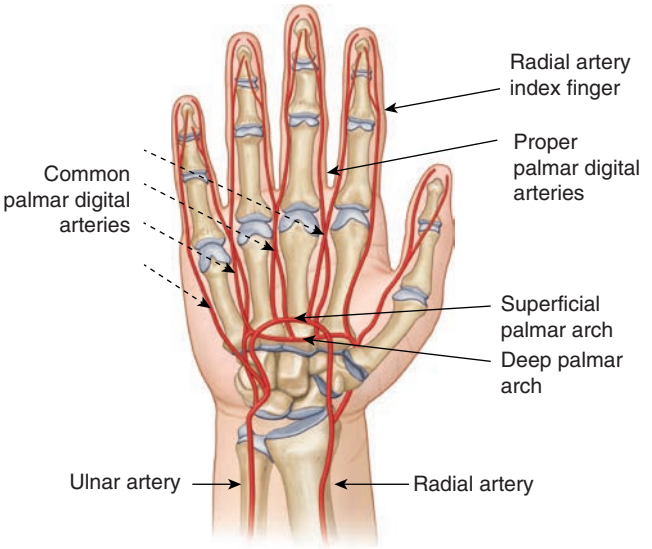

FIGURE 43-12 Vascular tree of the hand.

in an upper trunk lesion with paralysis of the shoulder and elbow.

The examiner should then test all major muscle groups of the upper extremity and their function, including, at a minimum, the following: shoulder abduction (deltoid); external rotation of the shoulder (supra- and infraspinatus, teres minor); elbow flexion (biceps/brachialis); elbow extension (triceps); wrist extension (extensor carpi radials brevis and longus); wrist flexion (flexor carpi radialis and ulnaris); finger extension (extensor digitorum); thumb extension (extensor pollicis longus); finger flexion (flexor digitorum superficialis and profundus); and, particularly, thumb interphalangeal flexion (flexor pollicis longus). The Medical Research Council (MRC) muscle grading system is used to document the degree of strength and deficit (Table 43-7).

Deficits in strength and sensation are documented clearly in the medical record and relayed accurately to other treating physicians so that close monitoring of neurologic function can be accomplished, particularly in patients at risk for a compartment syndrome or an evolving neurologic deficit.

Determination as to whether or not a traction injury is pre- or postganglionic is important. Preganglionic lesions are generally devastating because no useful recovery of an avulsed, preganglionic lesion can be expected. In regard to physical examination, Horner syndrome (ptosis, miosis, and anhidrosis) is a critical finding because it results from a preganglionic avulsion and disruption of the sympathetic innervation controlling these functions and portends a poor outcome.

Diagnostic Studies

Plain radiography and standard CT will not provide specific diagnostic data related to peripheral nerve trauma. A concomitant bone injury, however, can give the clinician an appreciation for the zone of injury or severity of trauma. For example, although the degree of nerve trauma is highly variable in scapulothoracic dissociation, a severely displaced scapula is of course a potential harbinger of a brachial plexopathy. Additionally, several fractures are worth noting as having a high incidence of associated injuries to nerves as follows: clavicle (brachial plexus[86]); shoulder dislocation (axillary and radial nerve injury, uncommonly median nerve[87]); humerus fracture (radial nerve); and Monteggia injury (posterior interosseous nerve).

NERVE CONDUCTION AND ELECTROMYOGRAPHY

Nerve conduction studies will provide objectification of the presence, absence, amplitude, and velocity of the conductive signal propagated by a major nerve in the upper extremity. They are rarely indicated in the immediate posttrauma phase. It will take at least 3 to 4 days for a nerve to demonstrate conduction loss after even severe trauma. Similarly, electromyography (EMG) changes (fibrillations, positive sharp waves) are not apparent until several weeks after nerve trauma. Thus, physical examination remains the mainstay in the diagnosis of acute nerve trauma, whether blunt or sharp.[88]

In the weeks and months following nerve trauma, electrodiagnostic studies (nerve conduction studies and EMG) can provide evidence of nerve recovery, or lack thereof, which will direct the clinician toward either further observation or intervention.[89] The decision to proceed with nerve reconstruction or tendon transfer in the absence of meaningful recovery is based on the wishes of the patient, the surgeon's knowledge of the severity of the nerve trauma, the expected odds of functional improvement with further observation or intervention, the availability of suitable donor nerves or tendons, and the ability of the patient to comply and adhere to the postoperative rehabilitation program.

Importantly, a preganglionic lesion can be characterized by nerve conduction velocities with absence of motor nerve action potentials, as the motor nerve cell body lies within the spinal cord. In contrast, sensory nerve action potentials are maintained, as the sensory cell body lies in the dorsal root ganglion. In the dermatome absent of sensation and corresponding motor deficit and the above findings, particularly with a Horner syndrome, the prognosis is grim.

MRI/CT MYELOGRAM

Advanced imaging of the brachial plexus can include MRI, CT myelogram, or magnetic resonance neurography.[90] In most cases, the history and physical examination will provide the diagnosis, and further clarification as to whether nerve trauma may recover or not will be provided with enough specificity to warrant immediate exploration in cases of blunt trauma.[91,92] In some instances, magnetic resonance neurography can provide images of sufficient quality to discern preganglionic avulsion, prompting early nerve transfers.

TABLE 43-6: Nerves and Muscles of the Upper Extremity

Nerve	Muscles innervated	Test for function	Sensory distribution
Spinal accessory	Sternocleidomastoid	Ipsilateral head tilt, contralateral head rotation; scapular elevation rotation, adduction: head extension, rotation	
	Trapezius		
Dorsal scapular	Rhomboid	Scapular retraction; scapular stabilization	
Suprascapular	Supraspinatus	Arm abduction	
	Infraspinatus	Arm external rotation	
Long thoracic	Serratus anterior	Scapular protraction: scapular stabilization	
Subscapular	Subscapularis	Arm internal rotation, adduction	
Thoracodorsal	Latissimus dorsi	Arm extension, internal rotation	
Pectoral (medical and lateral)	Pectoralis major and minor	Arm internal rotation, flexion, adduction	
Musculocutaneous	Biceps	Arm and forearm flexion; forearm supination	Lateral forearm (lateral antebrachial cutaneous)
	Coracobrachialis	Arm flexion, adduction	
	Brachialis	Forearm flexion	
Axillary	Deltoid	Arm abduction; internal, external rotation	Lateral aspect of shoulder
	Teres minor	Arm external rotation, adduction	
Radial	Triceps	Arm and forearm extension	Dorsoradial hand, thumb (superficial radial)
	Anconeus	Forearm extension	
	Brachioradialis	Forearm flexion	
	Extensor carpi radialis longus and brevis	Wrist extension	
	Extensor carpi ulnaris		
	Supinator	Forearm supination	
	Extensor digitorum communis	Finger, thumb extension	
	Extensor indicis proprius		
	Extensor digiti minimi		
	Extensor pollicis brevis and longus		
	Abductor pollicis longus		
Median	Flexor carpi radialis	Wrist flexion	Volar thumb, index, long, radial half of ring finger; dorsum index, long, radial half of ring finger
	Pronator teres and quadratus	Forearm pronation	
	Flexor digitorum sublimis	Finger proximal interphalangeal joint flexion	
	Flexor digitorum profundus (index, long)	Finger distal interphalangeal joint flexion	
	Abductor pollicis brevis	Thumb abduction	
	Opponens pollicis	Thumb opposition	
	Flexor pollicis brevis (superficial head)	Thumb metacarpophalangeal joint flexion	
	Lumbricals (index, long)	Metacarpophalangeal joint flexion	
		Interphalangeal joint extension	
Ulnar	Flexor carpi ulnaris	Wrist flexion	Entire little finger, ulnar half of ring finger, and ulnar border of hand
	Flexor digitorum profundus (ring, little)	Finger distal interphalangeal joint flexion	
	Abductor digiti minimi	Little finger abduction	
	Flexor digiti minimi	Little finger metacarpophalangeal joint flexion	
	Abductor pollicis	Thumb adduction	
	Flexor pollicis brevis (deep head)	Thumb metacarpophalangeal joint flexion	
	Interossei (volar, dorsal)	Metacarpophalangeal joint flexion, interphalangeal extension	
	Lumbricals (ring, little)	Metacarpophalangeal joint flexion, interphalangeal extension	

TABLE 43-7: Medical Research Council Strength Score

Score	Muscle strength
0	No movement
1	Flicker of movement
2	Movement with gravity eliminated
3	Movement against gravity intact
4	Movement against resistance
5	Full power

0, no contraction; 1, identifiable contraction without movement; 2, identifiable contraction with movement with gravity eliminated; 3, contraction with movement with gravity; 4, contraction with movement against resistance; 5, full power.

Treatment

The treatment for a stretch or concussive injury to the brachial plexus or a peripheral nerve is generally observation for a period of at least 3 to 6 months. Many of these patients will demonstrate a spontaneous recovery. Yet, this algorithm is at odds with the patience of many patients and providers and hopes for an immediate recovery or intervention. Nerve recovery, compared to that of vascular or skeletal treatment, is not immediate. It will take many months for a nerve deficit resulting from a stretch or contusion to recover.

In concussive, blast, avulsed, or crush type injuries, initial treatment is generally observation, therapy directed at maintaining joint suppleness, and splinting. A determination as to whether or not meaningful recovery will occur can be difficult. The presence of a Horner sign, the aforementioned nerve conduction/EMG findings, and lack of motor recovery by 3 to 6 months generally favors surgical management. In instances where pre- or postganglion avulsion can be identified with certainty, early surgical intervention is performed.

Currently, the available literature supports nerve transfers over grafting in the treatment of injuries of the brachial plexus. Injuries that involve the upper trunk are readily addressed with a series of nerve transfers that use expendable and reliably intact nerves. The spinal accessory transfer to the suprascapular nerve will permit reinnervation of the supra- and infraspinatus muscles. The branch of the radial nerve to the medial head of the triceps to axillary transfer will permit reinnervation of the deltoid muscle.[93] Finally, fascicles of the median and ulnar nerves transferred to the branches of the musculocutaneous nerve to the brachialis and biceps muscles will provide elbow flexion.[94,95]

Sharp penetrating injuries result in a partial or complete nerve transection. In these cases, early exploration is indicated. Repair of sharp transections of the brachial plexus, particularly nerves that control the proximal shoulder muscles and elbow flexors, will yield useful function.[96] Similarly, repair of a sharp injury to the radial or median nerve will allow the majority of patients to regain strength against resistance (MRC score of 4).[97]

Fortunately, the majority of gunshot wounds to the upper extremity resulting in a complete deficit of a discrete nerve will recover spontaneously.[98] In some patients, a nerve deficit is associated with either vascular or skeletal trauma, which then leads the surgeon to consider operative treatment. If the nerve is exposed for the treatment of the vascular or skeletal trauma, it is inspected carefully with loupe magnification. If there is obvious disruption of fascicles, repair or grafting is indicated. For injuries where the gross appearance is abnormal but the nerve remains in continuity, observation is indicated. A plan for subsequent reconstruction is made if recovery has not occurred within the expected time. For example, a radial nerve found to be contused during fixation of an associated fracture of the humeral shaft will typically recover within 8 months or less. If no recovery is demonstrated, the patient is advised that future nerve grafting or tendon transfers will be necessary.

MUSCLE AND TENDON INJURIES IN THE UPPER EXTREMITY

Physical Examination

Trauma to the upper extremity almost always includes some degree of injury to muscles or tendons. Contusions are common and will generally heal with a period of prescribed rest and therapy. Lacerations involving tendons of the upper extremity are treated operatively, as there is an excellent potential for recovery and healing.

Any wound deep to the fascia of the shoulder, arm, or forearm should lead to a meticulous physical examination and begin with a "top-down" approach.

Aside from ensuring joint suppleness, the examiner should assess the patient's ability to maintain external and internal rotation and forward elevation against resistance. A drop arm test, performed with passive elevation of the internally rotated humerus with the elbow extended, will localize control of the rotator cuff. With a massive cuff tear, the arm falls abruptly with the action of gravity.[99]

Injures to the antecubital fossa and associated elbow flexors are ominous because transection of the biceps and brachialis muscle will frequently involve injury to the brachial artery and median nerve. The associated findings of an anterior elbow wound and profuse bleeding should alert the clinician to a high probability of injury to each of these critical structures. In addition to the vascular examination, the examiner should pay specific attention to the posture of the hand. The "benediction sign," where the thumb and index finger assume an extended posture, is indicative of a median nerve deficit, where the flexor pollicis and index profundus and superficialis muscles are paralyzed, while the ulnar nerve maintains digital flexion through its innervation of the more ulnar profundi (Fig. 43-13). Injuries to the triceps muscles with loss of extension against gravity and/or resistance indicate need for repair. Injures involving the triceps muscle will frequently include some trauma to the ulnar nerve, so the examiner should assess the patient's sensation about the ulnar digits and the ability to abduct and adduct the fingers.

FIGURE 43-13 Benediction sign after compression or injury of the median nerve at the elbow or forearm.

Lacerations deep to the fascia of the forearm or hand will involve injury to a critical tendon or nerve in a large percentage of cases and, thus, should be explored. The extended posture of the digit with transected flexors or the wrist lying in flexion with transected extensors is easy to diagnose. In the awake patient, isolation of individual digital flexion and extension should be performed, "blocking" the other digits and isolating the proximal and distal interphalangeal joints individually to demonstrate the integrity of the flexor systems.

Diagnostic Modalities

The vast majority of tendon injuries in the upper extremity and hand are diagnosed with physical examination alone. In certain cases, such as injury to the rotator cuff, triceps, or biceps muscles, and/or in certain instances involving the digits, a tendon injury can be accurately assessed with MRI. Ultrasound can also aid in diagnosis but requires a well-trained ultrasonographer or institutional familiarity.

Treatment

Ruptures of the pectoralis major are infrequent. Commonly the result of an eccentric contraction, such as during a bench press or forced extension of the shoulder against resistance, these injuries present with a defect overlying the anterior shoulder that is both visible and palpable. Operative treatment is preferred in the young patient for restoration of cosmesis and strength.

Ruptures of the rotator cuff are common in trauma patients, particularly in those over 50 years of age sustaining a first-time shoulder dislocation.[100] Massive tears are frequent and can result in significant dysfunction of the shoulder. These tears require prompt recognition, as the tear will retract to an irreparable level within weeks. Arthroscopic or open repair is indicated for the majority of these injuries.

A proximal injury of the biceps tendon will present as a "Popeye" deformity and is most commonly the result of preexisting tendinopathy of the rotator cuff. Nonoperative management is usually prescribed.

Lacerations of the biceps and triceps tendons at the elbow similarly warrant expeditious repair, as excellent results can be expected. A delay in treatment will result in the need for tendon grafts to overcome the shortening inherent to delay. As noted earlier, these lacerations should be approached with the anticipation of an associated vascular or nerve injury.

FOREARM AND HAND

Lacerations involving tendons in the forearm and hand require an expeditious repair.[101,102] Complete transection results in immediate loss of length, due to unopposed contraction of the muscle. The contracted state will preclude repair in a period as short as 2 to 3 weeks. The flexors and extensors of the wrist and hand provide critical function, and appropriate repair should be by a trained hand surgeon[103] (Table 43-6). Flexor tendon injuries to the palmar surface of the thumb and fingers within "no-man's land" are notoriously difficult to treat, requiring specialized tendon handling, suture repair, and postoperative therapy to achieve a good result.

Tendon repairs of the upper extremity are generally completed using a braided nonabsorbable suture, appropriate to the size of the tendon undergoing repair. For example, tendons within the finger are typically repaired with a 3-0 or 4-0 suture, those in the forearm and wrist typically with a 2-0 or 0 suture, and those in the distal biceps with a #2 suture. Restricting active motion of the repaired tendon is generally prescribed as part of the rehabilitation protocol, whereas passive motion of the crossed joint is initiated immediately. Gradual progression to active motion and then strengthening is permitted over a period of 6 to 8 weeks.

SKIN INJURIES IN THE UPPER EXTREMITY

Physical Examination

Perhaps the most readily assessed component of the upper extremity is the skin. Even so, a careful and experienced eye is required to complete a thorough inspection. Good lighting and palpation are generally all that is required to yield a near-complete assessment. There are, however, many qualities of the skin that require objectification. The clinician, in formulating

a treatment plan, is well served by learning how to articulate these specific and detailed qualities. For the majority of non-burn or chemical injuries to the skin, trauma mechanisms can be divided into ischemic and direct tissue loss categories.[104]

ISCHEMIC CHANGE

Skin, like all other tissues, relies on a continuous source of perfusion and oxygenation. Although skin will tolerate ischemia significantly better than muscle tissue, it remains susceptible to necrosis with a prolonged ischemic time. The speed of progression to frank necrosis is dependent on the degree of hypoxia. Discerning the degree of hypoxia/ischemia can be challenging and is done based on the mechanism of injury, physical examination, and ancillary studies.

A variety of mechanisms are responsible for ischemia of the skin.[105] Direct trauma or thrombosis of the regional artery can result in obvious disruption of perfusion. Pressure on the skin, whether external (eg, ill-fitting splint or cast, bandage, traction device, restraint, or any form of external compression) or internal, will result in relative ischemia to the affected area and some degree of skin loss, depending on the duration and severity of the pressure.[106] Hypoxia can also result from edema or a hematoma. Edema or hemorrhage in the tissue immediately below or within the skin can result in focal pressure, decreased perfusion, and resultant local hypoxia. Finally, skin sustaining a shear and degloving injury will lose the arterial connections to the axial vessels below. If this area is significant, the skin will necrose.

Assessment of skin perfusion is accomplished with an assessment of capillary refill. Skin that is well perfused in the fair-skinned individual will be pink and blanch with modest pressure. Excellent lighting, preferably incandescent, is required to assess the color of the skin, as previously noted. Perfusion assessment of the nonglabrous skin in dark-skinned individuals can be particularly challenging, as the blanching associated with pressure can be difficult to demonstrate. In instances where severe venous occlusion or insufficiency has occurred, the part will become congested, manifesting as rapid capillary refill and a bluish color. In advanced stages, compression of the capillary beds becomes impossible, and no refill phenomenon is present. In late stages, this leads to capillary leaking and "bruising" of the skin, appearing as a port-wine discoloration.

Turgor, or the "fill" of the skin, is another important characteristic. Normal turgor is maintained in the uninjured extremity with appropriate degrees of perfusion and venous return. Comparison of the affected part or extremity to its uninjured partner will provide an accurate gold standard in regard to color and turgor. In instances of venous congestion, the turgor becomes abnormally increased to the point of gross swelling.

Skin that has sustained trauma will frequently blister. These blisters should alert the clinician that the skin has, to some degree, lost perfusion. Blistering around fractures of the knee, ankle, foot, and elbow is common.[107] This is believed to be the result of hypoxia induced by the abnormally elevated subcutaneous pressure from edema or hemorrhage, particularly in those areas where the skin is directly overlying bone, such as the medial tibial plateau or calcaneus.

Skin that has sustained substantial degloving will frequently demonstrate a "tomato skin" color and friability. Predicting whether or not this skin will recover to provide a sufficient barrier for the desired functional recovery can be challenging at best. If the patient is warm and normotensive, with no correctable trauma to an axial vessel, incised skin should bleed. If the skin does not bleed, the surgeon can be assured that the skin will eventually demarcate and turn to eschar. Delaying excision will typically complicate the patient's course. In cases where there is no underlying fracture, hardware, or vascular injury, allowing the skin to "declare" can be preferable. Excising large portions of skin should be done with caution and with a subsequent reconstructive plan in consultation with a soft tissue/microsurgeon.

Skin that has "declared" will be black. These changes typically take several days or, in some cases, weeks. In these instances, particularly in areas where skin coverage is critical (eg, open fracture, hardware, or critical vascular repair), the necrosis is typically debrided and replaced with adjacent, distant, or a free tissue transfer.

Diagnostic Modalities

As described earlier, discerning the degree of perfusion can be challenging. Several adjunctive methods can assist the provider in determining relative degrees of ischemia.

LASER-ASSISTED ANGIOGRAPHY

Indocyanine green dye will fluoresce when exposed to light in the near-infrared spectrum and has been used to assess soft tissue perfusion in cardiac, ophthalmologic, bowel, plastic, biliary, and orthopedic surgery.[108,109] Commercially available cameras and devices using this technology provide an objective assessment of the perfusion of skin with results provided in both relative and absolute values.[110] Through its assessment of perfusion of the skin and flaps, it has been effective in decreasing the risk of soft tissue complications in breast and soft tissue reconstructions.[111] Also, it can be used to quantify differences in skin perfusion with different closure techniques and assess viability in free tissue transfers and frostbitten extremities, and is undergoing significant investigation in predicting soft tissue complications in at-risk fractures.

Thermography using forward-looking infrared cameras has become increasingly accurate, available, and portable.[112] Temperature differences on the order of 0.1°C are easily and reproducibly measured with smart phone adapters. This technology has been used to assess the perfusion of free tissue transfers,[9] burn wounds, and thermal changes in skin during fracture healing.[113,114]

Treatment

Potentially compromised skin should be first addressed by ensuring adequate warmth, stability, and perfusion. This is accomplished by maintaining an appropriate core temperature of the patient and applying a warming blanket to the extremity. Reducing dislocated joints and aligning fractures via either operative or nonoperative measures are imperative

to reduce the risk of vascular torsion, kinking, or spasm. Also, this further limits the catecholamine response from the painful stimulus of an unstable limb. Finally, ensuring adequate volume resuscitation is imperative to maintain adequate perfusion of the extremities.

SKIN GRAFTING

In cases with preservation of the underlying muscle, periosteum, peritenon, or subdermal tissue, skin grafting is appropriate.[115] In those cases with exposed muscle alone (eg, fasciotomy wounds), split-thickness grafting will suffice. Because the degree of contracture is inversely proportional to the thickness of the dermis within the skin graft, graft thickness is an important consideration over areas such as the axilla, neck, palmar hand, and antecubital fossa. These areas are prone to intolerable contracture, and full-thickness skin grafts are indicated.

ADJUNCTIVE AND TEMPORIZING TREATMENTS

In patients with massive skin loss or areas that are deemed not "ready" for skin grafting, dermal matrix substitutes have gained in popularity.[116] These commercially available products are applied to the wound bed to allow for vascular ingrowth over a period of several weeks. The skin graft is then applied to the integrated collagen matrix. These products have led to favorable results over exposed tendon, joint capsule, and large areas of atrophic wound beds. This technique still requires a nutritionally restored patient and adequate perfusion to the extremity. In the author's experience, the products do not provide adequate supple coverage for areas that require tendon excursion for function or elevation for subsequent reconstructions, and are used sparingly.

Allograft skin provides an additional option for temporary wound coverage.[117] When the patient is malnourished or unstable and/or a large wound bed of indeterminate viability and quality is present, allograft skin can be used as a trial run. This skin grafting technique depends on the typical imbibition and inosculation common to all skin grafts, with the added advantage of almost no biologic or surgical morbidity to the patient. It provides the benefit of decreasing insensate losses and dressing changes while providing a biologic barrier. Upon operative removal in 7 to 10 days, the underlying tissue has been "primed" with the ingrowth of a superficial capillary network favoring autograft skin. In these wounds, the quality of the allograft skin "take" will provide the clinician and patient confidence that the wound bed is amenable to precious autograft skin, particularly in patients with large skin defects and severe trauma, where donor skin is in limited supply.

FLAPS

In cases where the underling tissues will not support a skin graft, the transfer of a healthy tissue "flap" is indicated.[118] In the extremities, these are most commonly performed over open fractures, exposed orthopedic implants, vascular repair or reconstructions, tendon, joints, or joint creases such as the antecubital fossa.[119]

Flaps can be divided into local, distant, and free. Local skin flaps of the upper extremity typically include transfer of full-thickness skin using either advancement, transposition, or a pedicled or a propeller-type transfer. Other local flaps include muscle, such as the pedicled flexor carpi ulnaris flap.[120]

Distant flaps, such as the groin flap, rely on vascular ingrowth into the transferred flap from the recipient bed[121] (Fig. 43-14). This flap requires a period of 3 weeks of relative immobility of the hand while attached to the groin region but provides the benefit of not requiring a donor vessel. This is relevant in patients with a severely traumatized limb. In cases where axial vessels will be subsequently used for additional free tissue transfer, the groin flap can provide a suitable source of supple and expendable skin. After an appropriate period, the flap is then divided and inset.

In patients in whom local or distant flaps are deemed unsuitable, a large array of microvascular free tissue options exist, provided there are an adequate recipient artery and vein. Flaps composed of skin, muscle, bone, tendon, nerve, or artery and vein are available and can be tailored to the requirement of the defect. Most commonly, skin is required, and flaps such as the anterolateral thigh or parascapular flap are suitable and provide large volumes of supple skin with minimal donor site morbidity (Fig. 43-15). Smaller defects are amenable to flaps such as the lateral arm, and in cases of

FIGURE 43-14 Groin flap for coverage of a mangled hand and replanted thumb.

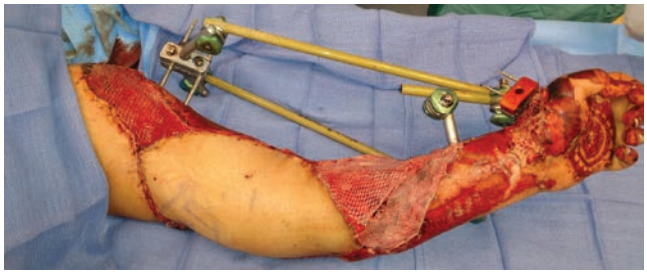

FIGURE 43-15 Anterolateral thigh flap for coverage of a large antecubital wound.

missing diaphyseal bone of the upper extremity, osteocutaneous flaps such as the free fibula are chosen.[122]

Lower Extremity

Yohan Jang • Greg E. Gaski • Walter W. Virkus

KEY POINTS

- Compartment syndrome, mangled extremities, high-grade open fractures, irreducible dislocations, and fractures with vascular compromise require emergent treatment.
- Low-grade open fractures, femur fractures, and hip fractures are ideally treated within 24 hours.
- Evidence shows decreased infection rate for open fractures when antibiotics are administered within 1 hour of admission.
- Extreme diligence is required in the care of knee dislocations due to a 7% to 15% incidence of injury to the popliteal artery.
- Unnecessary testing delays surgery, increases costs, and does not provide clinical benefit in geriatric patients with hip fractures.
- Geriatric hip fractures are often life-changing events, with only 60% of patients returning to preinjury activity level and a 30% 1-year mortality.
- External fixation is an excellent option for rapid initial stabilization of many fractures in the lower extremities.
- Non–life-threatening injuries such as pilon, calcaneus, and Lisfranc fractures can have a dramatic long-term negative impact on a patient's functional status.
- Advances in prosthetics currently make below-knee amputation a better functional option than limb salvage in many patients.

INTRODUCTION

Lower extremity injuries are a common cause of hospital emergency department visits. These injuries and their effect on patient function have a great impact on society.[1] Lower extremity fractures can occur as simple injuries or as complex, high-energy injuries in a polytraumatized patient. Patients with significant injury to their lower limbs are at risk for a wide variety of complications including ischemia, infection, nonunion, chronic pain, and long-term functional deficits. Complex extremity trauma requires prompt assessment of the injury including bone, neurologic, vascular, integument, and muscular evaluations. Technical advances in both osseous and soft tissue reconstruction have led to improvements in treatment, mobilization, and postinjury rehabilitation of severely injured patients. Rehabilitation concepts have changed from prolonged rest to the present emphasis on rapid restoration of skeletal stability allowing prompt mobilization. Appropriately timed management and well-executed surgical interventions are critical to prevent infection, achieve wound healing, promote osseous union, avoid systemic complications, and maximize functional outcome. Many victims of extremity trauma also have associated life-threatening injuries to the head and torso. Therefore, the initial evaluation of lower extremity fractures must focus on the patient as a whole and not exclusively on the injured limb.[2-4]

The wide prevalence of safety belt usage and changes in vehicular design, such as crumple zones and mandatory air bags, has improved the survival rates in high-energy crashes. This has led to an increasing number of severe lower extremity injuries previously "unseen" because the patient did not survive. Additionally, with an aging population, there has been an increase in the rate of fractures in elderly patients, often accompanied by multiple medical comorbidities that can compromise their response to traumatic insults.[5] Many of these patients are on anticoagulants or other medications that can dramatically amplify the effects of even low-energy trauma. These patients require a high level of diligence, from both the trauma and orthopedic surgeons, because of the potential for a larger systemic impact due to medical comorbidities and polypharmacy.

There is considerable controversy surrounding the timing of many orthopedic interventions, which has led to variations in recommended practice over the past 20 years.

Current evidence supports "urgent" management of some injuries historically treated "emergently," including talus fractures, femoral neck fractures, and most open fractures, with a higher emphasis on the quality of the surgical intervention rather than on the timing.[6,7] In contrast, compartment syndrome, fracture-dislocations associated with neurovascular compromise, and severe soft issue injuries including mangled extremities remain true orthopedic emergencies.[7] Failure to recognize the significance of these injuries can lead to severe sequelae such as limb loss or death. Open fractures of the lower extremities require timely surgical treatment by an appropriately skilled team to minimize the risk of infection and limb loss. A quality debridement, including (1) removal of contamination; (2) excision of nonviable tissue; and (3) excision of extra-articular bone fragments lacking soft tissue attachments, is regarded by most orthopedic traumatologists as more important than debridement occurring on an emergent timeline. However, data and widespread clinical practice support the practice of irrigation and debridement of open fractures within 24 hours of injury, with crush injuries and badly contaminated fractures likely benefiting from a more emergent treatment.[6]

The concept of "damage control orthopedics" was established based on the principle that prolonged early definitive treatment of long bone fractures can be detrimental for severely injured patients who are physiologically unstable.[8,9] In these patients, the early mitigation of the "lethal triad" of persistent metabolic acidosis, hypothermia, and coagulopathy represents the prime goal for survival.[2] Resuscitation strategies have improved over the past decade, however, and multiple recent studies have shown improved outcomes using an early appropriate care model, in which early care is titrated based on a patient's overall injury constellation and physiologic status.[10-13] The initiation of surgical care when considered safe has not only improved clinical outcomes, but has also been shown to have a dramatic effect on the overall cost of care.[14]

BIOMECHANICS AND MECHANISM OF INJURY IN LOWER EXTREMITY TRAUMA

Biomechanics is a term that relates physics to the musculoskeletal system and can add to the understanding of how an injury occurred. Fractures occur when the applied load to the bone exceeds its load-bearing capacity. Bone is a complex living tissue consisting of collagen fibers embedded with mineral in an intricate fiber orientation and a varied density of the Haversian system (microscopic functional unit of bone). The ratio of collagen to mineral has a significant effect on the elastic modulus (resistance to deformation) of bone, which decreases with loss of mineral content.[15] The orientation of collagen fibers influences the ability of bone to withstand load in specific directions. The fiber orientation of fracture callus in the initial healing phase is random and disorganized. Fibers progressively reorganize along the direction of load to which the bone is exposed. The density of the Haversian system directly affects bone strength. As bone mineralizes and matures from childhood to adulthood, the bending strength and modulus of elasticity increase. Bone density begins to decrease in the fourth decade of life, which can progress in accelerated fashion in patients with osteoporosis, rendering the bone more fragile and susceptible to fracture with lower energy mechanisms.

There are four basic forces that lead to fracture: compression, tension, torsion, and bending. These forces, when applied purely, cause the bone to fracture in predictable ways. A compressive force results in shortening the length of bone, causing oblique fracture lines or comminution (multifragmentary fractures). Tensile force elongates bone, causing transverse fractures. Bone is weakest in torsion, and spiral fractures can result from relatively low torsional forces, leading to long oblique fractures often with little associated soft tissue injury. When a bending force is applied to a bone, there is a compressive force on the side where the force is applied and a reciprocal tension on the opposite side. The bone initially fails in tension, and as the fracture propagates toward the side of the applied load in which the bone is compressed, the fracture becomes oblique both proximal and distal to the force, creating a wedge-shaped "butterfly" fragment.

The amount of energy that produced a given fracture is suggested by the patient's history and the fracture pattern. Basic physics dictate that kinetic energy = 1/2 (mass)(velocity)^2 (see Chapter 1). Thus, as the velocity or mass increases, an exponentially higher amount of energy is absorbed by the musculoskeletal system. This energy is manifested as comminution and local damage to soft tissues. Obtaining a thorough patient history provides useful information that may alert the physician to a high level of injury severity. Although an accurate history may be difficult or impossible to obtain initially in a seriously injured patient, more detail should always be sought and reconfirmed as the patient improves or more information becomes available. A history inconsistent with the extent of injury suggests either a pathologic fracture or possibility of abuse.

HEALING OF FRACTURES

Fracture healing is a form of tissue regeneration that mimics bone formation from fetal development. It follows specific regenerative patterns and involves changes in the expression of many genes.[16] In general, bone heals by two pathways: direct (intramembranous ossification) and indirect (endochondral ossification). Direct bone healing, also known as primary bone healing, occurs in a low-strain (no motion between fracture fragments) environment and requires anatomic reduction of fracture ends without gap formation and stable fixation. Therefore, it does not commonly occur as a natural process but is typically achieved only by surgical means with open reduction and internal fixation. On the contrary, indirect fracture healing, also known as secondary bone healing, occurs in a moderate-strain environment (moderate but not excessive fragment motion) and does not

require anatomic reduction or rigid stable fixation. Nonoperative and certain surgical treatments that provide relative stability such as intramedullary nailing, external fixation, and bridge plate fixation for comminuted fractures ideally lead to indirect fracture healing.

Indirect fracture healing, in contrast to the regeneration of lamellar bone and the Haversian system in direct fracture healing, follows a specific biological pathway. This pathway involves an acute inflammatory response (interleukin [IL]-1, IL-6, IL-11, IL-18, and tumor necrosis factor-α) followed by mesenchymal stem cell–induced cartilaginous callus formation, which undergoes revascularization and calcification until complete bony remodeling is achieved.[17] Despite the regenerative capacity of bone, the process can fail and lead to nonunion.

CLINICAL EVALUATION OF PATIENTS WITH LOWER EXTREMITY TRAUMA

Patient evaluation according to the Advanced Trauma Life Support (ATLS) protocol provides a systematic method of thoroughly examining the trauma patient, assuring appropriate sequence of care, and minimizing missed injuries.[2,18] In addition, the importance of continuous detailed documentation of the physical findings cannot be overemphasized. Patients with extremity injuries require thorough and serial examination. All assessments should be well documented to facilitate comparison by all members of the care team. Although care of multiply injured trauma patients with extremity injury is primarily driven by the general surgery trauma team, multidisciplinary input and efficient communication among consulting services including orthopedic surgery, neurosurgery, vascular surgery, emergency medicine, anesthesia, and radiology are critical to rapidly institute an appropriate treatment strategy.

The secondary survey is a head, torso, and extremity examination after the life-threatening injuries have been identified and initial stabilization measures have been employed. Examination of extremities starts with an inspection. Contusions, open wounds, and deformities are noted. Patients should be carefully rolled to inspect the posterior portion of the patient for wounds. Palpation of extremities for tenderness and abnormal movement aids in identification of injuries. When possible, asking the patient to move each extremity can be a quick screen for injuries. In high-energy mechanisms, the palpation portion of the exam should include the principle of "touch every bone" to elicit areas of abnormal motion or tenderness, which can go unnoticed in a multiply injured patient. Markers of injury can be easily masked in intubated and sedated/obtunded patients. This vulnerable population cannot complain of pain, neurologic examination is unobtainable, severe life-threatening injuries may take precedence, and assessment of deformity or swelling can be difficult, especially in obese patients. The exam should be revisited when an initially obtunded patient is first extubated. A "tertiary survey" should be completed after the initial resuscitation and operative interventions are complete or when a patient's neurologic function improves. Detailed knowledge of lower extremity anatomy and understanding the function of structures and location in relation to injuries are key elements of the physical exam. The extremity exam should proceed in a methodical order to assess the following components of injury: skin, muscle, tendon/ligament, nerve, vessels, and bone.

Nerve Injuries and Evaluation

The neurologic status of the extremity should be documented as early as possible. Nerve injury is usually in proximity to the extremity injury; however, the possibility of an axial (head, spine) source of injury exists in trauma patients. Starting proximally in the lower extremity, the sciatic nerve may be injured in hip dislocations, acetabulum fractures, and thigh injuries, leading to lack of motor function and sensation below the knee. Approximately 10% of adults and 5% of children have neurologic injuries after traumatic hip dislocation.[19] More commonly, the peroneal branch of the sciatic nerve is injured with sparing of the tibial branch in hip and knee fractures and dislocations. The peroneal nerve is smaller with less neuron redundancy, and it is tethered as it passes around the fibular neck, making it more prone to traction injury. Up to 25% of knee dislocations (with or without fracture) lead to common peroneal nerve palsy.[20] Injury to peroneal division can cause decreased sensation in the lateral leg and lateral, plantar, and dorsal foot and weakness or palsy of foot and toe extension (foot drop). The sensory deficit is most easily identified by numbness in the first dorsal web space and dorsum of the foot. Injury to the femoral nerve results in diminished sensation on the anterior thigh and weakness of hip flexion (psoas muscle) and knee extension (quadriceps muscle). Tibial nerve injury, which is often involved in a mangled extremity or as part of a complete sciatic nerve injury, results in loss of sensation to the heel and plantar foot, accompanied by the inability to plantar flex the foot and toes. Although less common than peroneal nerve injury, tibial nerve injury is much more functionally debilitating because the loss of plantar foot sensation and decreased push-off strength dramatically affect normal gait. Simple screening active motion tests for lower extremity nerve assessment include raising the knee and foot off the bed (hip flexion and knee extension—femoral nerve) and caudal (tibial nerve) and cephalad (peroneal nerve) movement of the foot and toes (plantarflexion and dorsiflexion, respectively). Unfortunately, active motion can be limited by pain, in which case an exam based on passive motion and palpation becomes increasingly important.

Most peripheral nerve injuries of the leg are neurapraxias (temporary damage to the myelin sheath) that result from stretching mechanisms or blast effect secondary to projectiles. The vast majority of neurapraxias resolve without intervention by 6 to 8 weeks. Peripheral nerve recovery is assessed by outpatient serial examination. If there is no recovery, nerve conduction studies and electromyography within 3 to 6 months after trauma can aid in defining the extent and prognosis of injury. Axonotmesis occurs after a crush or stretch injury to

a peripheral nerve and implies axonal damage with maintenance of an intact endoneurium and perineurium. Wallerian degeneration occurs, and axonal regeneration occurs at a pace of approximately 1 mm/d. Neurotmesis refers to complete disruption of the axons and the overlying nerve sheath. Patients with acute neurologic deficits following lacerating trauma may benefit from acute surgical exploration and consideration of acute nerve repair. However, even with modern surgical techniques, prognosis for functional nerve recovery following complete nerve disruption is often poor in the lower extremity. Patient and injury factors such as age, medical comorbidities, nerve injury location, and smoking all play a role in the surgical decision making and recovery of nerve injuries.

Vascular Injuries and Evaluation

A detailed vascular assessment of the injured extremity begins with a pulse examination of femoral, popliteal, dorsalis pedis, and posterior tibial arteries. Capillary filling is not, by itself, adequate clinical evidence of intact vascular flow. Distal pulses may be present after a significant arterial injury. It is crucial to take a detailed history regarding time of injury because delays of postinjury revascularization in excess of 8 hours carry a risk of limb loss as high as 86%, compared to 11% if treated within 8 hours.[21] A high level of suspicion for associated vascular injuries is important in lower extremity trauma. The pulse assessment should be repeated after resuscitation and reduction of deformities, because most patients with abnormal pulses on initial examination demonstrate normalization of the flow following resuscitation, limb reduction, and splinting. Therefore, invasive arterial evaluation should be deferred until limb reduction and splinting are performed unless there will be a significant delay. Even in the absence of an abnormal pulse exam, leaving an obviously deformed lower extremity in its deformed position can have an adverse effect on perfusion, skin tension, and nerve traction. Simple, general realignment of an obviously deformed extremity should be performed early and can be safely done without concern of causing additional injury. Any pulse deficit or measurable reduction in arterial pressure index (API) or ankle-brachial index (ABI) after extremity realignment must be considered a potential vascular injury. The ABI is measured using systolic blood pressure in the extremity distal to the zone of injury divided by the systolic blood pressure in the brachial artery of an uninjured extremity. The API is measured by dividing the Doppler arterial pressure distal to the zone injury by the Doppler arterial pressure in an uninvolved upper extremity. Patients with symmetric peripheral pulses or an API or ABI less than 0.9 should undergo further assessment including imaging studies (eg, computed tomography [CT] angiography, duplex ultrasonography) and prompt evaluation by a surgeon experienced in the repair of vascular injuries.[21] The accuracy of pulse examination alone for the detection of arterial injury is very low. The five clinical hard signs of an arterial injury (Table 44-1) are present in more than two-thirds of all dislocations with an associated vascular injury.[22,23] Injuries with a high incidence of associated vascular injuries such as knee dislocations, displaced distal femur and proximal tibia fractures, open tibial shaft and ankle fractures, and mangled extremities should prompt a high level of diligence in the vascular evaluation.

TABLE 44-1: Signs of Vascular Injury

Hard signs	Soft signs
Active or pulsatile hemorrhage	Asymmetric extremity blood pressure
Pulsatile or expanding hematoma	Stable and nonpulsatile hematoma
Clinical signs of limb ischemia	Proximity of wound to major vessel
Diminished or absent pulses	Peripheral neurologic deficit
Bruit or thrill, suggesting arteriovenous fistula	Presence of shock/hypotension

A common arterial injury in the lower extremity involves the popliteal artery in association with a knee dislocation or periarticular fracture (Fig. 44-1). Knee dislocations will often spontaneously reduce, appearing relatively benign, and thus injury severity may be underappreciated. The popliteal artery is tethered at the adductor hiatus to the distal femur and at the soleus muscle on the proximal tibia, placing it at risk for vascular injury. In particular, fractures of the medial tibia plateau are often underestimated and should be considered akin to a knee dislocation.[24] Late thrombosis of an initially nonocclusive injury may result in limb loss. Frequent assessment of pedal pulses is required for these patients. Posterior knee dislocation often presents with transection of the popliteal artery, whereas anterior knee dislocation generally causes an intimal tear due to traction.[25] Anterior knee dislocation caused by a hyperextension injury is the most common type, accounting for approximately 40% of all knee dislocations, whereas posterior knee dislocation caused by a direct force such as a dashboard injury is the second most common type, accounting for approximately 30%.[26] Risk factors for limb loss include delayed surgery, arterial contusion with consecutive thrombosis, and, most importantly, failed revascularization. In penetrating extremity trauma, the presence of a hard sign of arterial injury was nearly 100% predictive of a significant vascular injury necessitating surgical intervention.[27] The majority (>95%) of arterial injuries occur in proximity to the site of fracture or joint dislocation. Delay in diagnosis secondary to missing a hard sign can result in limb loss.

The use of soft signs (Table 44-1) to detect occult vascular injury is less clear. The incidence of arterial injuries in patients with soft signs ranges from 3% to 25% depending on which soft sign or combination is present.[27,28] The yield of arteriography in the setting of clinical soft signs alone is very low, and the lesions that are typically identified are nonocclusive: intimal flap, contusion, spasm, and pseudoaneurysm. A high level of suspicion is still required, however, for identifying and treating potentially catastrophic vascular injuries in high-risk injuries such as knee dislocations. Persistence of soft signs on

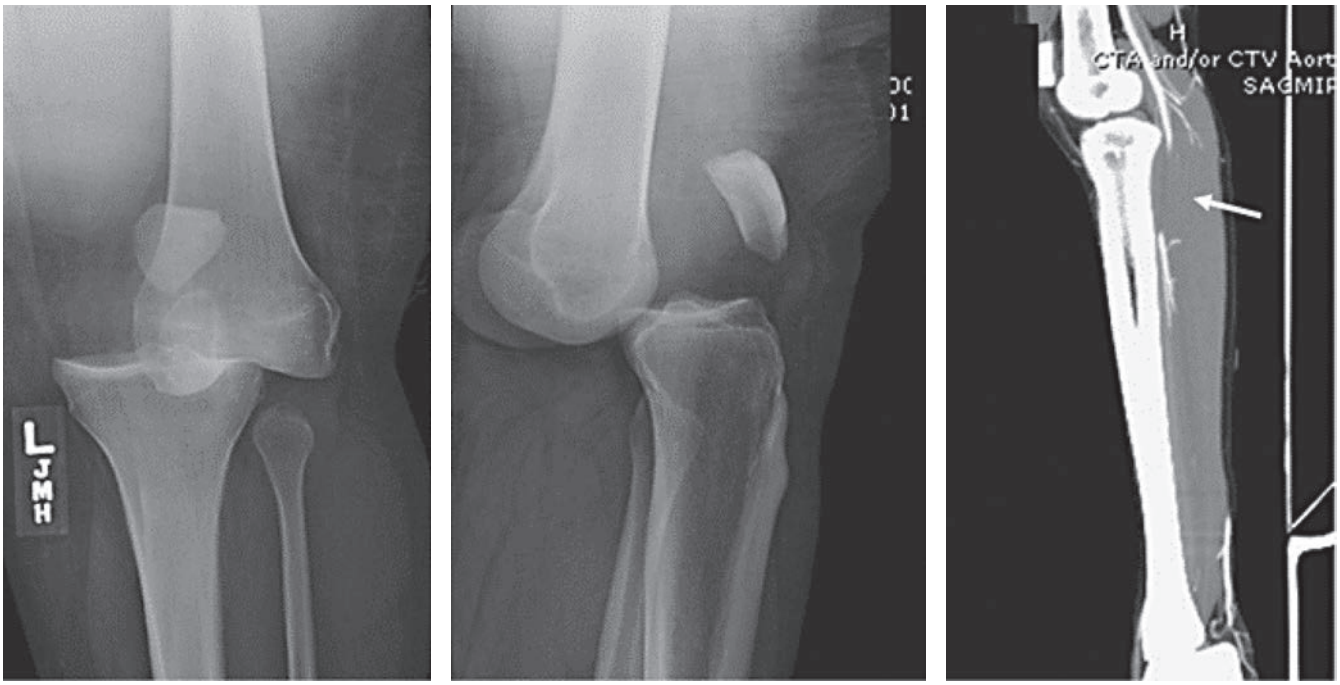

FIGURE 44-1 (**A**) Anteroposterior knee radiograph and (**B**) lateral knee radiograph demonstrating an anteromedial knee dislocation. (**C**) Sagittal computed tomography angiogram image depicting disruption of the popliteal artery just distal to the knee joint (arrow).

serial examinations is an appropriate indication for obtaining a CT angiogram to rule out underlying vascular injuries.

An arterial injury associated with a fracture or dislocation requires a coordinated approach by the trauma surgery and orthopedic teams. A temporary arterial shunt can be placed to restore limb perfusion and minimize tissue ischemia. The limb is reduced out to length and stabilized, often using external fixation. Subsequent to this, arterial repair or bypass is performed. Many institutional protocols leave the shunt after provisional limb stabilization and defer formal revascularization for 12 to 24 hours to allow patient resuscitation and optimization. There is controversy as to whether temporary fracture stabilization should precede vascular repair or vice versa. Clear communication of the treatment plan and sequence among treating surgeons is critical to optimize the care of these limb-threatening injuries. Care must be taken to avoid repairing the artery in a shortened position if vascular repair takes precedence as the repair can be damaged when the limb is lengthened and stabilized. In some fractures, formal osseous repair can be completed in less than 60 minutes, allowing vascular reconstruction to be performed on a stabilized limb that will not require repeat manipulation.

Evaluation of Soft Tissue Envelope

Soft tissue injuries (skin, muscle, nerve, vessels) are key drivers of functional outcome and decisions regarding limb salvage. Reconstruction of large osseous defects is possible through modern techniques including nonvascularized (iliac crest) and vascularized (free fibula) bone grafting, limb lengthening, and bone transport. Advancements in soft tissue reconstruction, most notably muscle and nerve regeneration, trail progress made in the treatment of bone defects. Energy associated with fractures is absorbed into surrounding soft tissues and causes varying degrees of injury. Soft tissue classification systems used to describe such injuries are relatively subjective based on observation, mechanism of injury, and severity of the fracture.[29] Significant swelling and blistering are signs of substantial soft tissue injury. Any wound in proximity to a known fracture is presumed to communicate with the fracture (open fracture) until proven otherwise. Antibiotic treatment in open fractures is critical, as early antibiotic administration has been associated with decreasing incidence of infection.[30] Immediate removal of gross contamination is warranted followed by the application of a sterile dressing. The tenets of wound management are debridement and irrigation, appropriate prophylactic antibiotic coverage, and definitive timely wound reconstruction. Temporary local antibiotic delivery using antibiotic-impregnated cement beads or spacers is occasionally employed in the treatment of open fractures for dead space management. Temporary wound coverage may be facilitated with the use of negative-pressure dressings. Wet-to-dry dressings are rarely indicated in the contemporary care of open fractures. Selection of appropriate soft tissue coverage is based on careful evaluation of the location and extent of injury, associated injuries, and medical comorbidities. Definitive wound coverage options include acute or delayed primary closure, skin grafting, local rotational flap, and free tissue transfer. Definitive wound coverage should be achieved as soon as possible but only after all contamination has been

excised and remaining tissue is perfused and viable. The timing of definitive soft tissue coverage is directly related to the severity of the initial wound. Recent evidence has demonstrated higher rates of deep infection with definitive soft tissue coverage after 7 days.[31]

Compartment Syndrome

While most limb injuries are appropriately prioritized after the care of axial trauma, compartment syndrome is a surgical emergency. Extremity compartment syndrome occurs due to raised pressure within a confined space (leg compartment) that causes permanent and irreversible damage to the contents of the space, including nerve and muscle. It is precipitated by an event that elevates compartmental pressures leading to decreased microcirculatory blood flow, resulting in a positive feedback loop and ultimately muscle and nerve necrosis. This damage may be reversible within the first 4 to 6 hours if an adequate fasciotomy is performed to relieve the pressure. However, there is an increased risk of soft tissue necrosis as time progress, and authors have reported the damage to be irreversible after 8 hours.[32]

Fracture is the most common cause of compartment syndrome, accounting for 69% of cases in one study.[33] Tibial fracture is the most common etiology with a prevalence of compartment syndrome reported up to 15%.[33,34] High-energy injury is typically associated with acute compartment syndrome. High-energy or crush injuries, segmental or widely displaced fractures, severely comminuted fractures, and patients with impaired sensorium are at high risk. Paradoxically, the prevalence of acute compartment syndrome in lower extremity fractures can be significant even in low-energy injuries.[33] Additional common etiologies of compartment syndrome include crush injuries, forearm fractures, vascular injury (reperfusion), intravenous line infiltration, excessively tight circumferential dressings or casts, dog bites, high-pressure injection injuries, burns, prolonged immobilization (found down after drug overdose), and intraoperative lithotomy positioning. Although ballistic injuries carry an overall low incidence of compartment syndrome (3%), isolated proximal tibia and fibula fractures due to gunshots have a 21% chance of developing compartment syndrome.[35]

The key to successful treatment of compartment syndrome is making diagnosis in a timely manner. Compartment syndrome should be suspected when pain is disproportionate to the injury and worsens over time across multiple exams. Other signs of significant soft tissue injury, including fracture blisters, diffuse ecchymosis, swelling, and tissue crepitus, should alert the medical team to a high-risk injury. Pain on passive stretch of the muscles in the affected compartment and paresthesia are the most important physical exam findings suggestive of early compartment syndrome when associated with swelling and firm soft tissues on palpation. Motor deficits and decreased pulses are late findings; however, poor diagnostic sensitivity and specificity of clinical symptoms and signs have been reported.[36,37] Compartment syndrome is widely accepted by most surgeons to be a clinical diagnosis. However, intracompartment pressure measurement can be obtained to assist in the diagnosis of acute compartment syndrome in patients with equivocal exam findings or obtunded/sedated patients. In a recent study of tibia fractures, compartment pressure measurement was found to have a high false-positive rate of 35% using accepted criteria for diagnosis (compartment pressure within 30 mm Hg of systolic blood pressure).[38] Continuous compartment pressure monitoring has reported higher diagnostic accuracy (98% sensitivity, 98% specificity, 93% positive predictive value, and 99% negative predictive value), but these results are interpreted with extreme caution because the diagnosis of "disease" in this study was "escape of muscle" at the time of surgery, which is regarded by most clinicians as highly subjective.[39]

Compartment pressure measurement, when used, should be performed in all compartments and within 5 cm of the fracture.[40] An arterial line setup, slit catheter, or side-port needle can be used, but one must be cognizant of the fact that an arterial line may read 5 to 15 mm Hg higher than a side-port needle. The two most commonly cited thresholds for diagnosis are pressure within 30 mm Hg of the diastolic blood pressure (delta P) and absolute compartment pressure greater than 30 mm Hg.[37,39,40] Clinical exam can be unreliable in an obtunded or anesthetized patient; therefore, compartment pressure measurement has an increased role in this population.[39] Institution-wide protocols (high-risk compartment syndrome protocols) that empower all team members (eg, nurses, residents, faculty) and promote rapid escalation when compartment syndrome is suspected are generally considered best practice.[41] Documentation is important both to compare physical examination findings as well as for medicolegal reasons because prolonged time from onset of symptoms to fasciotomy is associated with an increased medicolegal risk.[42]

Although various fasciotomy techniques are used for the lower extremity, the vital aspect of surgical treatment is complete release of the affected fascial compartments. The thigh is typically treated with a single lateral incision to facilitate release of both the anterior and posterior compartments. Rarely, the medial (adductor) compartment also requires release through a separate incision. The lower leg is typically treated with a dual incision technique, although single-incision techniques have been described.[43] Foot fasciotomies are often performed with two dorsal incisions to access the nine compartments. If feasible, communication between surgical services is helpful to avoid suboptimal placement of fasciotomy incisions that may compromise future fracture procedures and wound care. Tibia fractures with compartment syndrome are more likely to become infected and develop nonunion.[44] Cost and length of the hospital stay are more than double for these patients.[45]

GENERAL MANAGEMENT OF OPEN FRACTURES

An open fracture is defined as a fracture that communicates with the external environment through a traumatic soft tissue defect. It should be emphasized that the soft tissue injury may

not lie directly over the fracture. A fracture in the same region as soft tissue injury should be considered open until proven otherwise. History regarding the environment and extent of contamination, as well as the time elapsed from injury, are vital to appropriate management and determining appropriate antibiotic coverage. Open fractures should be quickly assessed on arrival to the emergency department. The patient should be adequately undressed so that all soft tissue injuries can be identified. This is especially important in patients who are unconscious or under the influence of alcohol or drugs. Size, location, orientation (transverse, longitudinal, irregular), and depth of the wound are documented, along with notation of any exposed bone, tendon, or muscle. The Gustilo-Anderson classification of open fractures is commonly used to convey information and dictate treatment (Table 44-2). It is important to recognize that significant internal soft tissue injury such as extensive periosteal stripping and fracture comminution can be present with even small wounds, suggesting a higher level of energy.

Ideally, photographic documentation of the wound is obtained prior to application of a sterile dressing and splint. This is important not only because visual documentation surpasses written descriptive documentation for planning treatment, but it also prevents exposing the wound to further contamination by removing the dressing multiple times for an evaluation by other team members. A detailed medical and social history is important because many chronic conditions and medications may influence the treatment plan and outcome, including diabetes mellitus, rheumatoid arthritis, immunocompromised state, renal failure, dementia, smoking, and substance abuse.

Early antibiotic administration in patients with open fractures has been shown to decrease the risk of infection.[46,47] There is little quality evidence describing the optimal antibiotic coverage and duration for open fractures. The duration and choice of prophylactic antibiotic therapy have been reviewed by the Orthopaedic Trauma Association, Surgical Infection Society, and the Eastern Association for the Surgery of Trauma, but all recommendations are based on low-level evidence. Prolonged antibiotic therapy may increase the risk of developing antibiotic-resistant systemic and nosocomial infections, including pneumonia and urinary tract infection.[48] Antibiotic treatment is dependent on the severity and contamination of the wound (Table 44-3).[49,50] Most authors advocate directing antibiotic coverage toward gram-positive organisms (first-generation cephalosporins) and adding gram-negative coverage (aminoglycosides) for contaminated fractures including severe type III injuries.[30] Aminoglycosides have an increased risk of nephrotoxicity in trauma patients. Fluoroquinolones are effective against gram-negative bacteria but should be used with caution due to their potential inhibitory effect on fracture healing and dose-dependent cytotoxic effects.[51] Penicillin G can be added for anaerobic coverage in severely contaminated (soil, grass, marine) wounds. As the prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) increases, special attention should be given to geographic area of practice and community prevalence of MRSA infection.[52] The role of vancomycin in MRSA-colonized patients is currently being investigated.

Following antibiotic administration, dressing application, and adequate resuscitation, the patient should be taken to the operating room for a surgical debridement and fracture stabilization in a timely manner. Extensive exploration or manipulation of exposed bone should not be attempted in the emergency department. Previously it was thought that debridement should be performed within 6 hours of injury. More recent data have shown that time to debridement is not associated with the rate of infection as long as it is performed within 24 hours of injury.[53] While quality of debridement is felt to be more critical than time to debridement, rapid transfer to a trauma center with appropriate resources capable of definitively treating severely injured extremities in an urgent manner has been shown to be beneficial.[53,54] A thorough debridement includes the following: (1) sharp excision

TABLE 44-2: Gustilo-Anderson Classification of Open Fractures

Type	Description
I	Clean wound <1 cm, inside-out perforation, little or no contamination, simple fracture pattern
II	Skin laceration >1 cm, surrounding soft tissue without signs of contusion, vital musculature, moderate to severe fracture instability
III	Extensive soft tissue damage, wound contamination, exposed bone, marked fracture instability due to comminution or segmental defects
IIIA	Adequate soft tissue coverage of the fractured bone
IIIB	Exposed bone with periosteal stripping
IIIC	Any open fracture with associated arterial injury requiring vascular repair

TABLE 44-3: Open Fracture Antibiotic Protocol

Type	Antibiotic	Duration
I	Cefazolin	24 hours
II	Cefazolin +/– aminoglycoside	24–48 hours
IIIA	Cefazolin + aminoglycoside Vancomycin + cefepime	72 hours
IIIB	Cefazolin + aminoglycoside Vancomycin + cefepime	72 hours
IIIC	Cefazolin + aminoglycoside Vancomycin + cefepime	72 hours
Soil contamination	Penicillin	Single dose
Marine contamination	Levaquin	Single dose

of all devascularized skin, subcutaneous tissue, muscle, fascia, and bone; (2) removal of all foreign material; and (3) copious irrigation of the wound bed using normal saline. There has been mixed evidence comparing high- versus low-pressure irrigation.[55] High-pressure lavage removed bacteria more effectively when compared to bulb syringe; however, some studies suggested that high-pressure lavage may further propagate bacteria into soft tissue.[56,57] A recent large multinational randomized controlled study of over 2500 patients demonstrated no difference in reoperation rate in patients treated with very-low-pressure (gravity), low-pressure, or high-pressure irrigation.[58] The same study reported a higher rate of reoperation in patients who received soap-based irrigation solution compared to normal saline irrigation.[58]

Fracture stabilization is performed after soft tissue and bony contamination and devitalization are adequately addressed. Primary closure of all open fracture wounds should be attempted if the surgeon feels all potentially nonviable tissue has been excised. Leaving an otherwise closable wound bed open can lead to the need for flap coverage and an increased infection rate in lower grade open fractures.[59] If there is any concern for ongoing contamination or tissue viability, a repeat surgical debridement should be planned independent of whether the wound is closed or left open. Lower deep infection rates have been observed with negative-pressure wound therapy (NPWT) using vacuum-assisted closure.[60] NPWT is frequently used in conjunction with local antibiotic delivery, such as antibiotic-impregnated cement beads or spacers, for severe open fractures. Wound coverage within 1 week should be the goal. One study demonstrated that flap coverage beyond 7 days is associated with a higher rate of infection that increases daily by 16%, after controlling for injury severity and multiple confounders.[31]

Mangled Extremity: Limb Salvage Versus Amputation

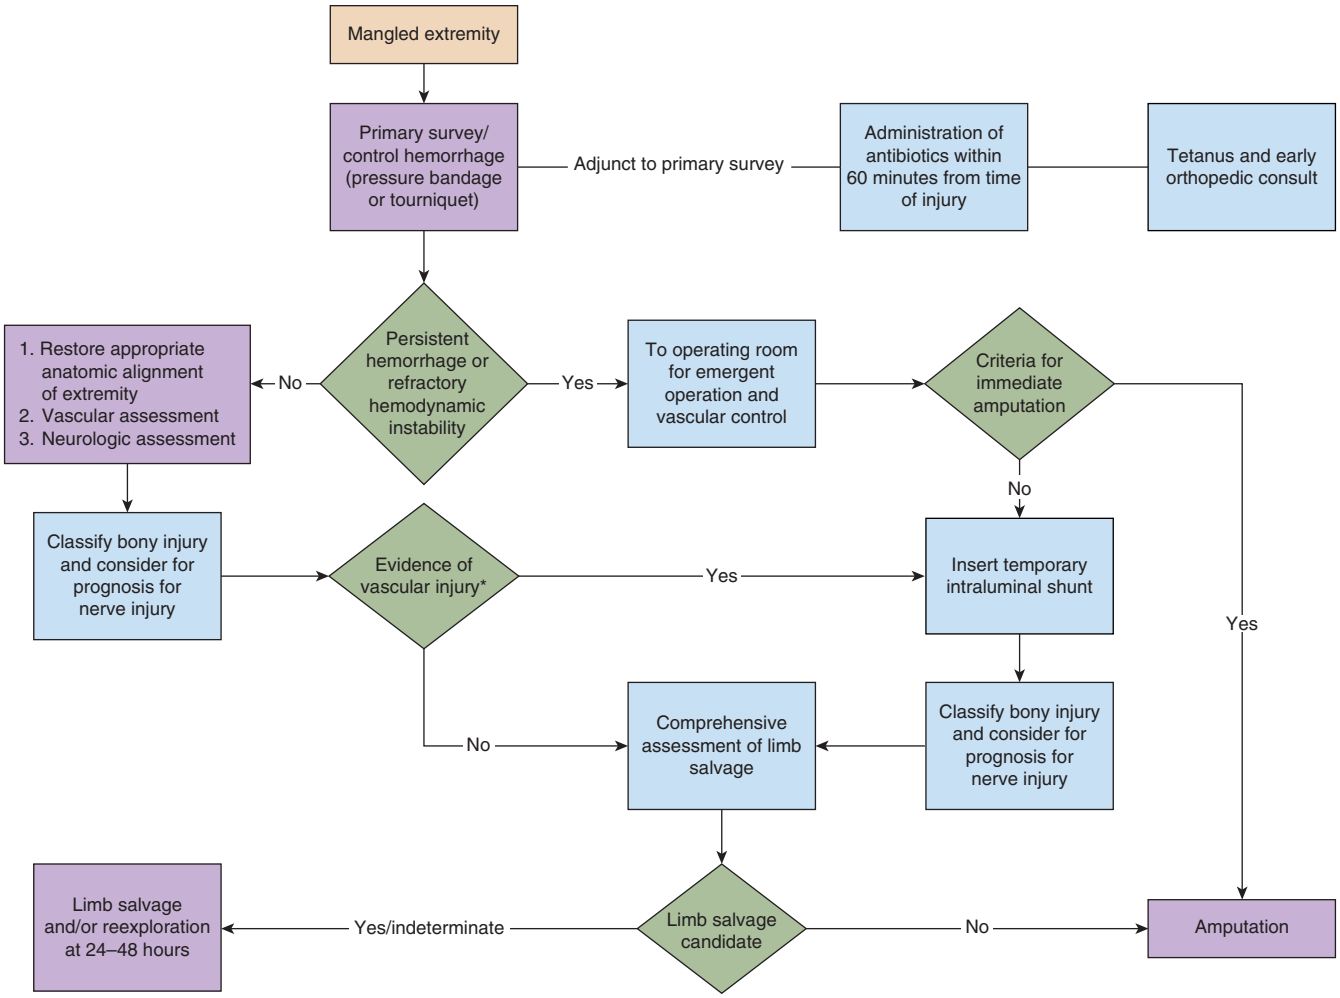
The term *mangled extremity* is used to describe a severely injured limb in which there is significant risk of amputation as a potential outcome. Irreparable injury to one or more structures in a mangled extremity, including muscle, tendons, ligaments, nerves, vessels, joints, or large segments of bone or skin, may significantly impair the function of a limb and lead to disability. Severe open fractures, especially type III open fractures and crush injuries, pose a great risk for significant injury to multiple elements critical to limb function. One of the most challenging decisions involved in the care of patients with a mangled extremity is whether to attempt salvage of a severely injured limb.[61] Initial efforts should be made to preserve functional and anatomic integrity. Amputation and ambulation with a prosthesis, however, may (1) provide better pain relief; (2) lead to a better functional outcome than an impaired native limb; (3) negate the need to undergo multiple procedures for limb reconstruction; and (4) avoid risk of systemic complications related to limb salvage such as infection, thromboembolic events, and anemia leading to blood transfusion(s).

In the acute phase, the decision to amputate will depend primarily on the physiologic condition of the patient and the feasibility of stabilizing and revascularizing the injured limb. An organizational protocol and multispecialty team approach to decision making are useful (Fig. 44-2). In the face of hemodynamic instability, significant hemorrhage, and the inability to revascularize the leg without increasing the risk of death, amputation becomes the primary option. In these cases, a guillotine-type amputation is appropriate, but every effort should be made to preserve length and all viable muscle and skin. Energy expenditure of an amputated limb depends on the level of amputation. Metabolic demand increases as the level of amputation ascends the lower extremity.[62] Proximal amputations have greater functional impairment, although technologic advancements (microprocessor knees) have significantly improved the function of above-knee amputees.

Similarly, meaningful strides have been made over the past decade with respect to foot and ankle prosthetics for below-knee amputees. Below-knee prostheses are highly functional; therefore, efforts to preserve the proximal tibia and knee may yield a better outcome. Free tissue transfers, rotational flaps, and skin grafts can all be used effectively to improve length and provide a durable stump. The decision to amputate during off hours in nonemergent scenarios, without opportunity for consultation with experienced limb salvage surgeons, should be avoided. Multidisciplinary decision making may provide more reconstructive options whether limb salvage or amputation is chosen.

When limb salvage is initiated, but complications arise, thoughtful informed decisions must be made regarding continuation of the salvage effort. Successful reconstruction typically requires multiple operations. The psychosocial factors that play into losing a limb are similar to the patterns of grief associated with losing a loved one.[63] Generally speaking, a patient who has sustained a catastrophic lower extremity injury will never have the same level of function as prior to the injury, whether salvage or amputation is performed. However, the functional recovery of a below-knee amputation can often outperform what can be obtained with a complex multistaged limb salvage. There is no difference in sickness impact profile, a multidimensional measure of self-reported health status, at 2 and 7 years between limb salvage and below-knee amputation.[64] Recovery, regardless of salvage or amputation, is more determined by economic, personal, and social factors than by injury or surgical factors.[64,65] If a patient is low functioning at baseline, a good functional outcome is unlikely regardless of which operation is performed.

Certain clinical findings can be key determining factors in limb salvage decisions. For example, necrosis of the plantar skin requiring free flaps and skin grafts to the sole of the foot are frequently not well tolerated and unlikely to be very functional (Fig. 44-3). Additionally, severe crush injuries to the foot, particularly when combined with severe open tibia fractures, may be best treated with early amputation due to the likelihood of foot and ankle stiffness and chronic pain with ambulation. Historically, several clinical indicators were used to help guide decision making, such as injury scoring



Practice guidelines are a resource of reference and do not replace clinical judgment.

FIGURE 44-2 Schematic algorithm of a mangled extremity protocol.

systems and the presence or absence of plantar sensation. The Lower Extremity Assessment Project (LEAP) found that injury scores were not predictive of a patient's likelihood to have success with limb salvage.[66,67] Similarly, the presence or absence of plantar sensation upon initial presentation was not predictive of plantar sensation after reconstruction.[68] A recent study comparing patients with severe lower limb injuries treated with limb salvage versus below-knee amputation may shed additional light on specific injury characteristics that dominate outcome.[69] Despite improvements in the body of evidence surrounding this difficult subject, much of the decision making remains patient and surgeon specific.

RADIOGRAPHIC EVALUATION OF PATIENTS WITH LOWER EXTREMITY TRAUMA

ATLS protocols suggest anterior-posterior (AP) chest and pelvis and adequate lateral cervical spine radiographs are indicated early in the evaluation and resuscitation of the injured patient during the primary survey.[2,18] The improved imaging capabilities of CT has led some to bypass the pelvis and cervical spine x-rays. CT provides better imaging of the cervical spine, but plain radiographs provide valuable information with pelvic fractures.

Radiographs of injured extremities are part of the secondary survey. Resuscitation of the patient should not be delayed or interrupted for radiographs of the extremities. Radiographs can be taken after urgent surgical treatment for other life-threatening injuries. In the unstable patient, care should be concurrent and not contiguous, such that radiographs and fracture stabilization occur concomitantly in the operating theater or resuscitation bay. If adequate extremity radiographs can be obtained without delaying other essential aspects of the evaluation and treatment of a trauma patient, they can be valuable in making the initial care plan.

Extremity radiographs should include orthogonal views of the entire bone in question (Table 44-4). Generally speaking, radiographs should be obtained prior to formal reduction and splint placement. Not only is the quality of the imaging better without overlying splint material, but knowledge

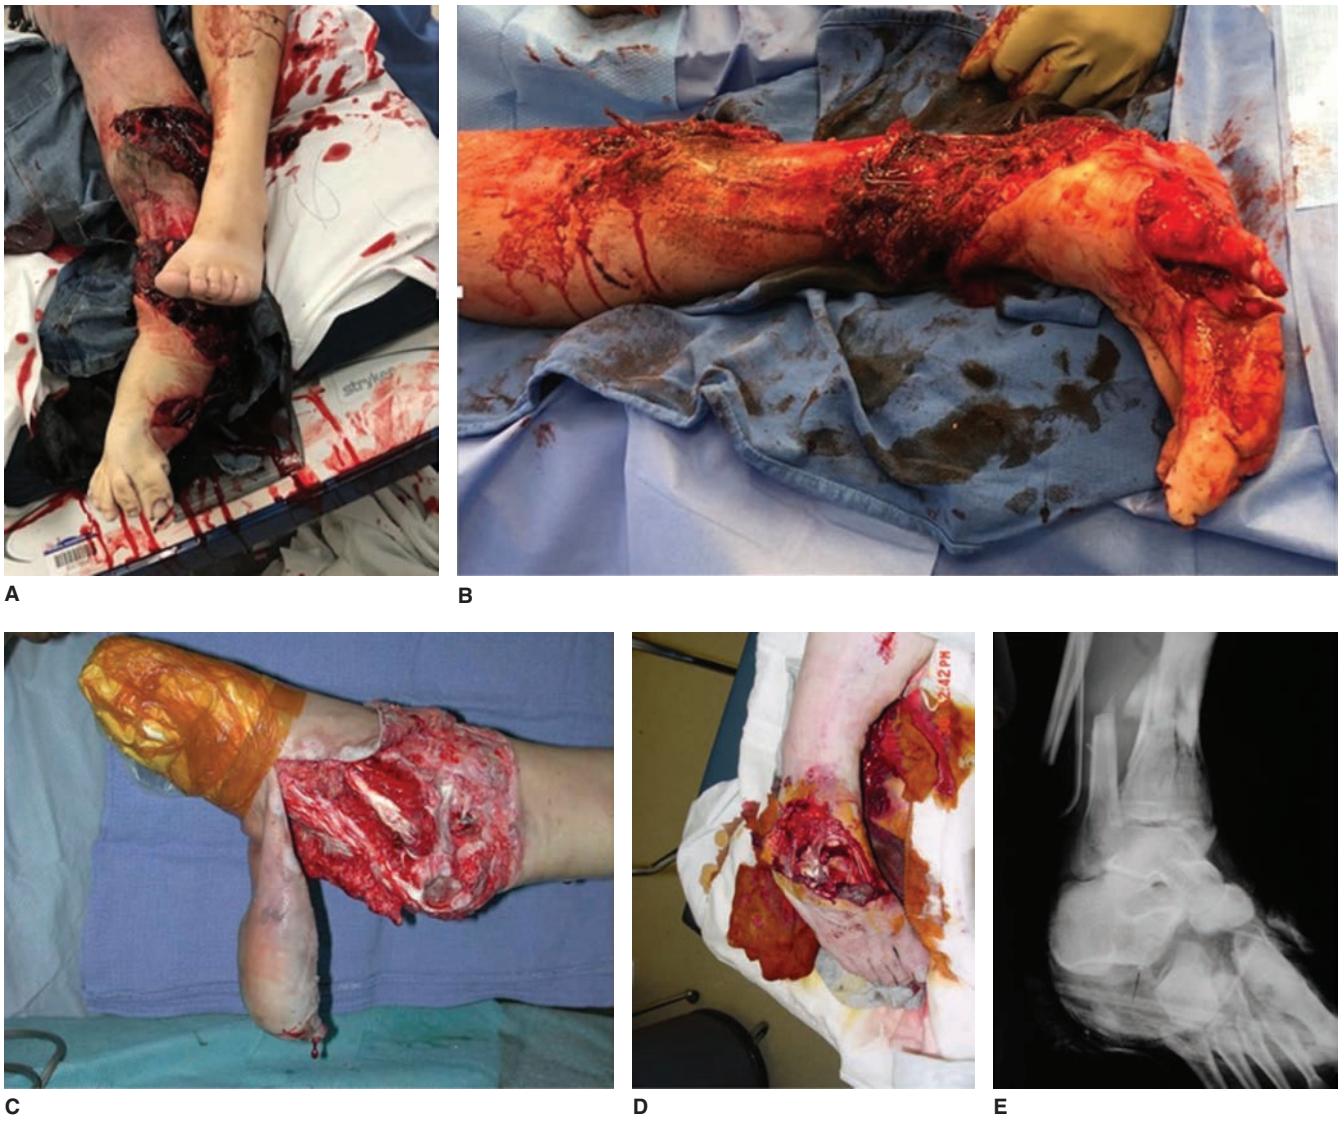


FIGURE 44-3 Examples of several mangled extremities. (**A** and **B**) Clinical images of combined severe tibia and foot trauma with extensive muscular damage, skin loss, and fractures. Clinical images of (**C**) a degloved plantar heel pad, (**D**) crushed foot with dorsal skin loss and tendon injury, and (**E**) corresponding oblique ankle radiograph illustrating the extent of osseous injury to the tibia, ankle, and foot. Severe combined tibia and foot injuries and dysvascular plantar heel pads are common indications for early below-knee amputation.

TABLE 44-4: Radiographic Views of the Lower Extremity

Body part	Standard views
Pelvis	Anteroposterior
Hip	Anteroposterior and cross-table or frog leg lateral
Femur	Anteroposterior and lateral
Knee	Anteroposterior and lateral
Tibia and fibula	Anteroposterior and lateral
Ankle	Anteroposterior, oblique (ankle mortise), and lateral
Foot	Anteroposterior, oblique, and lateral
Calcaneus	Lateral, Harris-Beath (axial)

of the injury pattern can guide surgical decision making. In the event of vascular compromise, reduction should proceed prior to imaging. This is more common with fractures and dislocations about the knee and ankle. After manipulation, reduction, and splint stabilization, the clinical exam should be repeated and radiographs obtained.

Some institutions have incorporated various forms of total-body CT as a rapid, comprehensive evaluation of the skeletal system. This has been common in Europe for many years. Depending on the protocol employed, the entire patient can be rapidly evaluated, obviating the need for multiple trips to the radiology suite, manipulation, and repositioning of the patient. Comprehensive body and extremity scanning may decrease discomfort for the patient, as well as minimize the time the patient is away from the resuscitation

area. Modern CT protocols can accomplish these scans with minimal increase in radiation exposure compared to multiple plain radiographs. Additionally, CT can identify subtle bone injuries that might go unnoticed on plain radiographs. Adoption of this type of imaging protocol requires collaboration between radiology, trauma surgery, emergency medicine, and orthopedic surgery and may require some practitioners to adapt to a different set of images than those to which they are accustomed.

Missed injuries in severely traumatized patients are common. One investigation reported an initial missed injury rate of 15% at a Level I trauma center, of which 70% were fractures.[70] Approximately 50% of missed fractures occurred in the lower extremities, with the foot being the most common.[70,71] Physical examination ("touch every bone"), identifying sites of tenderness, and radiographic imaging correlation can help avoid missed injuries.

Most complex articular fractures are best visualized with CT scan. CT provides detailed information crucial for preoperative planning prior to definitive articular fracture fixation. If a patient is hemodynamically stable and requires CT studies of the chest, abdomen, pelvis, or cervical spine, extremity CT may be obtained at the same time. However, if temporary stabilization with external fixation is planned, the CT is often more useful after restoration of limb length, alignment, and rotation achieved by external fixation. Early involvement of the orthopedic surgeon ensures proper imaging and may avoid unnecessary diagnostic studies.

TIMING AND MAGNITUDE OF FRACTURE FIXATION IN MULTIPLY INJURED PATIENTS

Initial treatment of orthopedic injuries in polytrauma patients is primarily dependent on the patient's evolving physiology. Hemodynamic stability, respiratory status, brain injury, resuscitation, coagulopathy, and additional traumatic injuries are considered prior to implementing a fracture treatment plan. The orthopedic traumatologist should coordinate with the general surgery trauma team and other consultants to formulate an individualized plan of care. Multiply injured patients can follow varying, often unpredictable, clinical trajectories. Continuous physiologic and resuscitative reevaluation is necessary to guide treatment.

Evolution of Early Total Care and Damage Control Orthopedics

In the 1950s, fracture management by traction and prolonged bedrest led to poor outcomes in trauma patients.[72] In the 1980s and early 1990s, early definitive fixation, termed *early total care*, was promoted, which facilitated early restoration of function. Increased complication rates were reported in patients undergoing early total care, and thus more conservative approaches were advocated.[73] In the 1990s and early 2000s, the term *damage control orthopedics* (DCO) was introduced, and studies demonstrated an improved survival in severely injured and underresuscitated patients initially treated with external fixation of femoral fractures in contrast to primary intramedullary nailing.[9,74]

DCO refers to the expedient provisional stabilization of pelvic and long bone fractures, typically via external fixation, in severely injured and physiologically unstable trauma patients. Common indications for DCO include hemodynamic instability (systolic blood pressure <90 mm Hg despite resuscitative efforts), persistent acidosis without trending improvement (pH <7.25, lactate >4.0 mmol/L, base excess –8 mmol/L), severe chest injury requiring significant ventilator assistance, and severe brain injury (Glasgow Coma Scale score [GCS] ≤8). The purpose of DCO is to avoid exacerbating the patient's altered physiologic condition by contributing to ongoing hemorrhage, which could worsen systemic acidosis, induce hypotension, and lead to organ perfusion deficits (eg, decreased cerebral perfusion pressure). DCO also avoids the second-hit phenomenon from major orthopedic surgeries. Immediately after trauma, there is a marked surge of inflammatory mediators.[75-77] The second hit can be a result of a variety of circumstances including infection, sepsis, ongoing hemorrhage (from injury or surgery), and an exaggerated inflammatory response (also from injury and/or secondary surgical procedures). A heightened and dysregulated postinjury inflammatory response has been implicated in the development of several adverse short-term outcomes including acute respiratory distress syndrome (ARDS), prolonged systemic inflammatory response syndrome, nosocomial infection, and multiple organ failure.[8,77-81]

Current Concepts of Early Appropriate Care

There is little debate that hemodynamically unstable and severely underresuscitated trauma patients benefit from DCO measures. Likewise, most agree that it is generally safe to proceed with early definitive fracture fixation in physiologically stable patients without significant head injury. There is considerably more controversy surrounding the care of polytrauma patients with "borderline" physiology (systolic blood pressure 80–100 mm Hg, lactate ~2.5 mg/dL, blood transfusion of 2–8 units, abdominal and/or chest Abbreviated Injury Scale score of 2 or 3). Pape et al[77] reported a lower risk of systemic complications, especially pulmonary dysfunction, with DCO (external fixation) compared to early intramedullary nailing of borderline patients with femur fractures. Recent data by Vallier and colleagues support the concept of early appropriate care, defined as early definitive fixation of spine, pelvis, acetabular, and femur fractures in appropriately resuscitated patients, to minimize systemic complications, including infection, and reduce hospital length of stay.[12,82,83] Early appropriate care of axially unstable fractures is generally recommended when the following physiologic parameters are met: pH greater than 7.25, lactate less than 4.0 mmol/L, base deficit less than 5.5 trending positive, systolic blood pressure greater than 90 mm Hg, and absence of brain injury causing

elevated intracranial pressure.[82-85] Inappropriate timing of surgery not only impacts outcomes in severely injured patients but is also associated with an increased cost of care.[10,14]

Considerations in Polytrauma Patients with an Associated Injury to the Head or Chest

Although some studies have reported higher rates of ARDS (>25%) in patients with lung injuries when early definitive femoral fixation strategies were used, a recent investigation showed no difference in outcome with early total care (2%).[9,13,86] The debate is compounded by the wide spectrum of acute lung injury and subjectivity encompassing the diagnosis of posttraumatic ARDS after fracture fixation. An international panel of experts, the ARDS Definition Task Force, was charged with refining the Berlin Definition, which resulted in improved mortality predictive validity.[87] A careful assessment of a patient's chest injury should be an integral part of decision making when choosing the timing of long bone fracture stabilization.

Secondary brain injury is a result of systemic inflammation, hypoxia, acidosis, fat embolization from a fracture site, and coagulopathy.[88] The GCS is a valuable tool in evaluation of neurologic status and timing of surgery.[88] GCS >13 with a normal CT is appropriate for early definitive treatment of a femur fracture. Patients with a moderate brain injury (GCS 9–13) and minor intracranial pathology are candidates for early appropriate care, but DCO measures should be considered based on recommendations from the neurosurgical and trauma services.[89] Severe traumatic brain injury (GCS <9) patients should be treated with damage control measures, especially in the face of significant intracranial pathology (eg, edema, midline shift, subdural/epidural bleeding).[89] Conversion from external fixation to internal fixation can be planned once GCS is greater than 11 and/or stable intracranial pressure (<20 mm Hg) and cerebral perfusion pressure (>80 mm Hg) over 48 hours are achieved.[89]

Postinjury Immunologic Response of Trauma Patients

Trauma incites a robust systemic inflammatory response. Endogenous "danger" signals, termed *alarmins* or *damage-associated molecular patterns* (DAMPs), are released following injury and propagate inflammation.[90] An exaggerated postinjury inflammatory response, often manifested by the systemic inflammatory response syndrome, has been implicated in adverse outcomes, such as multiple organ failure, nosocomial infection, complicated clinical course, and death.[91]

The two-hit hypothesis refers to an initial traumatic event (eg, tissue damage, hemorrhage) and secondary insults (eg, ischemia/reperfusion, necrotic tissue, infection, additional surgery) that activate the innate immune system in a potentially amplified fashion. This is followed by a compensatory anti-inflammatory response, characterized by suppression of the adaptive immune system. An imbalanced and dysregulated immune response can render host defenses vulnerable to infection and organ dysfunction.[91] An alternative model of the postinjury immunologic response, often referred to as a *genomic storm*, was proposed following a large-scale genomic analysis.[92] Authors described a rapid upregulation of the innate immune system and simultaneous suppression of the adaptive immune system.[92] Recent computational analyses have linked inflammatory biomarker networks with an increased risk of developing nosocomial infection and organ dysfunction.[81,93] Few studies have examined the impact of immunoactive mediators in an orthopedic trauma population.[94-96]

An improved understanding of the immunologic response following trauma may offer additional insight into decisions surrounding the timing and magnitude of fracture fixation. Titration of initial and staged orthopedic interventions in polytrauma patients is a collaborative effort and directed by multidisciplinary input.

MANAGEMENT OF COMMON FRACTURES AND DISLOCATIONS

Acetabular Fractures

Fractures of the acetabulum are articular injuries of the pelvic portion of the hip joint, which can have profound implications on its long-term function. The weight-bearing dome of the acetabulum is defined as the superior 10 mm of the acetabulum as measured on CT, which corresponds to 45° roof arc measurements on radiographs.[97] Fractures with displacement of 2 mm or greater within the dome typically are treated surgically. Fractures involving the lower half of the acetabulum often do not require treatment unless an associated pelvic ring injury requires treatment or there is hip instability. Successful open reduction and internal fixation (ORIF) of displaced acetabular fractures significantly improves the prognosis of these severe injuries. Judet et al[98] developed a classification system that illustrates five simple and five associated fracture types. Their seminal work has significantly improved the understanding and management of acetabular fractures.[98]

An understanding of acetabular morphology and surrounding anatomy is essential for identifying and classifying fracture patterns, formulating a treatment plan, and safely executing surgical treatment. The acetabulum is located in the concavity of an arch (open arms of an inverted "Y") formed by two columns of bone. The anterior column (iliopubic segment) includes the iliac crest, anterior iliac wing (including the anterior superior iliac spine and anterior inferior iliac spine), anterior wall, anterior pelvic brim, and superior pubic ramus. The posterior column (ilioischial segment) consists of the inferior aspect of the sciatic buttress (adjacent to the greater sciatic notch), posterior wall, majority of the quadrilateral plate, ischial spine, and ischial tuberosity. Compact bone between two columns at its apex constitutes the roof of the acetabulum and forms the keystone of the arch. Assessment of radiographic landmarks on the AP pelvis view can allow for rapid identification of acetabular injuries. A break

or discontinuation of any of these radiographic lines should warrant further investigation with obturator oblique and iliac oblique Judet radiographs and CT scan with three-dimensional reconstructions.[99] CT aids in fracture classification, measurement of displacement, identification of incarcerated fracture fragments, assessment of marginal impaction, and determination of the ideal surgical approach. Knowledge of the vascular tree of the true and false pelvis is critical to safely performing acetabular surgery. ORIF of the acetabulum is typically performed by orthopedic trauma surgeons with pelvic operative experience. Cautious identification and protection of the external iliac artery/vein, obturator artery/vein, deep branches of the internal iliac system, and ligation of the corona mortis is critical in anterior approaches. Posterior approaches necessitate careful mobilization of the sciatic nerve, avoidance of the medial femoral circumflex artery, and protection of the superior and inferior gluteal vessels.

Specific acetabular fracture patterns result from the direction of force applied to the hip and the position of the femoral head when it impacts the acetabulum. An axial load to the femur with the hip in the flexed or neutral position will force the femoral head against the posterior articular surface of the acetabulum, leading to a posterior wall fracture, with or without hip dislocation. An abducted leg position directs the force on the acetabulum more medially and will lead to a transverse fracture that is occasionally associated with posterior wall. A transverse fracture of the acetabulum is a major injury that separates the acetabulum into cephalad and caudal fragments. The degree of displacement and comminution in acetabular fractures depends on not only the magnitude of energy involved, but also an individual's bone density. As in most lower extremity injuries, there is a bimodal distribution in acetabular fractures: high-energy fractures typically occur in young patients, and low-energy fractures usually result from falls in elderly patients with poor-quality bone. In high-energy injuries, fracture patterns closely reflect those described by Judet et al.[98] However, in osteopenic patients, a low-energy fall with an impact on the lateral thigh often results in an anteromedial force through the greater trochanter, leading to a displaced anterior column fracture with quadrilateral plate (central portion of acetabulum) involvement. This fracture is classified as an anterior column–posterior hemitransverse pattern. Very low anterior column fractures are typically extensions of superior pubic ramus fractures and are treated as pelvic ring injuries rather than acetabular fractures (Fig. 44-4). The bone quality and fracture mechanism should be considered when evaluating patients with acetabular fractures because there is a high association of other orthopedic

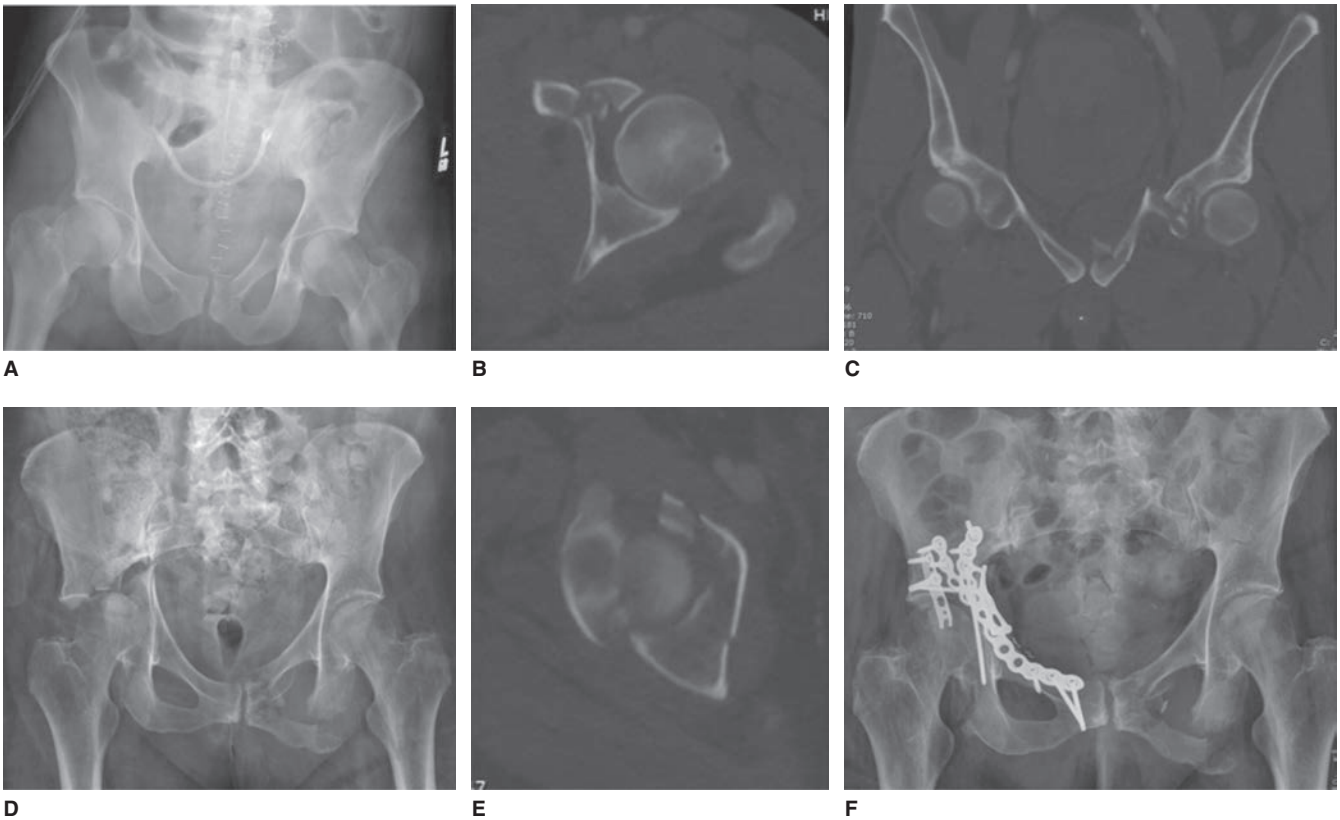

FIGURE 44-4 Low anterior column acetabular fracture of the left hip: (**A**) anteroposterior (AP) pelvis radiograph, (**B**) axial computed tomography (CT) scan, and (**C**) coronal CT scan. Although technically an acetabulum fracture, low anterior column fractures are typically manifestations of pelvic ring injuries and may not require anatomic fixation as in acetabulum fractures that involve the weight-bearing dome. Transverse–posterior wall acetabular fracture of the right hip: (**D**) AP pelvis radiograph, (**E**) axial CT scan, and (**F**) postoperative AP pelvis radiograph following treatment with open reduction and internal fixation via a combined anterior and posterior approach.

and systemic injuries. Careful evaluation of skin overlying the pelvis, hip, and thigh may identify a Morel-Lavallée lesion, defined as a closed, internal degloving injury when the subcutaneous fat avulses off the deep fascia, creating a potential space for fluid accumulation. Nerve palsies, most commonly affecting the peroneal division of the sciatic nerve, occur in up to 15% of acetabular fractures associated with posterior hip dislocations.[100,101]

Common indications for surgical management of acetabular fractures include displacement greater than 2 mm within the weight-bearing dome,[102] instability noted on examination under anesthesia,[103,104] hip incongruity, intra-articular fragments superior to the fovea, and open fractures. The surgical approach is dictated by the fracture pattern and the overall condition of the patient. Options for anterior column and transverse fracture patterns include the ilioinguinal approach, anterior intrapelvic approach (Stoppa),[105] lateral window portion of the ilioinguinal, and limited iliofemoral approach (extension of a lateral window into an anterior approach to the hip). The majority of posterior column fractures and most transverse fractures are exposed via the Kocher-Langenbeck approach. The extended iliofemoral approach is extensile but rarely used due to high rates of infection and heterotopic ossification. Occasionally, combined anterior and posterior approaches are employed to address both anterior and posterior column displacement in associated fracture types (eg, both-column, T-type, transverse-posterior wall patterns) that cannot be reduced by a single exposure. Occasionally the optimal approach must be abandoned due to associated wounds or initial treatments such as laparotomy, suprapubic catheter, and nonselective arterial embolization to major pelvic vasculature.[106] Restoring articular congruity and achieving stable fixation are critical in acetabular surgery as accuracy of fracture reduction has been shown to correlate with hip survival (prevention of posttraumatic arthritis and conversion to arthroplasty).[107] Minimally invasive percutaneous screw fixation represents a viable alternative to ORIF in minimally displaced fractures or in patients at risk for significant wound complications due to an extensive surgical procedure.[108,109]

Timing of acetabular surgery depends on the patient's physiologic condition. Fixation and mobilization within 24 hours in appropriately resuscitated patients carry a lower risk of systemic complications.[82] Acetabular fractures are usually closed injuries, without need for immediate operation. Some authors contend that intraoperative blood loss can be minimized if surgery is delayed for 2 to 3 days. However, two recent investigations found no difference in blood loss when anterior column fractures were treated within 48 hours compared to after 48 hours[110] or when posterior wall fractures were repaired before 24 hours compared to after 24 hours.[111] Short-term traction may be indicated in unstable fracture patterns to maintain hip reduction and prevent femoral head protrusion into the pelvis. Postreduction CT is preferred to prereduction CT when fractures are associated with dislocations, as it not only confirms reduction, but also identifies incarcerated or intra-articular fracture fragments that may influence surgical planning.

Acetabular fractures in osteoporotic individuals pose unique problems. There is frequently significant comminution, protrusion deformity, and poor bone quality, which increases the chance of postoperative fixation failure. In these instances, immediate total hip arthroplasty, either combined with ORIF or specialized acetabular reconstruction devices, allows improved fixation and early weight bearing in elderly patients.[112,113]

Patients with pelvic and acetabular fractures have a significant risk of thromboembolic complications. Intermittent venous compression devices, pharmacologic anticoagulation, and insertion of retrievable inferior vena cava filters for high-risk patients are all appropriate strategies. Prophylaxis against heterotopic ossification following open reduction through a posterior approach is preferred by most surgeons. Evidence supports radiation-based prophylaxis (single dose of 700 cGy) compared to pharmacologic-based prophylaxis (indomethacin), which has been shown to be associated with acetabular nonunion.[114]

Treatment of acetabular fractures is also associated with significant blood loss. Cell saver has been shown to be potentially useful for select anterior fracture patterns when large-volume blood loss is anticipated.[115] Two recent meta-analyses reported that intraoperative administration of tranexamic acid may reduce rates of blood transfusion in orthopedic trauma surgery.[116,117] However, a randomized controlled trial on the use of tranexamic acid in acetabular surgery reported no benefit to its use.[118] Acetabular fracture surgery remains among the most challenging procedures in orthopedics. These difficult and high-risk reconstructive surgeries should be performed in specialized trauma centers with experienced surgeons to ensure optimal treatment.[119]

Hip Dislocation and Femoral Head Fractures

The hip joint depends on bony architecture and soft tissue constraints for its stability. Significant force is required to dislocate the native hip joint. The most common mechanism of injury is a direct posterior force through a flexed knee and adducted hip in a motor vehicle accident. Some patients with pure hip dislocations may have slightly abnormal native anatomy (acetabular retroversion) predisposing them to hip dislocation.[120] The clinical appearance of a patient with a posterior hip dislocation is hip flexion, adduction, internal rotation, and resistance to motion. Patients are usually in significant pain. This appearance may be lacking if a significant fracture of the posterior wall exists. Anterior dislocation results in external rotation and abduction of the affected extremity with slight hip flexion. The typical mechanism of injury leading to anterior dislocation is forced external rotation and abduction of the hip joint. Anterior dislocation occurs less frequently (<10%) compared to posterior dislocation.[121]

The primary blood supply to the femoral head in adults is predominantly from the medial femoral circumflex artery through the retinacular arteries that branch off from an extracapsular ring at the base of the femoral neck. The lateral

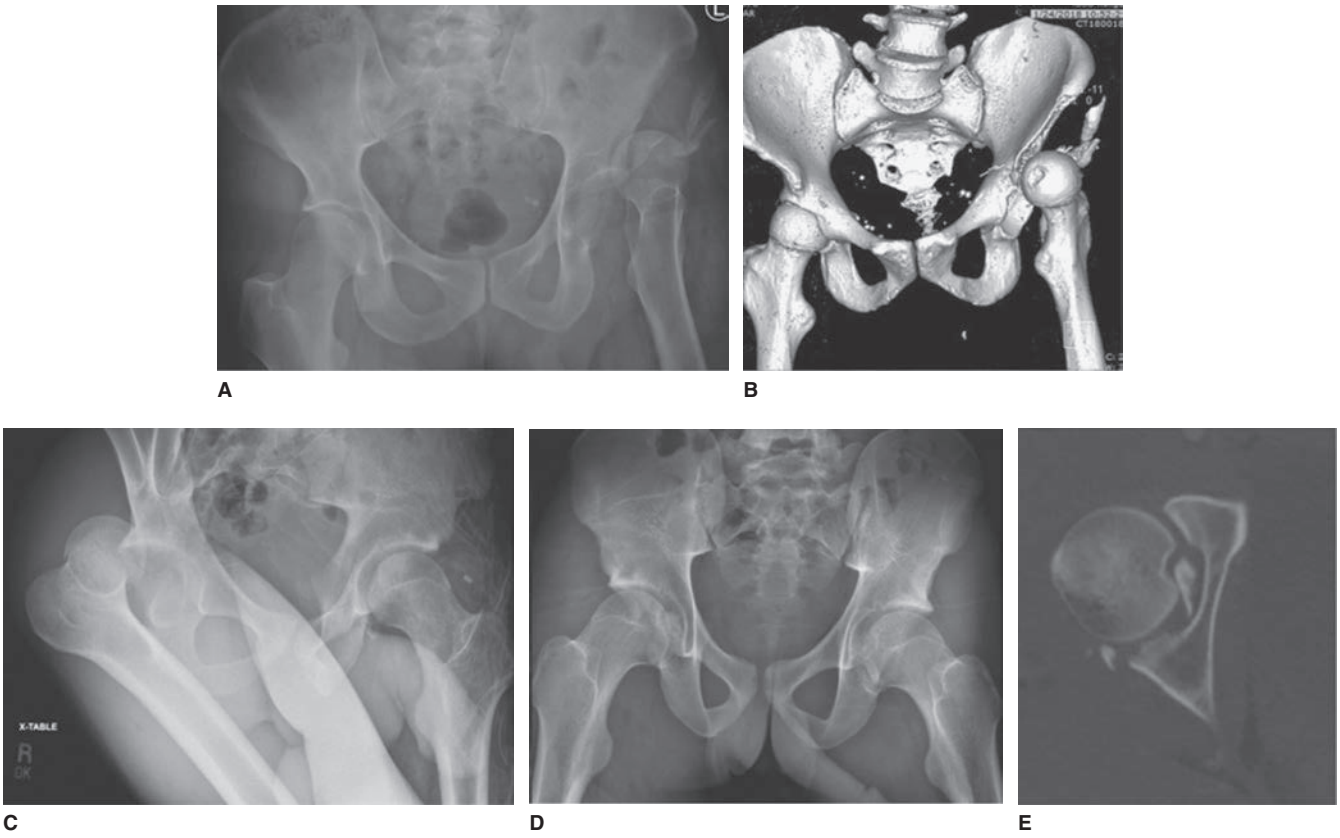

FIGURE 44-5 Examples of hip dislocations. (**A**) Anteroposterior (AP) pelvis radiograph and (**B**) three-dimensional computed tomography (CT) reconstruction of a left anterior hip dislocation. femoral circumflex artery and the superior and inferior gluteal arteries provide minor contributions to femoral head perfusion. High-energy injury involving damage to the blood supply can result in osteonecrosis and resultant collapse of the femoral head. This can be a devastating complication with lifelong implications, particular for young patients, as total hip replacement is usually the only viable treatment. The sciatic nerve runs in close proximity to the posterior aspect of the hip joint. Ipsilateral sciatic nerve injury occurs in 10% to 15% of hip dislocations, with the peroneal trunk being most commonly affected, leading to foot drop. Urgent hip reduction is critical to minimize ongoing compression injury to the nerve and minimize the risk of osteonecrosis of the femoral head. There is no specific treatment for sciatic nerve injuries. Up to 70% to 80% of sciatic nerve palsies resolve over a period of months. Associated orthopedic injuries occur in 60% to 70% of patients with traumatic hip dislocations and fracture dislocations.[122] Ipsilateral knee injuries including ligamentous disruption, patella fracture, distal femur fracture, and proximal tibia fracture are quite common.[123] Other systemic injuries such as head, craniofacial, thoracic aortic, and abdominal visceral injuries may be seen in deceleration injury patterns.[122,124]

An AP pelvis radiograph should be obtained as part of the ATLS protocol. This radiograph usually shows obvious signs of a hip dislocation or fracture-dislocation. A posterior hip dislocation will show a smaller femoral head on the injured side as the femoral head is closer to the cassette. An anterior dislocation, in contrast, will demonstrate a larger femoral head as the femur is further from the cassette, creating a larger radiographic shadow (Fig. 44-5). Anterior dislocations may show combined superior (pubic) or inferior (obturator) dislocation if the hip is in extension or flexion at the time of injury, respectively. Care should be taken to scrutinize radiographs for ipsilateral femoral neck fractures, which are a contraindication for closed hip reduction in the emergency department.

Urgent closed reduction of the hip joint should be performed to decrease the risk of irreversible avascular necrosis or sciatic nerve injury. The importance of prompt reduction less than 6 hours from injury has been demonstrated in retrospective and prospective studies to minimize the risk of avascular necrosis.[125] Closed reduction is best performed with adequate intravenous sedation and muscle relaxation. Ideally, reduction would occur before the patient has the standard trauma head/neck/chest/abdomen/pelvis CT scan because delays can increase the risk of avascular necrosis and sciatic nerve injury. Additionally, all hip dislocations require a postreduction CT scan to evaluate for concentric reduction and identify residual incarcerated bone fragments

(Fig. 44-5). Therefore, if reduction occurs before the trauma scan, an additional pelvic CT scan can be avoided.

There are various described techniques for reduction of the hip joint, with the general principle being in-line traction combined with re-creation of the injury pattern. For posterior dislocations, a direct anterior force applied through a bent knee is often effective while two assistants are holding counterpressure on the patient's anterior superior iliac spines bilaterally. This maneuver should begin with the leg internally rotated and adducted to clear the posterior wall. The clinician should then progress to external rotation once traction is applied. Care must be taken to avoid unnecessary force because iatrogenic fracture, particularly femoral neck fracture, is a rare complication. After relocation of the femoral head, the hip should be taken through a range of motion in order to examine for instability that will guide treatment. Postreduction skeletal traction may be necessary if the hip remains unstable or if incarcerated fragments remain in the joint. Acetabular wall fractures of significant size can result in instability, which is an indication for traction. If the hip is reduced, the surgery can be delayed until the patient is properly resuscitated and optimized. Purely ligamentous injuries are usually inherently stable, and most surgeons recommend a 4- to 6-week period of protected weight bearing and hip precautions based on the direction of the dislocation.

Fracture of the femoral head is a rare injury pattern and often associated with hip dislocations. The presence and size of a femoral head fragment depend on the position of the hip at the time of impact, with a straighter leg and hip associated with larger fracture fragments. These injuries are usually seen in high-energy mechanisms. The incidence of femoral head fractures is increasing as resuscitation protocols improve. Radiographic characteristics of irreducible femoral head fracture-dislocation are posterior-superior dislocation with sagittal plane femoral head fracture, intact posterior wall of acetabulum, and close apposition of proximal femur to the supra-acetabular ilium (Fig. 44-6).[126] Postreduction CT scans should be obtained in order to assess the concentricity of

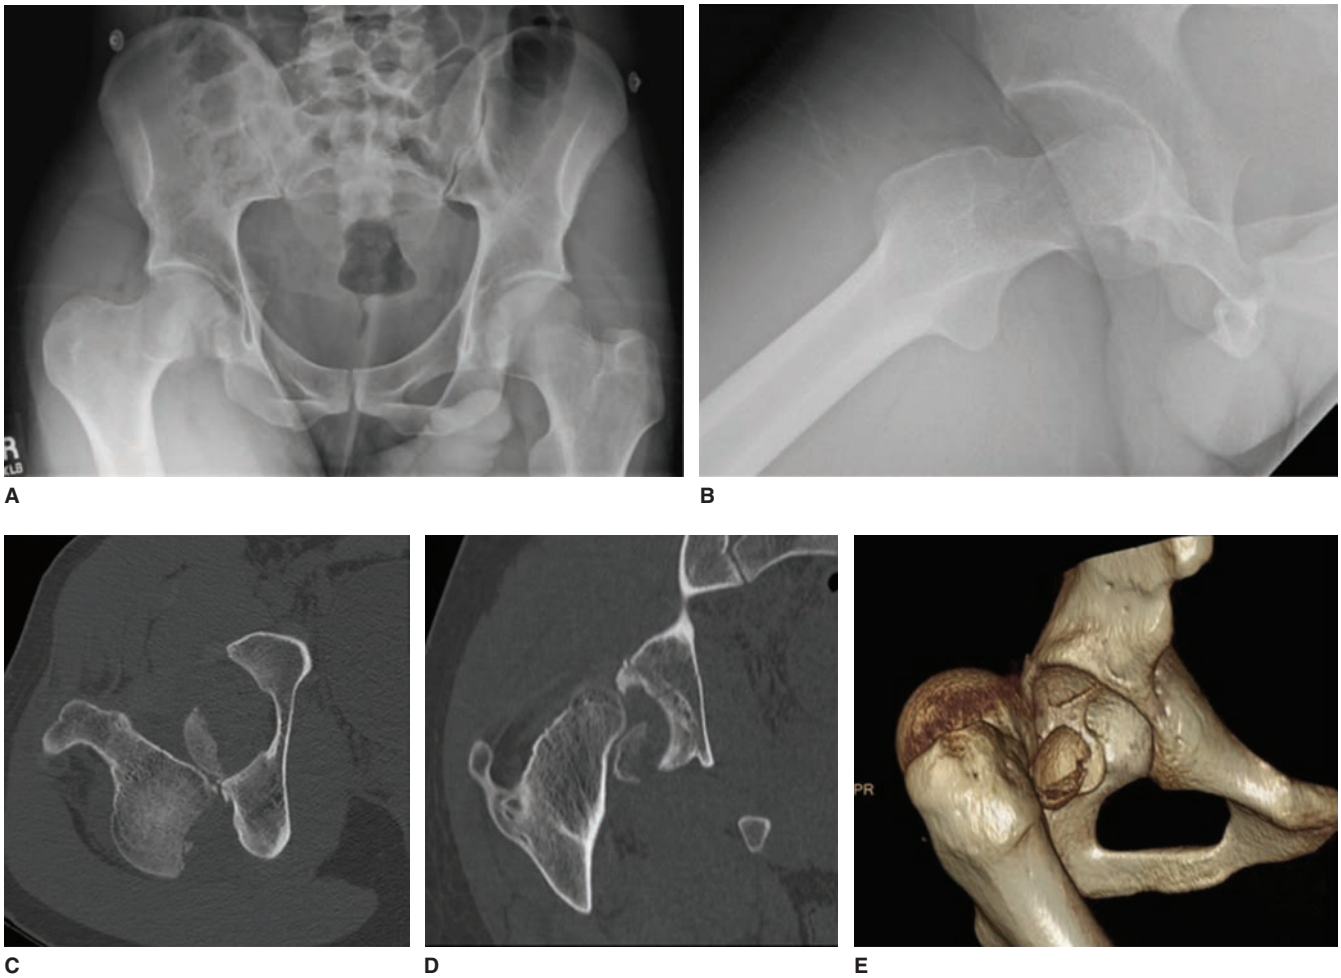

FIGURE 44-6 Irreducible hip dislocation. (**A**) Anteroposterior (AP) pelvis radiograph and (**B**) cross-table lateral radiograph of the right hip demonstrating a right posterior hip dislocation. Note the nearly normal appearance of the right hip joint on the AP image in contrast to the cross-table lateral view that clearly demonstrates the posterior dislocation. reduction, the size and location of the femoral head fracture fragment, and for associated bony injuries of the acetabulum and femoral neck. Irreducible femoral head fracture-dislocations should be taken promptly to the operating room for an open reduction, but only after the appropriate orthopedic trauma surgical team is mobilized because the reduction can be technically challenging.[127] Surgical approaches include a posterior Kocher-Langenbeck approach with or without a trochanteric osteotomy and surgical hip dislocation[128] and an anterior Smith-Peterson approach to the hip.

The Pipkin classification describes the femoral head fracture in relation to the fovea (depression in the femoral head where the ligamentum teres attaches) as follows: type 1, fracture inferior to the fovea; type 2, fracture superior to the fovea; type 3, any head fracture with an associated femoral neck fracture; and type 4, any fracture with an associated acetabular fracture.[129] The majority of Pipkin type 3 and 4 fractures are treated operatively, along with most displaced (≥2 mm) Pipkin type 2 fractures. Most minimally displaced Pipkin type 1 fractures can be managed nonoperatively if the hip is concentrically reduced. Nonoperative management consists of a period of protected weight bearing, often with motion restrictions to prevent dislocation. Older patients with osteoporotic bone or comminuted fractures may be treated with arthroplasty to facilitate early mobilization and immediate weight bearing.

Posttraumatic arthritis and avascular necrosis are the most common complications following hip dislocation and fracture-dislocation. These are life-altering complications when they occur in young patients. The treatment for both of these complications is total hip arthroplasty. Although somewhat undesirable in younger patients, arthroplasty provides excellent pain relief and function, with modern implants lasting much longer than earlier generation implants (up to 20–30 years). Heterotopic ossification can be seen, particularly with patients with concomitant head injuries. Hip arthroscopy has improved substantially over the past decade and warrants a consideration in the treatment algorithm to address loose bodies and other intra-articular pathology after hip dislocation and fracture-dislocation.

Fractures of Proximal Femur—"Hip Fractures"

Hip fracture is a term often used to describe femoral neck and intertrochanteric femur fractures (Fig. 44-7). Like most orthopedic injuries, hip fractures have a bimodal distribution. In young patients (<50 years), fractures of the proximal femur are typically high energy with more comminution and displacement. The more common geriatric hip fracture tends to be lower energy. Worldwide, there were 1.7 million hip fractures in 1990, and this is projected to increase to 6.3 million in 2050. In the United States alone, this number is expected to be between 500,000 and 1 million hip fractures per year.[130] Hip fractures are associated with significant morbidity and mortality, often to the surprise of patients and

families who suffer this often life-changing injury. Up to 20% of elderly hip fracture patients require long-term nursing home care, and only 40% regain their prefracture level of independence.[131] By definition, a patient over age 55 who sustains a hip fracture has osteoporosis and carries a risk of future osteoporotic fractures as high as 17 times that of age-matched controls.[132,133] Reported mortality rate following the hip fracture surgery is 9% at 30 days, 19% at 90 days, and 30% at 12 months.[134] The mortality associated with osteoporotic fractures is greater than the combined mortality of breast and ovarian cancer.[135] Various classifications based on fracture location, displacement, and stability help define treatment options. Although often grouped together, fractures of the proximal femur can have significantly different treatment methods based on a patient's age, function, and intracapsular or extracapsular location.

Fracture healing rates and prognosis for hip fractures are highly dependent on the vascular supply to the femoral neck and head. The ascending cervical arterial branches that supply the femoral head arise from an arterial ring at the base of the femoral neck. Extracapsular fractures at the base of the neck (basicervical) or distal to it (intertrochanteric) usually do not damage these arteries. Intracapsular fractures proximal to the arterial perforation of the femoral neck can disrupt these vessels or cause local circulatory compromise due to intracapsular bleeding and tamponade. In addition, an intracapsular fracture will be exposed to the synovial fluid within the hip joint, which can interfere with healing. Blood supply to the femoral head may not be compromised in nondisplaced fractures.

The medial aspect of the femoral neck is the compressive side and the lateral aspect the tension side. The average neck-shaft angle is 130° with 10° of anteversion. Hip abductors (gluteus medius and minimus) insert on the greater trochanter, and the iliopsoas muscle inserts on the lesser trochanter. Standard diagnostic imaging consists of an AP pelvis, cross-table lateral hip, and orthogonal femur films. CT scan can aid in diagnosis and preoperative planning in select circumstances.

Femoral neck fractures are classified based on the following: (1) location: subcapital (below the head), transcervical (mid neck), or basicervical (base of the neck); (2) stability: Garden classification; and (3) fracture line orientation (Pauwel's classification). Displaced (Garden 3 and 4) femoral neck fractures portend more instability and are associated with a higher likelihood of fracture fixation failure. The AO Foundation (AO)/Orthopaedic Trauma Association (OTA) classification is often used for intertrochanteric femur fractures.[136] Intertrochanteric fractures without comminution, lesser trochanteric involvement, multiple fragments, or posteromedial buttress extension are considered stable. Fractures that extend laterally below the greater trochanter render the lateral wall incompetent and are considered unstable.[136] Reverse obliquity intertrochanteric fractures are also considered unstable.[136]

Nearly all patients with hip fractures benefit from operative stabilization to promote healing and allow immediate mobilization. Young femoral neck fracture patients are typically treated with closed reduction and internal fixation for nondisplaced fractures or ORIF for displaced fractures. An intracapsular femoral neck fracture in a young patient should be addressed as soon as possible because viability of the femoral head is at risk. Not only can the ascending arteries along the femoral neck be severed or avulsed if the fracture is displaced, but also they can be kinked and subsequently thrombose. These small-caliber vessels cannot be repaired, although timely fracture reduction may potentially preserve vascularity. The efficacy of intracapsular hematoma decompression is controversial. Because there is no way to preoperatively assess femoral head perfusion, attempts to preserve the viability of the femoral head should proceed when the appropriate surgical team is assembled, ideally within 24 hours. Reduction quality is still considered to be more important than timing to fixation; thus, emergent surgery with an inexperienced and ill-equipped team is discouraged.

Avascular necrosis is a complication reported in 10% to 30% of femoral neck fractures. Portions of the subchondral bone may collapse, leading to joint surface irregularity, loss of femoral head sphericity, and posttraumatic arthritis. Total hip replacement is usually the only reconstructive option is these situations. Degenerative changes due to avascular necrosis contribute to a reoperation rate ranging from 17% in young patients to 53% in an older population.[137,138] Despite the complication rates, internal fixation usually remains the best option for patients less than 50 to 55 years old due to the superior function of the native femoral head compared to total hip arthroplasty.

Displaced geriatric femoral neck fractures are usually treated with arthroplasty to minimize the rate of reoperation and facilitate immediate mobilization. In general, high-functioning elderly patients without extensive medical comorbidities should undergo total hip arthroplasty, regardless of age.[138] Lower functioning geriatric patients with minimal ambulatory capacity and multiple comorbidities are better candidates for hemiarthroplasty.[138] Elderly patients with nondisplaced femoral neck fractures can be treated effectively with in situ pinning permitting immediate weight bearing.

Intertrochanteric fractures in patients of all ages are treated surgically. For stable fractures, either a sliding hip screw or cephalomedullary nail (CMN) is appropriate (Fig. 44-7). For unstable fractures (lateral wall incompetence, four-part fracture, and reverse obliquity patterns), however, CMN is the implant of choice due to a higher failure rate of sliding hip screw.[139] Greater than 90% of intertrochanteric femur fractures heal uneventfully, and precise placement of the lag screw in the center of the femoral head close to the subchondral bone minimizes the risk of fixation failure.[140] Recently, an analysis of American College of Surgeons National Surgical Quality Improvement Program illustrated that although the overall outcomes are similar between the sliding hip screw and CMN, patients treated with CMN had a greater than 1 day shorter hospital length of stay after hip fracture, thus negating the extra cost incurred by using CMN.[141]

Geriatric patients with hip fractures benefit from expeditious medical optimization and surgical fixation within 24 to

48 hours from injury. Delay in surgery for patients with hip fractures has been associated with increased rates of mortality, increased in-hospital complications, and slower return to function.[142,143] Surgical delay of more than 24 hours increases the risk of 30-day and 90-day mortality.[134,144] An echocardiogram should be obtained to assess patients with a new-onset or previously undiagnosed murmur because significant aortic stenosis may influence anesthetic management. However, authors have found that most preoperative testing for hip fracture patients often delays surgery and rarely influences management.[145] Communication between the medical and surgical teams and adherence to the American College of Cardiology/American Heart Association guidelines on indications for preoperative testing may avoid delays in surgical treatment by foregoing testing that will not impact the care of the patient.[146,147]

Many hospitals have recently developed a multispecialty hip fracture service to provide comprehensive inpatient and outpatient care for hip fracture patients. This includes rapid, cost-effective preoperative testing and optimization. Surgical decision making focuses on choosing an implant that allows the patient to bear weight immediately postoperatively. A coordinated inpatient team includes the following: orthopedic surgeon, hospitalist or geriatrician, dietician, physical therapist, social worker, and case management. This team focuses on initiating osteoporosis management, delirium prevention, mobilization, and appropriate discharge disposition. Close multidisciplinary follow-up is established to optimize the patient's bone health during the healing stages of the fracture with establishment of an osteoporosis treatment plan. There is considerable evidence to suggest that a comprehensive approach decreases complications and opioid use, shortens length of stay, and decreases readmissions, while improving 30-day and long-term mortality and return to activities of daily living, all without an increase in costs.[148]

Subtrochanteric and Femoral Shaft Fractures

Subtrochanteric femur fractures are defined as fractures involving the region between the lesser trochanter and 5 cm distal, including patterns that extend into the intertrochanteric region and base of the femoral neck. Physiologically, subtrochanteric and femoral shaft fractures are very similar; however, there are some nuances between them that dictate varying treatment considerations.

Femoral shaft fractures are usually due to high-energy trauma and can be associated with blood loss of up to 1500 to 2000 mL in the thigh. Thus, these injuries can cause, or contribute to, hemorrhagic shock. Many patients suffer severe associated injuries to the torso, pelvis, and other extremities. The femur is the strongest bone in the body; therefore, the force required to fracture it in young, healthy patients is significant. Patients present with a shortened, externally rotated limb, pain on palpation, and gross deformity. A detailed neurovascular exam should be documented, and thigh compartment tension should be assessed. Radiographs of the entire femur should be obtained, as femoral neck fracture occurs in association with approximately 9% of femoral shaft fractures (Fig. 44-8).[149,150] Up to 10% of ipsilateral femoral neck fractures in patients with femoral shaft fractures were not identified during the initial assessment and were found after shaft fixation.[151] Although several historical classification systems exist, they are not often used in daily practice. Femoral shaft fractures are typically described by location (proximal one-third, mid-shaft, distal one-third) and pattern (transverse, short/long oblique, segmental, comminuted).

Both femoral shaft and subtrochanteric fractures can be initially treated with skeletal traction prior to definitive fixation if prompt surgical fixation is not possible. Traction can minimize fracture-related blood loss by decreasing the

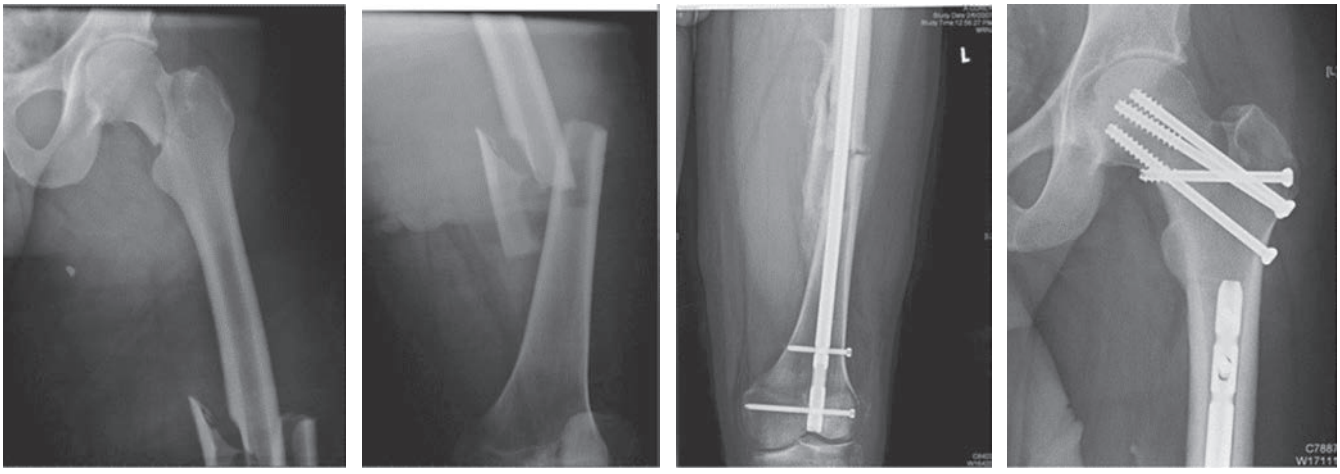

FIGURE 44-8 (**A** and **B**) Injury radiographs of a femoral shaft fracture with an ipsilateral femoral neck fracture. (**C** and **D**) Postoperative radiographs following intramedullary nail fixation of the shaft fracture and cancellous screw fixation of the femoral neck. The femoral neck fracture in this injury is often missed. Close inspection of the hip on injury radiographs, the trauma pelvis computed tomography scan, and intraoperative fluoroscopy can prevent missed injuries.

potential third space and lessen pain. Traction for femur fractures is typically applied through a pin in the proximal tibia to avoid contaminating the distal femur site of future fixation. Early (<24 hours) femur fixation is beneficial in appropriately resuscitated patients without lung and head injuries.[10,12,14,77,82,83] Patients who are too unstable to undergo definitive treatment typically benefit from placement of an external fixator. External fixators can typically be placed in less than 30 minutes, with minimal blood loss and without special positioning. External fixator placement minimizes fracture motion, decreases pain and fat emboli, and allows improved patient mobilization and pulmonary toilet.

The vast majority of femoral shaft and subtrochanteric femur fractures are treated with a reamed, statically interlocked, intramedullary nail.[152] This procedure is associated with high union rates (>95%), low complication rates, and immediate weight bearing. Intramedullary reaming permits use of a larger-diameter nail to provide sufficient strength and durability, minimizing the risk of failure. Awareness of extravasation of reaming debris such as fat, bone marrow fragments, and inflammatory mediators has led to concern that embolization of this debris to the lungs may increase the risk of pulmonary complications.[153] There are conflicting data surrounding the impact of reaming on perioperative pulmonary complications.[154,155] In most circumstances, the clinical benefit of reamed nails is superior to unreamed nails.[156,157] Proximal one-third femur fractures are often treated with an antegrade nail (passage of the nail from the hip to the knee; starting point on the greater trochanter or piriformis fossa) and distal one-third femur fractures are typically treated with a retrograde nail (passage of the nail from the knee to the hip). However, many proximal one-third fractures can be successfully treated with a retrograde nail, including polytrauma patients who benefit from supine positioning. Mid-shaft femur fractures can be treated with either technique. Antegrade nailing is associated with a slightly higher rate of postoperative hip pain, and retrograde nailing is associated with a slightly higher rate of postoperative knee pain.[158]

Subtrochanteric fractures represent challenging injuries as muscle forces on the proximal fragment (flexion, abduction, external rotation) often lead to widely displaced fractures that are difficult to properly align. Intramedually nailing remains the optimal treatment of subtrochanteric fractures; however, open reduction is often necessary to obtain adequate alignment and promote fracture healing. Use of a sliding hip screw is not recommended due to a high rate of loss of fixation and early failure.[159] Multiple recent reports have demonstrated a high failure rate with the use of fixed-angle locking plates in the treatment of peritrochanteric femur fractures.[160]

Atypical subtrochanteric femur fractures may occur in patients who have been taking bisphosphonate medication for the treatment of osteoporosis for several years. The mechanism of action of bisphosphonates interferes with normal bone turnover. Subsequently, the ability of bone to repair itself is altered. Bisphosphonate fractures occur with low-energy or even no trauma, often with prodromal pain. Hallmarks of an atypical femur fracture include a short oblique or transverse fracture pattern, thickening or beaking of the lateral cortex, and a medial spike (Fig. 44-9).[161,162] Radiographs of the contralateral femur should be taken, as these fractures often occur bilaterally. Patients with these fractures should have their bisphosphonates stopped, and medical reevaluation of their osteoporosis is warranted.

Fractures of the Distal Femur

Fractures of the distal femur have historically been a significant treatment challenge because it can be difficult to obtain adequate fixation in the short residual bone segments, especially in osteoporotic patients. Distal femur fractures account for approximately 7% of all femur fractures.[163] Similar to hip fractures, distal femur fractures are mostly seen in two patient populations: young patients sustaining high-energy trauma and low-energy injuries in the elderly. There is a range of injury patterns that vary from complex intra-articular injuries to simple transverse or short oblique extra-articular fractures. Historically, weight bearing was limited following fixation; however, recent reports support immediate weight-bearing protocols in elderly patients to facilitate early mobilization without an increase in fixation failure or impairment of healing.[164]

The most common mechanism for a distal femur fracture is a dashboard-type injury with direct trauma to the flexed knee. These injuries are associated with concomitant acetabular fractures, hip dislocations, and knee injuries such as patella fractures. Because of the close proximity of the tethered femoral artery in the adductor hiatus, vascular injury can occur. Vascular studies are indicated if abnormal pulses are detected or if the ABI is less than 0.9. Radiographic evaluation should include standard AP and lateral films of knee and femur. CT scan is obtained if there is concern for intra-articular extension. The prevalence of a coronal plane fracture of the femoral condyle (Hoffa fracture) has been reported to be as high as 38% (Fig. 44-10).[165] Lateral condyle fractures are more common than medial condyle fractures and can be associated with late displacement and poor functional outcomes if left untreated.[165]

Most patients initially have a knee immobilizer applied for pain control in anticipation of surgery. Similar to femoral shaft fractures and hip fractures, patients benefit from early fracture stabilization and mobilization. In patients with significant soft tissue injuries or polytraumatized patients requiring prolonged resuscitation, a temporary knee spanning external fixator may be applied to maintain length and stability until definitive fixation is appropriate. The primary aim of distal femur fracture treatment is anatomic reconstruction of the articular segment, followed by restoration of appropriate length, alignment, and rotation of the femur. Failure to achieve appropriate articular reduction and alignment may result in an abnormal gait, pain, posttraumatic arthritis, and a poor functional outcome. Treatment options include ORIF with plate fixation and intramedullary nailing.[166] Complex total knee arthroplasty may be warranted in rare circumstances.[167] Elderly periprosthetic distal femur fractures have

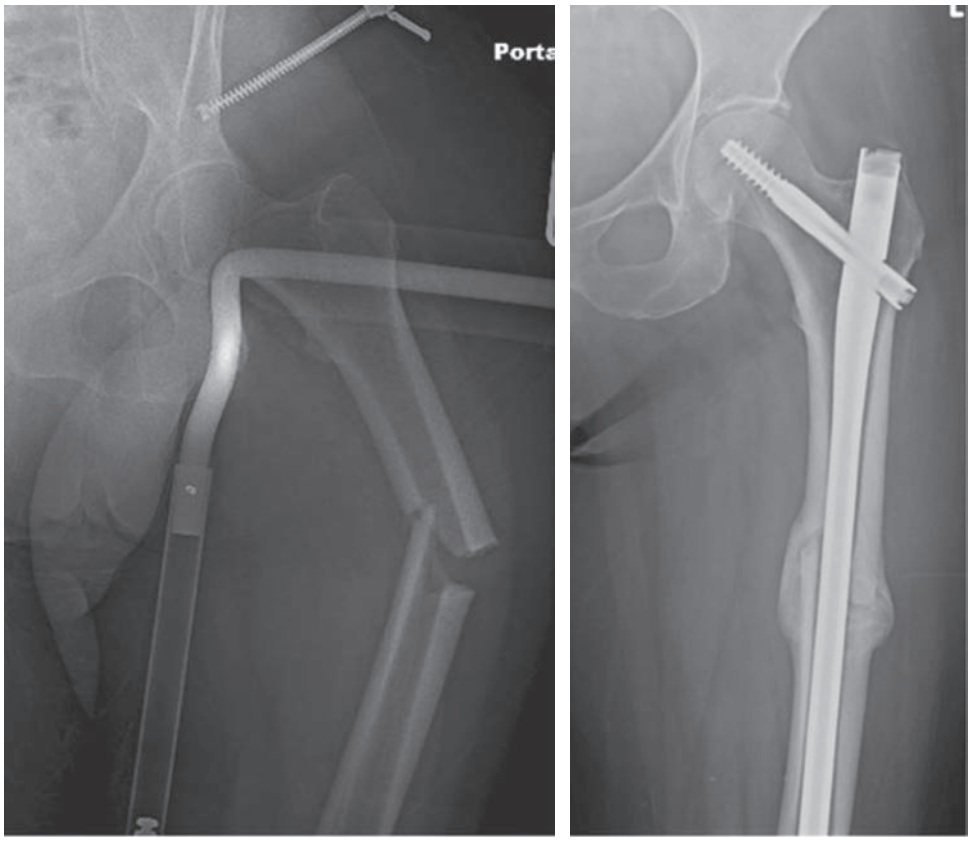

FIGURE 44-9 Atypical femur fracture. (**A**) Anteroposterior left hip radiograph of an atypical subtrochanteric femur fracture often associated with long-term bisphosphonate use. Note the thickened lateral cortex, lateral beak, transverse lateral cortex fracture line, and oblique medial cortex fracture line. (**B**) Six-month postoperative radiograph of the healed fracture after treatment with a cephalomedullary nail.

increased in incidence over the past decade. Most surgeons advocate immediate weight bearing in this population after fracture stabilization with a plate or nail. Patients with fractures that extend into the articular surface typically have their weight bearing limited for 6 to 12 weeks to avoid loss of reduction. Distal femur fractures have historically been characterized by high rates of malunion, nonunion, infection, and hardware failure.[168] Recent advances in surgical technique, coupled with implant designs that are angularly stable, have resulted in improved outcomes.[169]

Patella Fractures and Injuries to the Extensor Mechanism

The patella is the largest sesamoid bone in the body and is encased within the extensor mechanism of the knee. The extensor mechanism allows the quadriceps muscles to extend the knee through pull on the proximal tibia. Patella fractures are clinically significant if they disrupt this mechanism. Quadriceps and patellar tendon ruptures have a similar clinical picture and functional deficit. The patella is stabilized within the trochlear groove of the distal femur by the medial and lateral portions of the quadriceps, as well as retinacular tissue that connects the quadriceps to the joint capsule.

Standard imaging in the setting of suspected extensor mechanism disruption includes AP and lateral knee radiographs. Advanced imaging is rarely indicated in the acute setting, although magnetic resonance imaging (MRI) or ultrasound can be used for diagnostically challenging cases. Patella fractures and extensor mechanism disruptions are diagnosed by history and physical examination. Patients will frequently present with knee pain and history of a direct blow to the knee or popping sensation. On physical examination, pain with palpation of the patella, a knee effusion, and the inability to actively extend the knee are clues that the extensor mechanism may be injured. Some patients might retain some extension in the setting of a patella fracture if the surrounding retinaculum is not injured. A palpable defect distal to the patella and patella alta (high-riding patella) suggest a patellar tendon disruption. Conversely, a palpable defect proximal to the patella and patella baja (low-riding patella) suggests quadriceps tendon rupture.

Patellar fracture management depends on the fracture displacement. Nonoperative treatment is reserved for patients with minimally displaced patellar fractures who are able to

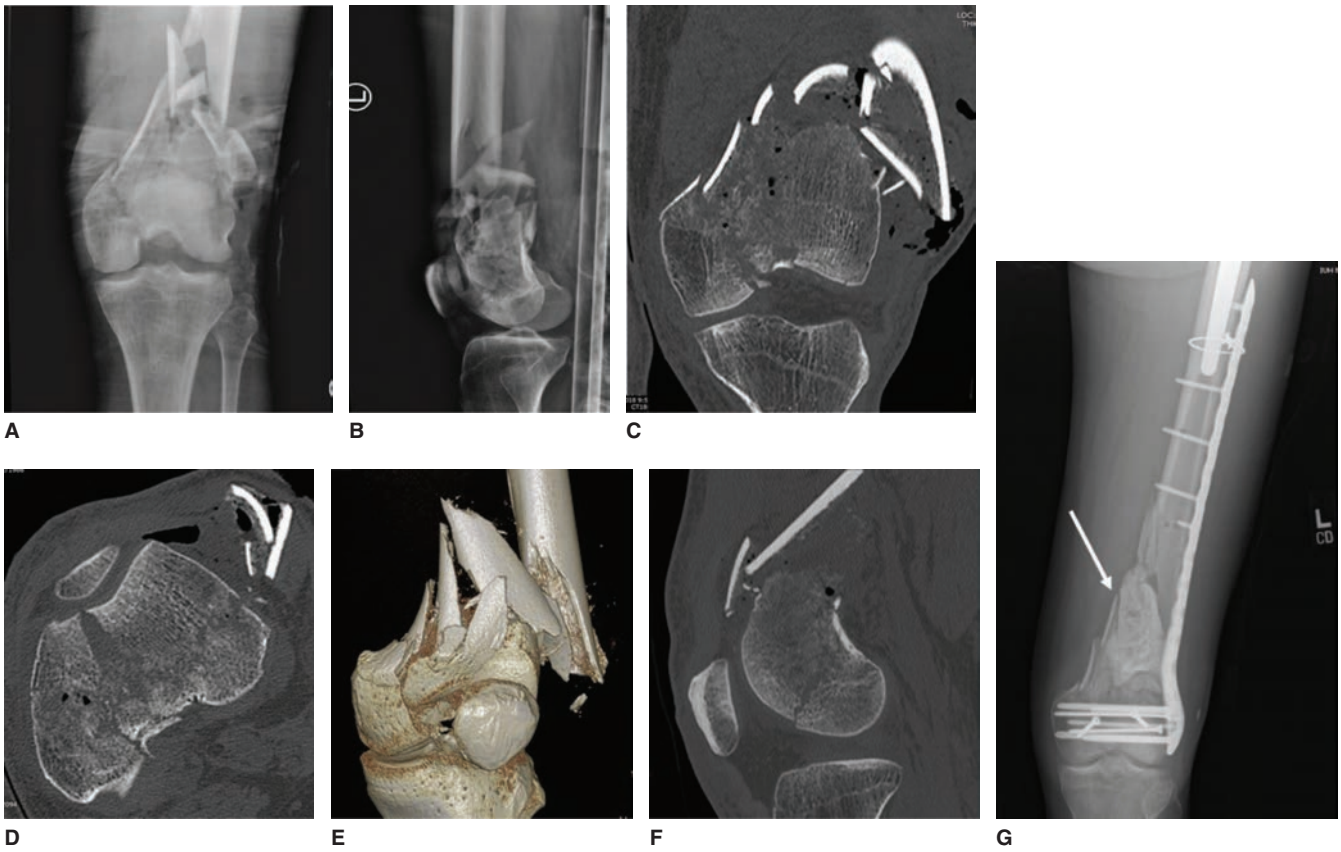

FIGURE 44-10 Complex, open intra-articular distal femur fracture with a Hoffa fragment. (**A**) Anteroposterior (AP) and (**B**) lateral knee injury radiographs. (**C**) Coronal computed tomography (CT), (**D**) axial CT, and (**E**) three-dimensional CT reconstruction. The Hoffa fracture of the lateral condyle can easily be missed on plain radiographs but is demonstrated on the (**F**) sagittal CT. (**G**) AP radiograph after open reduction and internal fixation of the distal femur fracture, also demonstrating an antibiotic-laden cement spacer in the metaphysis of the femur (arrow).

extend their leg against gravity. Nonoperative treatment consists of bracing or casting the knee in extension for 4 to 6 weeks. These patients are allowed to bear weight with the knee fully extended to protect the patella against tension load. Most patients with displaced patellar fractures, full-thickness patellar tendon ruptures, or full-thickness quadriceps tendon ruptures are treated surgically. The method of patellar fixation depends on the fracture pattern, location, and degree of comminution. Operative interventions include wiring, screw-based fixation, plating, partial patellectomy, and rarely total patellectomy. Tendon ruptures are repaired with heavy, braided sutures woven through the tendon and passed to the opposite side of the patella through bone tunnels. Chronic tendon tears typically require tendon lengthening and more complex reconstructions in order to overcome the shortening from quadriceps retraction. These injuries can be missed in polytraumatized patients who are unable to participate in a reliable physical exam. Extensor mechanism injuries typically require prolonged rehabilitation to achieve a functional range of knee motion and regain strength. It is not uncommon for patients with patella fractures that require operative treatments to have persistent pain and functional deficits.[170]

Knee Dislocation

Knee dislocations are severe injuries that involve multiple ligament disruptions of the knee. Knee dislocations are typically caused by high-energy blunt trauma such as a direct blow to a dashboard. Low-energy mechanisms can also lead to dislocation, typically in morbidly obese patients (females > males), which can occur after a seemingly trivial injury such as a ground-level fall.[171] A high index of suspicion is needed when a patient describes a "pop" or "shift" in their knee because knee dislocations can spontaneously reduce and have a normal-appearing radiograph. The knee is completely dependent on ligaments for stability. Ligamentous injuries can avulse fragments of bone seen on radiographs, which can be a sign of a dislocation. Examples include a posterior cruciate ligament (PCL) avulsion and a lateral capsular avulsion (Segond fracture) commonly seen with anterior cruciate ligament (ACL) injuries. MRI is indicated to precisely define the ligaments that are injured and determine the timing of treatment. Physical exam of the knee will demonstrate joint line tenderness and abnormal laxity compared to the contralateral knee. The Lachman test and anterior drawer test are performed to diagnose ACL injury. The posterior drawer test and posterior

sag sign detect PCL injury. Varus and valgus stress tests with the knee flexed 30° evaluate for lateral collateral ligament and medial collateral ligament injury, respectively. A positive Dial test (increased external rotation of the foot with the knee at 30°) is indicative of a posterolateral corner injury.

The proximity of the important neurovascular structures around the knee makes knee dislocations a potentially limb-threatening injury. The early recognition of an associated popliteal artery injury, which has been described in up to one-third of cases with traumatic knee dislocations, is crucial.[172] While a complete arterial disruption may be obvious early after trauma due to clinical signs of peripheral ischemia, an incomplete dissection or intimal injury by stretching forces may be missed. Intimal tears can lead to delayed thrombosis and secondary limb ischemia despite the absence of apparent early clinical evidence for a vascular injury. Because of the often-asymptomatic nature of these popliteal injuries, the amputation rate for blunt vascular trauma is about three times higher than that after penetrating injuries and lies in the range of 15% to 20%.[173] Thus, a high index of suspicion and defined diagnostic algorithms should help establish an accurate diagnosis. ABI should be measured and documented on all knee dislocations. ABI less than 0.9 and/or asymmetric pulses should prompt angiographic evaluation. Based on a large meta-analysis, the accuracy of pulse examination alone is very low, yielding a sensitivity of only about 79% for the detection of an arterial injury.[174] The hard and soft signs for an arterial injury, which are present in about two-thirds of all cases, are outlined in Table 44-1. Injury to the peroneal nerve with a resultant foot drop and impaired dorsal foot sensation is common. Less commonly, tibial nerve injury can occur, leading to absence of foot and toe plantarflexion and plantar foot numbness. This can interfere with recognition of ischemic pain due to arterial occlusion or an acute compartment syndrome. Serial examination and clear documentation and communication between team members are essential when treating these injuries. A popliteal artery injury associated with dislocation of the knee is often addressed in the operating room with both vascular and orthopedic surgeons. Adequate reduction and stabilization of the knee dislocation are required. External fixation is well suited for provisional stabilization because it can be applied rapidly without delaying arterial repair but can also readily be adjusted to allow intraoperative positioning of the knee, facilitating repair. Four-compartment prophylactic fasciotomy is advisable after popliteal artery repair in order to avoid compartment syndrome secondary to ischemia-reperfusion.

Initial management of knee dislocations is based on the knee stability after reduction. A knee dislocation without vascular injury that is concentrically reduced on postreduction radiographs may be treated in a splint or knee brace until definitive knee reconstruction. Foam knee immobilizers provide insufficient support to maintain reduction if there is concern for recurrent instability. Open dislocations, those with vascular injury, and reductions that cannot be maintained should be treated in a joint-spanning external fixator.[175] Definitive ligament reconstruction is typically performed 1 to 6 weeks after injury, depending on the ligaments involved. Outcomes of knee dislocation are more dependent on associated injuries rather than the timing of reconstruction.[176] Numerous protocols exist regarding staging of surgical interventions and selection of ligament to treat. In general, improved outcomes have been demonstrated with staged ligament reconstruction as opposed to acute ligamentous repair. Arthroscopy is avoided within the first 10 to 14 days of injury because fluid extravasation will likely occur due to the disrupted knee capsule and could potentially cause compartment syndrome.

Knee dislocations are devastating injuries, especially to athletes, because few return to the same level of performance. Common complications include knee stiffness (very common), instability (less common with appropriate treatment), and posttraumatic arthritis. Rehabilitation protocols are very patient and surgeon specific.

Tibial Plateau Fractures

Tibial plateau fractures are fractures involving the articular surface and the proximal 7 to 9 cm of the tibial metaphysis. Fracture pattern varies depending on bone quality, the magnitude and direction of force, and the degree of knee flexion at the moment of impact. Coronal plane forces, such as varus and valgus stress, coupled with axial compressive force, create medial and lateral fracture patterns, respectively. Young patients with good bone quality are more likely to sustain split or split-depression fracture patterns with associated ligamentous injury. Older patients with osteopenia are more likely to sustain a pure depression or split-depression fracture (Fig. 44-11). The examiner should carefully evaluate the neurovascular status and soft tissue conditions including swelling because the rate of compartment syndrome in bicondylar tibial plateau fractures approaches 20% and skin breaches may represent an open fracture. Open wounds in this region can also result in traumatic knee arthrotomy, even in the absence of proximal tibia fracture. A saline retention test with at least 150 mL injected into the knee away from the wound can be performed. Leakage of fluid from the open wound confirms diagnosis of an open joint injury.[177] Presence of intra-articular air in CT was found to be highly sensitive and specific for traumatic knee arthrotomy and may replace conventional saline retention test.[178] Presence of compartment syndrome must be considered, especially in high-energy injuries with comminuted fractures, and patients should be evaluated frequently as swelling evolves.

AP and lateral radiographs of the knee should be obtained to evaluate knee pain after injury. Radiographs should be inspected for articular depression, widening of the tibial plateau, metaphyseal fracture, and bony avulsions. CT scan with sagittal and coronal (with or without three-dimensional) reconstruction provides detailed information of the articular injury and aids in preoperative planning. Lower energy injuries typically lead to injury on one side of the joint, whereas higher energy injuries often result in complete injury to both sides of the joint. The AO/OTA classification and Schatzker classification are commonly referred to in daily practice when

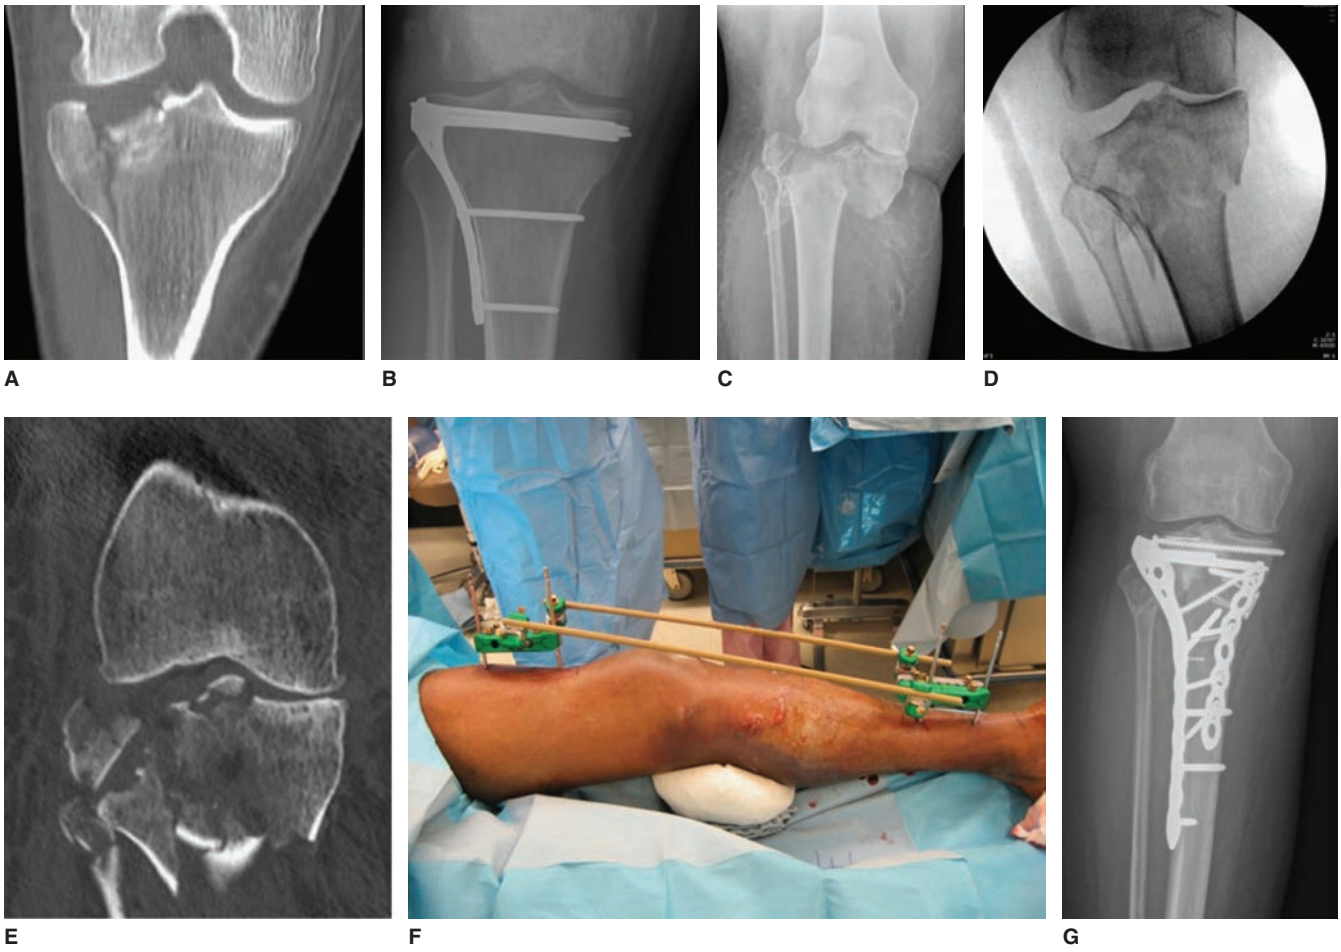

FIGURE 44-11 (**A**) Coronal plane computed tomography scan of a unicondylar tibial plateau fracture and (**B**) AP knee radiograph following open reduction and internal fixation (ORIF). (**C–G**) High-energy, comminuted bicondylar tibial plateau fracture as seen on (**C**) injury AP knee radiograph; (**D**) post–external fixation AP fluoroscopic image; (**E**) coronal computed tomography; (**F**) clinical image demonstrating knee-spanning external fixator and fracture blisters; and (**G**) postoperative AP knee radiograph following ORIF with a dual-incision approach.

formulating treatment plans.[136] Particular attention should be paid to medial tibial plateau fractures (Schatzker IV), which can be associated with a knee dislocation (Fig. 44-12). The stable fragment in these injuries is not the tibial shaft but rather is the portion of the medial tibial plateau that is still attached to the femur by its ligamentous attachments. The remainder of the tibia is dislocated from the femoral articulation. Vigilance in these fractures is critical, and vascular evaluation should be undertaken as described earlier.

Nondisplaced and minimally displaced fractures can be treated with early motion and a period of non–weight bearing in a hinged knee brace for 6 to 12 weeks. Indications for surgical management include open fracture, compartment syndrome, articular displacement, and knee instability. Timing of surgery is dependent on the soft tissue condition. Definitive surgery is delayed if severe swelling or blistering is present to minimize wound complications. Bicondylar tibial plateau fractures with poor soft tissue conditions are typically initially managed with external fixation to restore length and alignment. Historically, most bicondylar tibial plateau fractures were treated in staged fashion; however, recent evidence has shown that many injuries can be treated earlier in the absence of severe soft tissue injury.[179]

Historically, bicondylar plateau fractures were associated with a high rate of infectious and wound complications. More biologically friendly techniques including dual incisions, percutaneous instrumentation, and staged treatment protocols have significantly reduced wound and infectious complication rates from 50% to less than 10%.[180] Most tibial plateau fractures are stabilized by ORIF with plate and screw fixation. Locking screw technology has improved fixation in select patients with comminuted fractures or osteoporotic bone, but universal use of locking implants is not necessary.[181] Select metaphyseal and simple intra-articular plateau fractures are amenable to intramedullary nailing. Although technically challenging, one study demonstrated effective treatment of tibial plateau fractures with ring fixators.[182] At the time of definitive treatment, assessment for other soft tissue injuries of the knee should occur because they are associated with a high rate of meniscal tears and ligament disruptions.[183]

Despite the improved treatment methods detailed earlier, bicondylar plateau fractures have been recently reported to

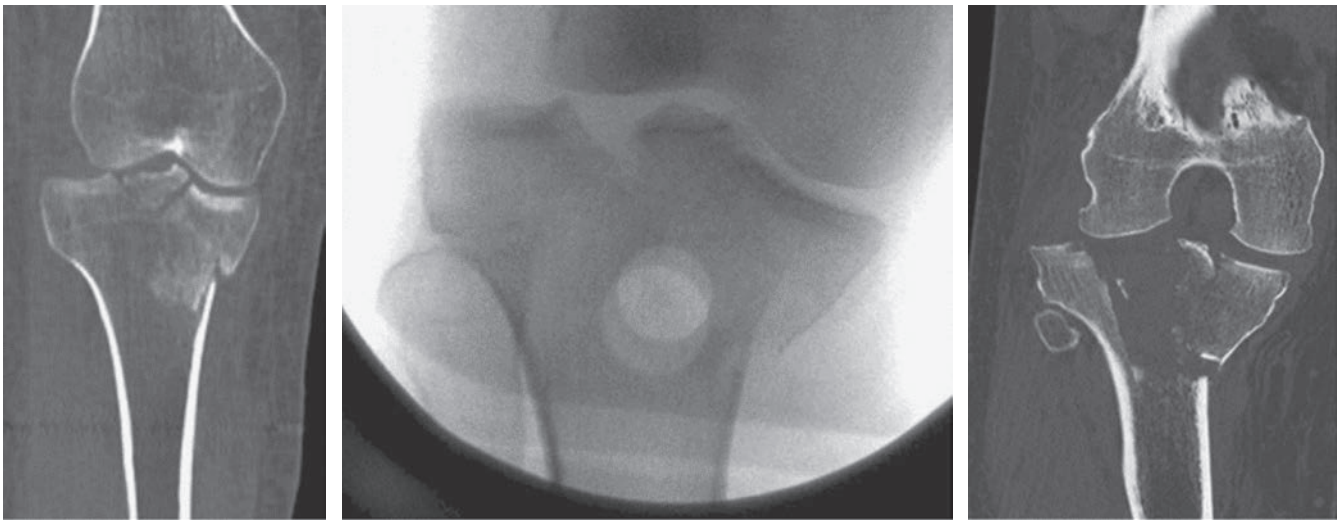

FIGURE 44-12 Examples of Schatzker IV medial tibial plateau fractures. (**A**) Anteroposterior (AP) knee radiograph, (**B**) AP fluoroscopic stress image, and (**C**) coronal computed tomography scan demonstrating variants of medial tibial plateau fractures with joint subluxation suggesting instability. This injury can behave similar to a knee dislocation, and a high degree of suspicion for vascular injury is required.

have an overall complication rate (including infection and nonunion) of 28%.[184] The long-term risk of posttraumatic arthritis has been reported to be as high as 30%; however, many patients remain asymptomatic, and the long-term conversion rate to total knee arthroplasty is 7%.[185] Some loss of motion and persistent knee pain may occur from joint stiffness. Articular injuries typically require 8 to 12 weeks of restricted weight bearing; however, early passive and active knee range of motion is usually encouraged.

Tibial Shaft Fractures

Fractures of the tibial shaft range from low-energy, indirect torsional injuries to severe high-energy injuries such as motor vehicle collisions that are associated with significant soft tissue damage and a high incidence of acute compartment syndrome. The amount of energy absorbed by the leg is suggested by the radiographic appearance and soft tissue condition. The severity of the soft tissue injury, whether open or closed, is closely associated with the overall outcome of tibial shaft fractures. The soft tissue envelope on the medial border of the tibia is very thin; thus, minor open fractures may have major therapeutic implications for soft tissue coverage of the exposed bone. Additionally, the close proximity of numerous vessels, nerves, and tendons can result in associated injuries that impact outcome.

A thorough examination of peripheral nerve (superficial peroneal, deep peroneal, tibial) function and vascular integrity (dorsalis pedis and posterior tibial pulses) should be performed. Clinical evaluation for compartment syndrome is extremely important because it occurs frequently in tibial shaft fractures.[33,34] Compartment syndrome is especially common if the soft tissues have been crushed or if a period of ischemia has occurred. Diagnosis of compartment syndrome is primarily clinical, and a coordinated effort by all members of the medical team is necessary to prevent delay in treatment. Open fractures are common, and the patient should be administered prophylactic antibiotics as soon as possible in the emergency department.[46,47]

Full-length AP and lateral radiographs of the affected tibia should be obtained. AP, lateral, and oblique views of the ipsilateral knee and ankle should be obtained if the fracture extends proximally and/or distally to assess intra-articular involvement. CT scan may be helpful if there is suspicion of fracture extension into either articular surface. Tibia shaft fractures are described by location (proximal, central, distal), shape (transverse, long/short oblique, spiral, segmental, comminuted), and direction of displacement (varus, valgus, apex anterior/procurvatum, apex posterior/recurvatum).

Timing and treatment modalities for tibial shaft fractures are dependent on the severity of injury, associated injuries, comorbidities, and the patient's physiologic condition. Limb-threatening injuries such as arterial disruption with ischemia and compartment syndrome require immediate surgery. As discussed earlier, open fractures should be treated in expeditious fashion by an experienced team because quality of surgical debridement is thought to be more important than timing to debridement as long as debridement occurs within 24 hours of injury.[6]

External fixation is typically indicated as the initial treatment of high-energy open tibia fractures with severe soft tissue injury, of vascular injury requiring repair, and in the setting of unstable polytrauma patients as a damage control procedure.[4] Many open fractures of the tibia require multistage treatment for decontamination, assessment of residual tissue perfusion, fracture repair, and soft tissue coverage. The wound bed is debrided and closed if possible during the initial surgery because delayed closure in adequately

debrided wounds increases infection risk.[186] Long-term use of an external fixator (>14 days) is associated with bacterial colonization of the pin tracts and a risk of infection from subsequent intramedullary nailing. Use of an external fixator for only a few days, however, can safely precede intramedullary nailing for definitive management of tibial shaft fractures.

In closed fractures, provisional closed reduction and application of a long leg splint provide initial immobilization. Historically, the majority of tibial shaft fractures were definitively treated by closed means with reduction and casting.[187] However, with advancements in surgical fixation, especially intramedullary reamed nailing, surgery is indicated in most cases. Intramedullary nailing provides excellent fixation and facilitates restoration of length and alignment in diaphyseal fractures. Nails allow immediate motion of the foot and ankle and permit early weight bearing. Reaming of the tibia medullary canal has a beneficial effect on fracture union.[188,189] The indications for intramedullary nailing have expanded to more proximal and distal metaphyseal fractures as new-generation interlocking nails provide multiplanar interlocking options and far proximal/distal opportunities for screws.[190] Plate fixation of acute fractures of the tibial shaft is generally reserved for periarticular injuries too proximal or distal for intramedullary nailing.[191] Alternatively, tibial shaft fractures with soft tissue compromise can be definitively managed with a ring fixator. Strategies to reconstruct tibial bone loss include secondary Masquelet bone grafting and distraction osteogenesis (via bone transport) with ring fixators.[192]

Knee pain after intramedullary nailing of tibia shaft fracture is a common complication and may persist for a long period of time.[193] Infection and nonunion occur in up to 10% of patients with closed fractures and 25% to 30% of open fractures.[189,194] Managing modifiable risk factors such as cessation of tobacco abuse and strict glucose control in diabetes is recommended in high-risk patients.

Distal Tibial Fractures

Mechanism of injury categorizes distal tibia fractures into two categories. An axial loading force on the tibial articular surface leads to a pilon fracture, whereas a rotational injury typically leads to an ankle fracture.

Ankle injuries represent the most common musculoskeletal injury. The ankle is a hinge joint, in which the body of the talus dorsiflexes and plantarflexes within a mortise-like socket formed by the medial malleolus, plafond of the distal tibia, and the distal fibula (lateral malleolus). Integrity of the mortise is maintained by the lateral ligaments, medial (deltoid) ligaments, and syndesmotic ligaments. The ankle syndesmosis is the joint between the distal tibia and the distal fibula immediately above the ankle joint, which is stabilized by its own ligamentous complex. Widening of this mortise is indicative of syndesmosis disruption and can result in talar instability and predisposition to posttraumatic arthritis. The Lauge-Hansen classification system has historically described four groups of rotational ankle injuries based on the position of the foot and direction of force applied at the moment of injury.[195] Pilon fractures, in contrast, result from a high-energy axial load to the ankle. Pilon fractures are classically described by characteristic fragments (anterolateral, posterolateral, central, medial), and the AO/OTA classification system is commonly referenced when discussing the injury.[136] Significant soft tissue damage can accompany pilon fractures, even in closed injuries. They are challenging intra-articular injuries that often carry a poor functional prognosis.[196,197]

Ankle sprains are ligamentous injuries of the ankle most commonly involving the lateral collateral ligament complex, which provide inversion stability of the talus. Inversion of the foot normally occurs at the subtalar joint. If forced to the limit, however, the lateral collateral ligament stretches or ruptures, producing the typical "sprained ankle" with lateral pain, swelling, ecchymosis, and tenderness over the injured ligaments distal and anterior to the lateral malleolus. It is difficult to differentiate a simple sprain from a fracture in the acute setting due to nonspecific symptoms such as pain, tenderness, and swelling. The Ottawa ankle rules can help determine the need for diagnostic imaging in ankle injuries.[198] Ankle radiographs are suggested in the following settings: (1) bony tenderness at the lateral malleolus, (2) bony tenderness at the medial malleolus, or (3) inability to bear weight for four steps. Three views of the ankle, including AP, mortise (15°–20° internal rotation of the foot), and lateral, are usually sufficient to adequately diagnose most ankle fractures. Tibia radiographs should be obtained in ankle fractures to rule out an unstable Maisonneuve fracture, defined as a spiral fracture of proximal fibula associated with medial malleolus or deep deltoid ligament injury and disruption of the syndesmosis or interosseous membrane. CT is typically obtained in pilon injures. If staged treatment is planned, CT is optimally obtained after ankle-spanning external fixation is placed. This not only improves fracture fragment visualization, but also minimizes radiation to the patient.

Minor ankle sprains can be treated with restricted activities, elevation, ice, and support as needed for comfort. More severe sprains require immobilization. After a brief period of rest, most ligamentous injuries are effectively treated with a functional brace. Ankle fractures should be examined promptly in the emergency department because prolonged deformity can lead to soft tissue injury and blistering. Timely closed reduction and splinting are optimal, especially in fracture-dislocations, to reduce the risk of skin necrosis secondary to osseous displacement. Postreduction radiographs and surgical consultation should be obtained to confirm adequate reduction. Surgical treatment of ankle fractures can occur any time within 10 to 14 days, with fixation deferred in severely swollen ankles.

The lateral malleolus is the prime determinant of talar alignment. Restoration of its proper relation with the distal tibia is the key to treating malleolar fractures. Lateral malleolus fractures can be distal to the joint, at the joint, or proximal to the joint. Isolated, minimally displaced lateral malleolus fracture below the joint can be managed conservatively in a

walking cast or a boot with immediate weight bearing. If the fracture is at or above the joint, stress exam may be helpful to determine a medial deltoid injury. Several authors have determined that a widened medial clear space of more than 4 to 5 mm under stress exam represents an indication for surgical ankle fracture fixation.[199] Patients who require syndesmotic fixation have significantly worse long-term outcomes than patients treated for ankle fractures without syndesmotic injury.[200] Isolated, minimally displaced medial malleolar fractures can be treated nonoperatively. However, displaced medial malleolar fracture should be reduced and surgically stabilized when part of a bimalleolar or trimalleolar fracture pattern (Fig. 44-13). The deltoid ligament does not need to be repaired if the remainder of the joint is reduced and stable. The posterior lip of the tibial plafond, known as posterior malleolus or Volkmann's fragment, is frequently fractured in an ankle fracture-dislocation. The designation of a trimalleolar fracture implies lateral, medial, and posterior fractures or fracture equivalent ligament injuries. Although it is controversial, large posterior tibial plafond injuries that involve more than one-fifth of the articular surface should be reduced and fixed to avoid posterior subluxation of the talus and incongruity of the joint.[201] Weight bearing is variable after ankle fractures, ranging from early weight bearing after suture removal in some rotational injuries to limited weight bearing for 2 to 3 months for syndesmotic and pilon injuries.

Historically, traditional pilon ORIF techniques carried a high risk of wound dehiscence and infection, particularly

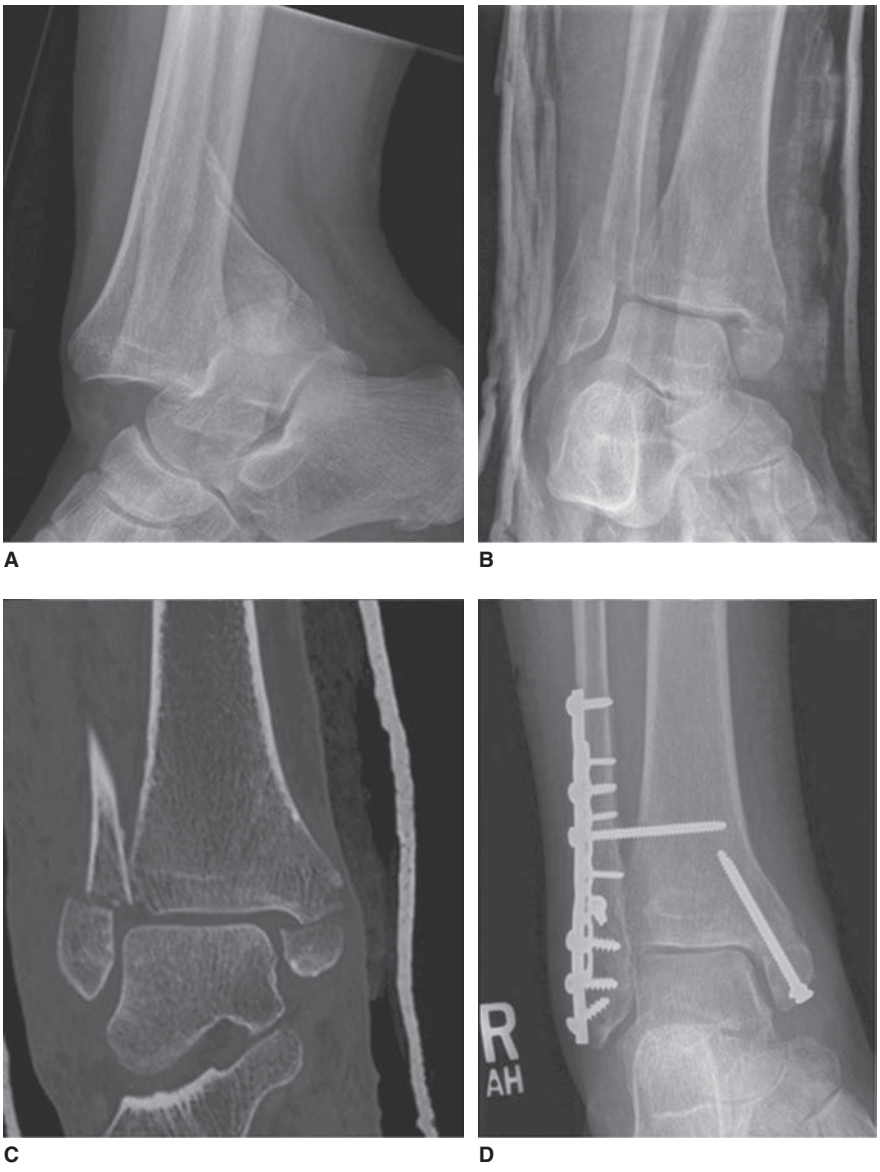

FIGURE 44-13 (**A**) Lateral ankle radiograph of a trimalleolar ankle fracture-dislocation. (**B**) Postreduction anteroposterior (AP) ankle radiograph and (**C**) coronal computed tomography scan. (**D**) Postoperative AP ankle radiograph of the trimalleolar ankle fracture-dislocation and syndesmotic injury treated with open reduction and internal fixation.

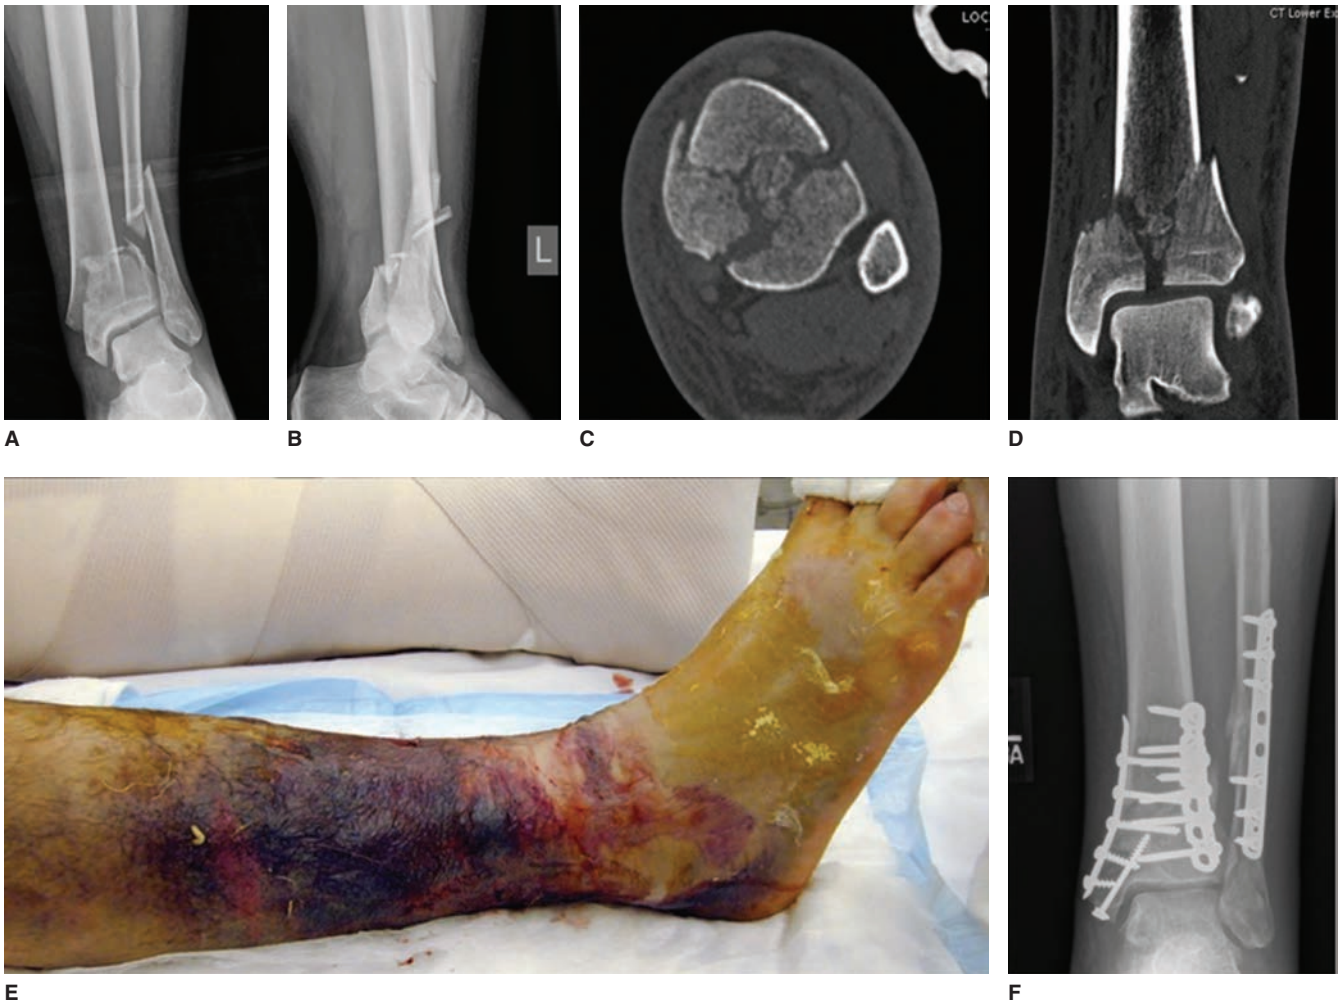

FIGURE 44-14 (**A**) Anteroposterior (AP) and (**B**) lateral ankle radiographs of a comminuted intra-articular pilon fracture with corresponding (**C**) axial computed tomography (CT) and (**D**) coronal CT scan. (**E**) Clinical image demonstrates the severe soft tissue injury that often accompanies this injury. (**F**) Postoperative AP ankle radiograph following pilon open reduction and internal fixation.

if early surgery was performed in the presence of significant soft tissue swelling or blistering.[202,203] Clinical studies have demonstrated an improved outcome of tibial pilon fractures with two-staged approach, typically early external fixation and staged ORIF once the soft tissue condition improved (Fig. 44-14).[204] Recent research has suggested that these fractures can be treated in most circumstances with early fixation without increased risk of complications.[205] Depending on the degree of comminution, bone quality, and extent of soft tissue compromise, the postoperative rehabilitation of pilon injuries may vary. Weight bearing is typically restricted for 10 to 12 weeks.

Outcomes of distal tibia fractures significantly vary depending on the severity and type of fracture. In general, fractures with significant articular involvement have a high incidence of persistent pain, poor function, and symptomatic posttraumatic arthritis.[196,197] Wound and infectious complications can have dire consequences and can potentially lead to loss of limb.

Calcaneus Fractures

The calcaneus is the most commonly fractured tarsal bone. Fracture is often the result of an axial load such as a fall from height. The calcaneus is the largest tarsal bone and is responsible for transmission of body weight to the ground during the heel strike phase of gait cycle. It has a complex shape that includes three subtalar joint facets (posterior facet, middle facet, and anterior facet) that articulate with the talus. The Achilles tendon attaches to the calcaneal tuberosity, forming a strong lever arm for the muscles of the calf.

A detailed history and physical exam are essential in decision making because age, gender, smoking status, worker's compensation injury, and comorbidities including diabetes and peripheral vascular disease play a critical role in outcome.[206,207] Concomitant injuries are common, with 7% to 15% of patients having associated spine fractures.[208] A spine exam should be thorough, with a low threshold for imaging, particularly of the lumbar spine. Calcaneus fractures

require careful soft tissue evaluation and should be initially immobilized in a well-padded splint with the foot in a neutral position. Open fractures of the calcaneus have a high rate of deep infection and are at risk of subsequent complications including amputation.[209] Fractures of the calcaneus can be associated with the development of compartment syndrome of the foot, particularly when the injury is due to a crushing mechanism. Surgical treatment of compartment syndrome of the foot is controversial because fasciotomy carries a significant risk of complications similar to sequelae of compartment syndrome.

AP, lateral, and oblique radiographs of the foot, and a Harris heel view of the calcaneus should be obtained for diagnosis. CT scan is usually required for making treatment decisions. The Sanders classification of intra-articular calcaneus fractures is a useful system that helps guide treatment.[210]

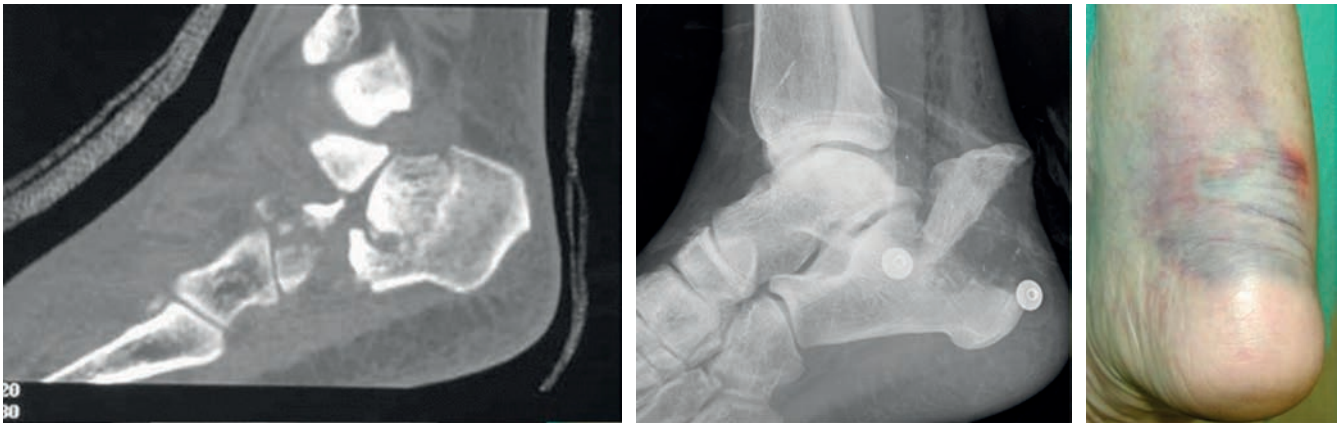
Many nondisplaced and extra-articular fractures of the calcaneus may be treated nonoperatively. Most calcaneal fractures can be treated in delayed fashion; however, the tongue-type variant (Fig. 44-15), which puts pressure on the posterior heel skin, must be reduced urgently to avoid skin loss. One randomized controlled trial comparing operative versus nonoperative treatment of intra-articular displaced calcaneus fractures found surgery to have a beneficial impact on physical function in select groups of patients, including younger patients (<29 years), females, those with comminuted fractures, those with excellent articular reduction (≤2 mm), patients with a lighter workload, and those who were *not* receiving worker's compensation.[206] In another randomized controlled trial with long-term follow-up, surgical treatment was not found to be superior at 1 year but was associated with a decreased rate of posttraumatic arthritis 8 to 12 years postoperatively.[211] Surgical treatment of calcaneus fractures is challenging and can be associated with relatively high complication rates.[209,210]

Historically, the majority of displaced calcaneus fractures were treated 2 to 3 weeks after injury when swelling had significantly subsided. The traditional lateral extensile approach has a risk of skin edge necrosis and wound infection. The blood supply to the skin in this region is tenuous because the angiosome of the heel has a distinctive watershed area at the traditional lateral extensile approach incision.[212] Recently, a limited sinus tarsi (lateral) approach has gained popularity. When compared to the traditional extensile approach, the sinus tarsi approach has been shown to have decreased wound complications.[213] Whether treated operatively or nonoperatively, calcaneus fractures require 6 to 12 weeks of non–weight bearing. Subtalar posttraumatic arthritis can occur after either surgical or nonsurgical treatment. Patients who develop symptomatic arthritis are candidates for fusion of the subtalar joint after failure of conservative treatment measures. Surgeons may elect to perform a subtalar fusion and calcaneus ORIF in the acute setting for comminuted, Sanders type IV intra-articular calcaneus fractures.[214]

Talus Fractures

The talus is the second most common tarsal bone injury after calcaneal fractures. Over 50% of the surface of the talus is articular cartilage. Typical mechanisms of injury involve forced dorsiflexion from falls or motor vehicle accidents. Talar neck fractures are the most common type of talus fractures. Displaced talar neck fractures can be associated with dislocation of the adjacent subtalar, talonavicular, or tibiotalar joints. Ipsilateral lower extremity fractures are common.

AP, oblique, and lateral radiographs of the foot should be obtained. CT is indicated when suspicion is high and aids in preoperative planning through precise determination of displacement and comminution. The Hawkins classification classically described three types of talar neck fractures and associated dislocations, with Canale and Kelly later amending the classification to add a type 4.[215,216] The risk of developing osteonecrosis increases with each type as follows: type 1, talar neck fracture; type 2, fracture with subtalar dislocation;



A B C

FIGURE 44-15 (**A**) Sagittal computed tomography scan of a joint depression-type calcaneus fracture. (**B**) Lateral radiograph of a tongue-type calcaneus fracture and (**C**) corresponding clinical image of the posterior heel demonstrating internal skin pressure due to displaced tongue-type fracture fragment. Tongue-type calcaneus fractures are unique in that they require urgent treatment.

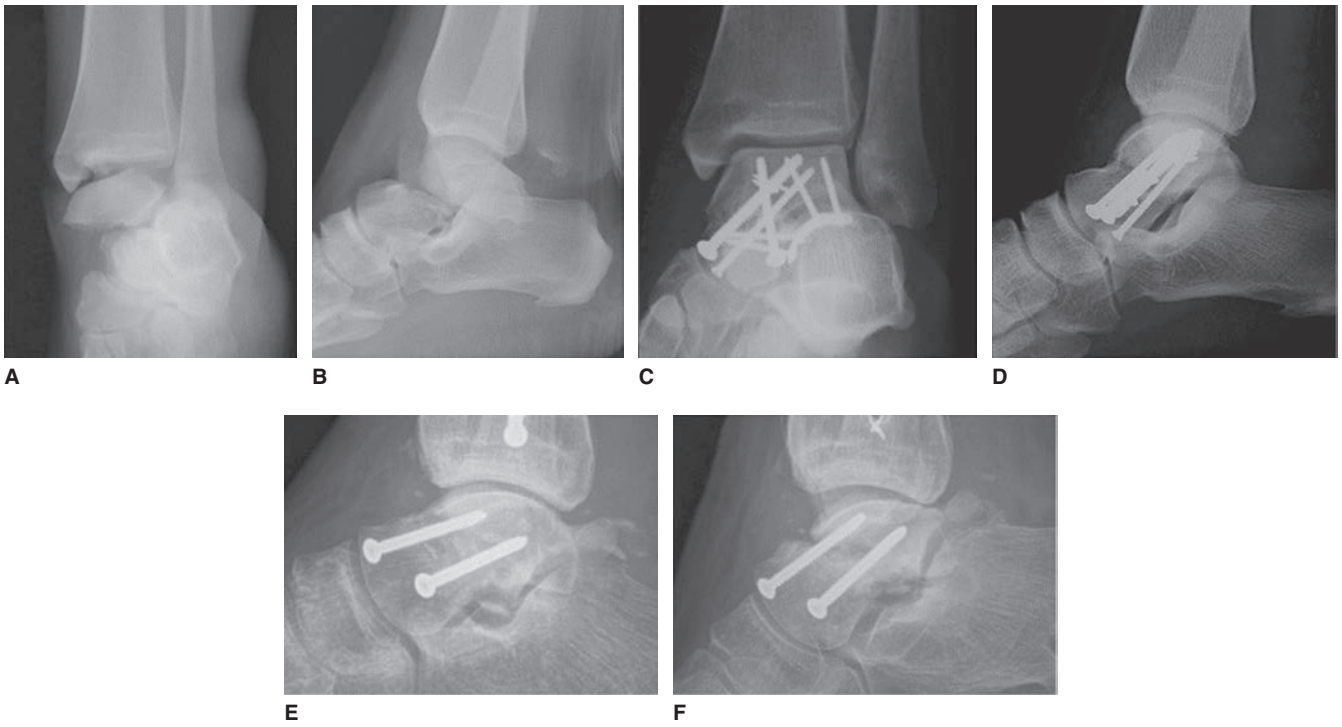


FIGURE 44-16 Talar neck fracture. (**A**) Injury oblique and (**B**) lateral ankle radiographs of a talar neck fracture. (**C** and **D**) Subsequent treatment with open reduction and internal fixation (ORIF). (**E**) Initial and (**F**) late lateral radiographs of a talus treated with ORIF that demonstrated avascular necrosis and collapse on the late radiograph.

type 3, fracture with subtalar and tibiotalar dislocations; and type 4, fracture with subtalar, tibiotalar, and talonavicular dislocations.[215,216]

Blood supply to talus is tenuous because less than half of the talus can be perforated by extraosseous vessels. There are no muscle attachments to the talus, and the blood supply is solely through ligaments and the joint capsule. Disruption of the blood supply to the talus can lead to avascular necrosis with subsequent collapse and posttraumatic arthritis (Fig. 44-16). Therefore, fracture-dislocations of the talus resulting in vascular disruption greatly impact long-term prognosis. Initial fracture displacement and timing of reduction are factors that affect the blood supply. Fracture-dislocations require emergent reduction in the emergency department to potentially restore vascularity. If the fracture cannot be reduced closed, the patient should be taken urgently to the operating room for an open reduction.

Peripheral fractures of the talus include the talar head, body, and lateral process. Unlike talar neck fractures, these fractures usually do not require emergent intervention. These fractures are frequently missed on x-ray; therefore, a CT scan should be obtained in any situation in which there is a high suspicion for a fracture and the radiographs are negative.

Subtalar dislocation is another severe injury of the foot that often involves open wounds, associated fractures of the tarsal bones, and neurologic injury. Urgent reduction is recommended to reduce the risk of permanent vascular insult to the talus and stretch injury to peripheral nerves. The reduction maneuver involves knee flexion, ankle plantarflexion, and either supination or pronation for lateral and medial dislocations, respectively. A postreduction CT scan is required to confirm a congruent reduction, identify associated fractures, and assess for loose fragments in the joint. Purely ligamentous injuries can be treated conservatively in a cast, but fracture-dislocations often require surgical intervention. Posttraumatic arthritis is the most common long-term complication.

Mid- and Forefoot Fractures

The Lisfranc joint complex refers to five tarsometatarsal (TMT) joint articulations between four proximal tarsal bones (medial cuneiform, middle cuneiform, lateral cuneiform, and cuboid) and the five distal metatarsals. The Lisfranc joint complex is composed of several ligaments: the Lisfranc ligament that runs plantarly from the base of the second metatarsal to the medial cuneiform; plantar TMT ligaments (strongest); dorsal TMT ligaments; and intermetatarsal ligaments (no ligament between first and second metatarsal).

There are variable patterns of dislocations and fracture-dislocations that can involve any or all of the TMT joints. Injury mechanism can be either direct or indirect. Direct injury usually involves a crush injury. Excessive plantarflexion and abduction force are the most common indirect mechanisms. They are occasionally associated with severe soft tissue trauma and compartment syndrome. These injuries present with significant swelling, pain, and plantar ecchymosis of the midfoot.

Radiographic findings may be subtle if only one or two TMT joints are injured. AP, lateral, and oblique radiographs of the foot should be obtained. Standing radiographs are obtained in order to stress the Lisfranc ligament when injury suspicion is high but radiographs are normal. A CT scan of the foot can also be obtained to better visualize avulsion fractures. These injuries require urgent closed reduction of the midfoot when dislocation is present. Residual displacement typically requires surgical fixation (Fig. 44-17). Midfoot arthrosis is the most common complication following these injuries.

Metatarsal fractures and forefoot phalanx fractures are common injuries. Due to the stability provided by intermetatarsal ligaments, the majority of these fractures are treated without surgery. In the setting of multiple metatarsal fractures, surgical treatment may be indicated to restore alignment and length of the forefoot, since intermetatarsal ligaments no longer prevent migration and deformity. Multiple metatarsal

FIGURE 44-17 (**A**) Anteroposterior (AP) foot injury radiograph of a subtle Lisfranc fracture dislocation of the first and second tarsometatarsal (TMT) joints and (**B**) AP foot following Lisfranc open reduction and internal fixation (ORIF). (**C**) AP foot radiograph and (**D**) coronal computed tomography scan demonstrating a significant Lisfranc fracture dislocation of all five TMT joints. (**E**) Postoperative foot radiograph following ORIF of TMTs 1 to 3 and percutaneous treatment of the fifth TMT.

fractures should raise suspicion of a Lisfranc injury. Metatarsal fractures and toe fractures are usually treated with a hard-soled shoe to minimize fracture motion during gait and can usually weight bear as tolerated. An exception is a Jones fracture involving the proximal metadiaphysis of the fifth metatarsal. Nondisplaced Jones fractures can be treated nonoperatively with 6 weeks of immobilization followed by progressive weight bearing, but the nonunion rate has been reported to be as high as 20%. Athletes are usually offered surgical repair to increase the rate of union and promote earlier mobilization.

COMPLICATIONS IN LOWER EXTREMITY TRAUMA

Nonunion

Nonunion occurs when a fracture fails to completely heal. Fractures have different expected healing times depending on the type of fracture and the location. Tibia fractures are relatively slow to heal, particularly when open and highly comminuted.[194] Femur fractures heal more rapidly, due in part to the fact that the femur is circumferentially surrounded by muscle and thus has an excellent osseous circulation. Nonunions can be complicated by bone loss, malalignment, or infection, resulting in difficult challenges for the patient and surgeon. They lead to prolonged recovery for the patient and add significant medical and societal costs. Costs were 2.3 times greater in patients who developed tibia nonunion compared to those who healed primarily.[217]

Mechanical stability and local biology play key roles in fracture healing, as noted earlier. The most common cause of nonunion is infection, which is initially evaluated by serologic markers of inflammation including a complete blood count, erythrocyte sedimentation rate, and C-reactive protein. Metabolic and endocrine abnormalities such as vitamin D deficiency, hyperglycemia (diabetes), malnutrition, hyper-/hypothyroidism, parathyroid disease, disorders of the hypothalamic-pituitary-gonadal axis, and diseases leading to calcium and phosphorous imbalances (including kidney disease) have also been linked to nonunion.[194] Therefore, it is important to screen patients for undiagnosed metabolic and endocrine diseases, especially in cases where uneventful healing is expected. When metabolic or endocrine abnormalities are discovered, a multidisciplinary approach to nonunion treatment including endocrinology and internal medicine consultation may improve a patient's outcome. Polytrauma patients with initial complicated clinical courses are at greater risk of nonunion. It has been proposed that tobacco abuse leads to an increase risk of nonunion.[194] Nonsteroidal anti-inflammatory drugs (NSAIDs) have also been shown to increase the risk of nonunion in some studies, but larger prospective studies are underway to better answer this question.[194,218] This concern must be remembered as the opioid epidemic has influenced surgeons to limit narcotic prescriptions and turn to alternative pain treatment strategies, potentially including the more liberal use of NSAIDs.

Nonunions are categorized as hypertrophic, oligotrophic, and atrophic.[219] These distinctions are critical in that they describe the underlying cause of the nonunion and therefore guide treatment. Hypertrophic nonunions are fractures that have failed to heal despite an adequate local blood supply and obvious formation of callus. Mechanical stabilization alone usually leads to union in this situation. Oligotrophic nonunions show minimal callus formation but no bony resorption. Atrophic nonunions show little to no callus formation and have local bone resorption. Bone grafting along with mechanical stabilization are required in oligotrophic and atrophic nonunions.

Nonunion treatment requires a comprehensive evaluation of both patient physiology and injury factors to arrive at realistic treatment expectations. In some cases, patients are better served with amputation rather than a long, painful, expensive treatment course that can result in a healed extremity that is painful and dysfunctional. Contemporary lower extremity prostheses can allow a wide range of functional activity including running, biking, working, and resumption of normal daily activity, especially in patients who were in good physical condition prior to injury.

Malunion

Malunion is an abnormally healed bone with residual shortening, angulation, or malrotation. The evaluation of a patient with malunion focuses on whether the deformity has a significant impact on the function of the limb. Physical examination should assess joint motion, gait, and coronal and sagittal plane alignment. Radiographic evaluation includes orthogonal radiographs of the affected bone, standing full-length radiographs, and CT scan to identify coronal, sagittal and rotational deformity. Functional limitations are the most common indication for surgical management of malunion in the upper extremity. However, pain as a result of long-term weight bearing on malaligned lower extremities is the primary indication for surgical intervention in the lower extremity. Significant malalignment may predispose a patient to progressive osteoarthritis from asymmetric joint loading. Length leg discrepancy can lead to both joint and low back pain. Complex malunion reconstructions require thoughtful consideration of both patient and injury factors prior to embarking on a prolonged treatment course.

Musculoskeletal Infection

Musculoskeletal infection after fracture surgery is a serious complication that can lead to significant treatment morbidity or even loss of limb. Polytraumatized patients are susceptible to organ dysfunction and infection from altered immunologic responses.[220] Open fractures, wound contamination, soft tissue coverage failure, multiple procedures, prolonged hospital stays, and perioperative malnutrition further increase the risk of infection.[221] The diagnosis of infection after fracture surgery can be challenging in the absence of the typical clinical signs of infection. Serologic testing, specialized radiographic imaging, and fracture site biopsy can all play a role in establishing

the diagnosis. Delayed healing, wound complications, and pain should lead to suspicion of infection. Patients with clinical symptoms of infection and negative culture results should be treated similarly to patients with culture-positive infections.[222] Delay in treatment of infection after internal fixation increases a patient's morbidity and risk for limb loss. Treatment depends on the chronicity of the infection and status of fracture healing. Acute postoperative infection within a few weeks of internal fixation can be treated with surgical debridement, retention of the orthopedic implants, and oral or intravenous antibiotics until fracture union.[223] However, the rate of successful eradication of infection with hardware retention is reported to only be 70%, and patients should be appropriately counseled.[223] Osteomyelitis in the setting of a healed fracture after internal fixation is treated with surgical debridement and removal of implants and a varied course of oral or intravenous antibiotics.[224] Management of septic nonunion should address both infection and mechanical instability. This usually requires multistage surgical treatment and a prolonged course of intravenous antibiotics.[225,226]

Other Sequelae

Lower extremity trauma can lead to loss of function from a variety of causes. Muscle injury can lead to weakness, soft tissue pain, and joint stiffness. Direct injury to articular cartilage, postfixation joint incongruity, and mechanical axis malalignment increase the risk of posttraumatic arthritis. Anatomic reduction of articular injuries and stable fixation that permits early range of motion of injured joints provide the best chance of preventing posttraumatic arthrosis and stiffness. However, an injured articular surface may still develop posttraumatic arthritis despite anatomic reduction due to irreversible cartilage damage at the time of injury. Significant arthritis leads to chronic pain and eventual loss of normal functional activities, necessitating arthroplasty or arthrodesis of affected joints.

Although ankle and subtalar joint arthrosis is usually evident within 1 year, hip and knee deterioration can be more variable. Rapid deterioration of the hip joint can be seen in avascular necrosis after hip dislocation or displaced femoral neck fracture. Joint collapse due to avascular necrosis is typically seen within 3 to 12 months after an injury. Posttraumatic arthritis, however, can take years to develop. Pain and disability from posttraumatic arthritis do not always correlate with x-ray findings. Initial conservative management includes bracing, anti-inflammatory medication, and intra-articular cortisone injection. Arthroplasty or arthrodesis options depend on the anatomic location and are reserved for patients with disabling symptoms. Although arthroplasty of the hip or knee is a highly successful reconstructive procedure for elderly adults with severe symptoms of arthritis, the functional limitations and finite life span of arthroplasty components make it a less attractive option in young patients. However, if no viable alternative options exist and the patient is disabled by pain, arthroplasty is an acceptable option even in young patients.

Contracture and joint stiffness of the hip, knee, and ankle are common complications after lower extremity trauma. This is particularly true for intensive care patients who remain intubated for extended periods. Equinus ankle contractures predictably develop if appropriate splinting, bracing, and/or stretching exercises are not performed. Flexion contractures of the knee can develop rapidly with prolonged bed rest, particularly if pillows are placed under the knees for patient comfort. Contractures of the knee and ankle significantly affect gait and slow the functional recovery. Prevention of contractures is far easier than treatment. A multidisciplinary approach including qualified physical and occupational therapists, nursing, and physicians to focus on early motion and contracture prevention may improve outcomes in this population.

CONCLUSION

Lower extremity trauma has a wide range of presentations, from simple isolated injuries to highly complex multiple injuries in severely injured, polytraumatized patients. Injury characteristics and patient comorbidities lead to an array of treatment paradigms. The treatment course of these patients can span from simple nonoperative measures to prolonged multistage surgical interventions spanning years. Injuries and their associated treatments carry a significant risk of complications, with a wide variation in functional outcome. Optimal results are obtained with a multidisciplinary approach by experienced and dedicated providers.

Peripheral Vessels

Steven R. Shackford

KEY POINTS

- Ischemia of greater than 3 hours can cause irreversible neuromuscular changes; expeditious diagnosis and management are essential to a good outcome.
- Significant prognostic factors related to secondary amputation are duration of ischemia, significant soft tissue loss, blunt mechanism, compartment syndrome, and multilevel arterial injury.
- Computed tomographic arteriograms have replaced catheter-based arteriography for *diagnostic* vascular imaging.
- In the presence of protracted ischemia and the absence of intracranial or intracavitary hemorrhage, systemic preoperative or intraoperative heparinization should be considered.
- In a stable patient with a bruit or thrill, catheter arteriography can provide both a diagnosis and treatment for an acute pseudoaneurysm or acute arteriovenous fistula.

INTRODUCTION

Injury to a major peripheral artery can be limb threatening. If active hemorrhage is present and not urgently controlled, peripheral vascular trauma can be life threatening. In either case, diagnosis and management must be expeditious. This chapter reviews the epidemiology, pathophysiology, clinical presentation, management, and outcome of extremity vascular injuries. Recently, algorithms have been developed for the evaluation and management of vascular injury and are useful for quick reference for the topics discussed in this chapter.[1,2]

EPIDEMIOLOGY

Vascular injuries of the extremities are uncommon. In civilian urban trauma centers, peripheral vascular injuries are present in 1% to 5% of admissions; in rural centers, they are even less common, occurring in less than 1% of admissions.[3,4] Most are penetrating, due to either gunshot or stab wounds, and occur predominantly in males in their third and fourth decades. Blunt trauma sufficient to produce fractures or dislocations is a much less frequent cause. Explosive ordnance and high-velocity projectiles are the predominant wounding agents in the recent military experience.[5]

Because of the increase in endoluminal procedures for diagnosis, vascular control, and therapy, the number of iatrogenic peripheral arterial injuries increased 40% between 1996 and 2003.[6] Iatrogenic arterial injuries occur in approximately 0.6% of patients undergoing endoluminal therapies, and they appear to be specialty related.[7] Most of these injuries involve the groin where access is most commonly obtained for interventional procedures. Iatrogenic vascular injuries can also occur during open operations on the extremities, such as during total joint procedures, intramedullary and external fixation, and plate osteosynthesis. They can present as hemorrhage or ischemia during the procedure or immediately after (usually in the recovery room), or they can present months or years later as claudication or acute limb-threatening ischemia due to thrombosis or emboli.[8] Iatrogenic arterial injuries are definitely not benign. Limb-threatening complications have occurred,[9] and recent reports have documented a 5% to 7% all-cause mortality following iatrogenic arterial injury.[6,10]

PATHOPHYSIOLOGY

Arteries and veins are composed of three tissue layers: the outer adventitia of connective tissue, the central media of smooth muscle and elastic fibers, and the inner intima or endothelial cell layer. Trauma to a blood vessel (artery or vein) can produce hemorrhage, thrombosis, or spasm, either alone or in combination, depending on the mechanism and the magnitude of the force applied to the vessel. Hemorrhage occurs when there is a laceration or puncture of all of three

layers. If the bleeding is tamponaded by the surrounding tissue (ie, muscle or fascia), a localized hematoma will form, which may be pulsatile. If local tamponade is ineffective or only temporarily effective, immediate or delayed hemorrhage ensues, which can be life threatening. Damage solely to the intima occurs when an artery is acutely deformed or angulated. The intima is the least compliant of the three layers; thus, it fractures when the more flexible layers (adventitia and muscle) bend when deformed by an adjacent broken bone or joint dislocation. Intimal injury exposes the subendothelial matrix, which is rich in tissue factor, resulting in activation of the clotting mechanism and subsequent thrombus formation. The thrombus may enlarge or propagate and occlude the vessel or embolize and produce a distal occlusion. The injured intima may also form a flap that can prolapse into the arterial lumen as a result of the forward blood flow dissecting under it. The prolapsed intima can partially or completely obstruct the lumen. Displaced bone from a fracture or dislocation can compress a vessel to the point of completely interrupting flow. Stretching or contusing an artery can produce spasm or segmental narrowing. Bleeding adjacent to a vessel also produces spasm due to the vasoconstrictive effects of hemoglobin on the external surface of an artery. Spasm that reduces a vessel diameter by 50% reduces the cross-sectional area by 75%, producing a significant reduction in distal flow.

Penetrating injuries produce focal injury, whereas blunt injuries tend to be diffuse and injure not only the vascular structures, but also the adjacent soft tissue, bone, and nerves. This adjacent tissue contains small, unnamed blood vessels that would normally provide collateral flow around an injured named vessel. This "collateral" damage worsens or exaggerates ischemia.

Velocity, rather than size, matters in penetrating injury because the energy imparted to a target by a projectile is equivalent to one-half the mass of the projectile multiplied by the velocity of the projectile *squared*.[11] As a result, penetrating mechanisms are classified as either low velocity (<2500 feet per second [ft/s]) or high velocity (>2500 ft/s). Low-velocity wounds include stabs, fragment injuries, and low-velocity gunshot wounds. High-velocity (>2500 ft/s) wounds are most commonly inflicted by a military assault rifle. Because of the imparted kinetic energy, high-velocity weapons are capable of producing significantly more tissue damage than low-velocity weapons.[11,12]

Peripheral vascular injuries can be subtle and go undetected. Symptoms or signs may not be present during the initial phases of care or even during the initial hospitalization. With time, however, they progress insidiously and eventually produce signs and symptoms. The most common late-detected indolent injuries are the arteriovenous fistula and the pseudoaneurysm.

An arteriovenous fistula typically occurs after penetrating trauma that causes a puncture or small laceration to both an artery and an adjacent vein. The high-pressure flow from the artery will follow the path of least vascular resistance into this adjoining vein. Because the fistula is small initially, it is undetected, but with time, it enlarges, diverting nutrient flow from the distal vascular bed. As it enlarges, it produces local, regional, and systemic signs and symptoms such as local tenderness and edema, regional ischemia from "steal," and congestive heart failure if the involved artery and vein are major conduits.[13]

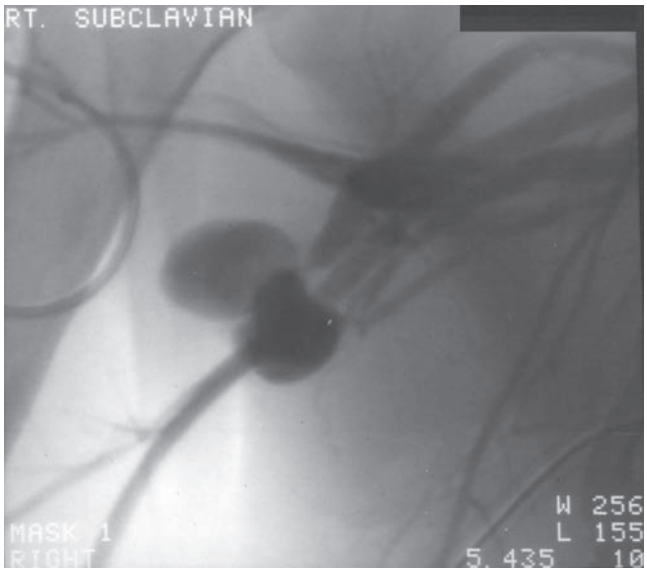

FIGURE 45-1 Acute axillary artery pseudoaneurysm and arteriovenous fistula following stab wound in right axilla. Vessels repaired by simple closure.

A pseudoaneurysm is a result of a puncture or laceration of an artery that bleeds into and is controlled by the surrounding tissue. The artery remains patent; blood flows into and out of the pseudoaneurysm, much like the ebb and flow of ocean water into and out of a tide pool. As a pseudoaneurysm enlarges, it can produce local compressive symptoms, erode adjacent structures, or, rarely, be a source of distal emboli (Fig. 45-1).

Minimal peripheral arterial injuries can heal without an intervention. Dennis and colleagues[14] were the first to demonstrate that small intimal flaps, intimal "irregularities," small pseudoaneurysms, and small arteriovenous fistulae can heal with little residual deformity. Most of these minimal arterial injuries will heal, but it is impossible to predict which ones will progress and eventually develop either acute or chronic symptoms. For this reason, close follow-up with periodic duplex color flow imaging is essential.

A reduction in blood flow produces ischemia when the oxygen demands of the tissue supplied by that artery are not met. The vulnerability of a tissue to ischemia depends on its basal energy requirement, substrate stores, and duration and severity of the ischemic insult. Peripheral nerves are the most vulnerable to ischemia because they have a high basal energy requirement and virtually no substrate (glycogen) stores. Therefore, sensory deficits are often the first manifestations of ischemia. Skeletal muscle is more tolerant of decreased blood flow; histologic changes are not evident unless ischemia has been present for 3 hours or more. In a porcine model, functional derangements and histologic change in both nerve and muscle occur in 3 hours following the onset of ischemia even

if reperfusion is established by the end of that interval.[15] With complete interruption of arterial inflow, such as occurs with occlusion of a major arterial conduit *and* disruption of collateral vessels, and the longer the duration of interrupted flow, the greater is the potential for irreversible ischemic damage.

After prolonged complete ischemia, damage can be extended rather than reversed by reperfusion. This ischemia/reperfusion injury is thought to be initiated by hypoxic disruption or "shedding" of the endothelial glycocalyx, which changes the normal endothelial cell phenotype from anticoagulant and anti-inflammatory to procoagulant and proinflammatory.[16,17] Recent evidence suggests that both the complement and kinin cascades are triggered, which exacerbate the injury by attracting neutrophils. In addition, vascular integrity is lost, resulting in interstitial edema. Interstitial edema raises the interstitial fluid pressure, eventually occluding venules, capillaries, and arterioles and resulting in the "no reflow" phenomenon, compartment syndrome, and myonecrosis or rhabdomyolysis with release of myoglobin and potassium from the irreversibly injured myocytes. Myoglobin is nephrotoxic, and hyperkalemia, if untreated, can lead to a fatal arrhythmia.[18]

PROGNOSTIC FACTORS

There are a several important factors that determine the outcome of an injury to a peripheral vessel. Outcome, in this case, is the need for secondary amputation (amputation following one or more attempts at revascularization). Based on a thoughtful meta-analysis of lower extremity vascular injury, the most significant prognostic factors are amount of significant soft tissue injury, duration of ischemia, presence of a compartment syndrome, high-energy transfer mechanism (ie, gunshot wound or blast injury), multilevel arterial injury, and anatomic location (ie, popliteal artery).[18] Of these, the surgeon can only impact the duration of ischemia, which is the elapsed time from *injury* to *restoration of flow*. Notice that it is the elapsed time from *injury*, not hospital arrival, that is critical, and it is the time to *restoration of flow*, not completion of the arterial repair. Because the time of injury is not always exactly known, it is best to estimate a longer prehospital interval than a shorter one and let this govern the urgency with which management occurs. Based on experimental work using a model of complete vascular occlusion, restoration of flow within 3 hours appears to be optimal to avoid any ischemic changes in nerve and muscle. A delay of greater than 6 hours from injury to restoration of flow results in myonecrosis and moderate Wallerian degeneration of the peripheral nerves.

Other factors that can adversely affect not only limb salvage, but also function include blunt mechanism, associated nerve injury, associated orthopedic injuries, and associated comorbidities. Shock may also be a contributor, but a recent meta-analysis did not find shock to be significant.[19] Compared to the lower extremity, all things being equal, the upper extremity appears to be more tolerant of ischemia, which is likely due to relatively better collateral flow around the shoulder and elbow joints.[20]

CLINICAL PRESENTATION

The presentation of extremity vascular injury varies from obvious life-threatening external hemorrhage from penetrating injury to ischemia from blunt force trauma. As stated previously, penetrating extremity trauma tends to be focal and is usually not accompanied by other injuries. The same is not true for blunt trauma, which is more diffuse and often associated with multiple injuries.

For the patient with a penetrating focal injury, it is important to obtain information from the prehospital providers regarding the approximate time of injury and the agent (eg, stab wound, gunshot wound) and an estimate of the amount of blood lost at the scene and during transport. For a patient with blunt trauma, additional history must include a description of the mechanism of injury (eg, pedestrian stuck, rollover with ejection) and, in the case of motor vehicle crashes, the amount of damage done to the vehicle. This information allows the physician to estimate energy transfer—the greater the energy transfer, the higher the index of suspicion should be for occult vascular injury, not only in the extremity, but also in the torso. Fracture and dislocation patterns can also suggest the possibility of vascular injury. For example, in the upper extremity, a supracondylar fracture of the humerus can be associated with a brachial artery injury. Similarly, in the lower extremity, posterior knee dislocation can be associated with a popliteal artery injury.

The presence of unexplained hemorrhagic shock in patients without evidence of head, neck, or torso injury should direct attention to apparently trivial extremity lacerations. This is particularly important in wounds in the antecubital fossa, groin, and popliteal fossa where initial hemorrhage from a laceration of the deep vessels may have led to hypotension and subsequent thrombosis.

At presentation, the following sequence of steps is recommended: primary survey as described by the Advanced Trauma Life Support (ATLS) course, control of ongoing hemorrhage by compression, or the use of a proximal tourniquet if compression is unsuccessful. Tourniquet use was discouraged in prior military conflicts and used only when all other methods failed primarily because of concerns about improper application.[21] The recent military and civilian experience with tourniquets has shown that proper placement can be lifesaving and improper placement is infrequent.[22,23] Next, a secondary survey, as described by ATLS, is performed, and the primary survey is repeated at regular intervals, particularly if there is a change in the patient's condition.

DIAGNOSTIC EVALUATION

History and Physical Examination

A detailed history and a thorough physical exam can eliminate the need for imaging and contribute to the expeditious management of a threatened extremity. In addition to the elements of the history obtained during the initial survey, the following are also important (particularly in a patient over

the age of 50 years): list of medications (including illicit drugs with vasoconstrictive properties, such as cocaine and methamphetamine), a history of claudication in either or both lower extremities, and a list of current comorbidities.

The physical examination must include systolic blood pressure and temperature, both of which affect the extremity vascular exam. Hypotension, causing peripheral vasoconstriction, will reduce or eliminate the peripheral pulse in an uninjured limb; hypothermia will prolong capillary refill. Therefore, resuscitation and rewarming may improve the pulse exam in the limb without a vascular injury but will have little or no effect in the limb with a vascular injury. Extremity dressings should be removed to assess and document the nature of the underlying wounds. The following should be noted and documented if present or absent (negatives are pertinent for subsequent examinations): active bleeding, hematoma (including whether it is soft or tense), bruit, or thrill. Examination of the uninjured contralateral extremity should precede that of the injured limb to provide the basis for comparison. This includes a vascular and neurologic examination (sensory and motor), careful palpation of peripheral pulses, and assessment of color, warmth, capillary refill, and venous filling. The vascular and neurologic findings in the injured and uninjured limbs must be accurately documented. This provides important information necessary for follow-up examinations, both preoperatively and postoperatively. There is an unfortunate tendency to "overcall" the presence of peripheral pulses. Once any examiner documents that a pulse is present when it is, in fact, absent, there is a tendency of subsequent examiners to do the same. When in doubt, declare the pulse absent and proceed to the use of a continuous-wave (handheld) Doppler device. Venous signals can be heard and mistaken for an arterial signal. Venous signals augment with distal compression; arterial signals do not. The experienced examiner can assess flow based on the character of the audible Doppler signals. However, when there is an abnormal (absent or reduced) pulse, the arterial pressure index (API) should be determined.[24,25] This is done by placing a blood pressure cuff just proximal to the wrist or ankle in the injured extremity. The probe is placed over the distal vessel. The cuff is slowly inflated, and the cessation of the arterial signal indicates the systolic blood pressure at the level of the cuff. The uninjured contralateral extremity and an uninjured arm pressure are then determined. The normal ankle–brachial index is 1.1. Unless the patient has preexisting peripheral vascular occlusive disease, the ankle–brachial index should be at least 0.9, and there should be less than a 20-mm Hg difference between the two lower extremities. An absolute pressure below 50 to 60 mm Hg at the wrist or the ankle indicates limb-threatening ischemia in the patient with a normal systemic blood pressure. The API is not useful in patients with advanced diabetes in whom the proximal conduit arteries are severely calcified making them noncompressible, even at high cuff inflation pressures.

There are very distinct physical findings ("hard signs") that indicate a *high probability* of a vascular injury (Table 45-1). There are equally important "soft signs" that suggest the *possibility* of extremity vascular injury. Of the hard signs, expanding hematoma, pulsatile bleeding, and advanced ischemia require immediate exploration. In the absence of hemorrhage, hemodynamic instability, or advanced ischemia, a bruit or thrill or the presence of one or more soft signs is an indication for further evaluation.

TABLE 45-1: Hard and Soft Signs of Vascular Injury

Hard signs	Indicate a very high probability of vascular injury: • Pulsatile bleeding • Expanding hematoma • Palpable thrill • Audible bruit • Evidence of regional ischemia –Pallor –Paresthesia –Paralysis –Pain –Pulselessness –Poikilothermia
Soft signs	Suggest the possibility of a vascular injury: • History of moderate hemorrhage • Injury (fracture, dislocation, or penetrating wound) • Diminished but palpable pulse • Peripheral nerve deficit

Vascular Imaging

The advent of high-resolution multidetector computed tomography (CT) angiography (CTA) has radically changed the approach to contrast imaging for extremity vascular trauma. Catheter arteriography used *solely* for the diagnosis of a potential vascular injury has been replaced by CTA. Multidetector (64-slice) CTA with the appropriate imaging protocols creates axial, coronal, and sagittal views within minutes.[26] The latest software produces three-dimensional reconstructions without the delays associated with workstation manipulations. In addition to being very accurate, CTA avoids not only the delay necessary to assemble the angiography team, but also the potential complications associated with arterial access. Catheter arteriography is now reserved for patients with suspected vascular injury in whom a catheter-based therapy may be necessary (eg, an arteriovenous fistula or a pseudoaneurysm),[27] patients with blast injuries or shotgun wounds in whom metallic fragments or pellets can produce artifacts on the CTA that obscure the arterial or venous lumen, patients with multilevel injury, and hemodynamically stable patients who have injuries of the thoracic inlet.[28] The indications for vascular imaging have not changed (Table 45-2). In the patient who is neurologically or hemodynamically unstable, a single-injection arteriogram in the trauma room or operating room is a quick and accurate method to evaluate an extremity with a suspected vascular injury (Table 45-3).[29]

TABLE 45-2: Indications for Vascular Imaging in Patients with Extremity Injuries

In patients with blunt force injury

Multilevel extremity fractures with distal ischemia
Crush injury with diminished blood flow
Extensive hematoma with intact distal flow
Presence of a thrill or bruit over an area of injury

In patients with penetrating injury

Significant hematoma in proximity to wound with intact distal flow
Multilevel penetration from a shotgun blast
Presence of a thrill or bruit over an area of injury

TABLE 45-3: Technique for "Single-Shot" Extremity Arteriography

1. Place a radiograph cassette beneath the area of concern in the extremity.
2. Insert and hold steady an 18-gauge needle or short 16-gauge catheter in the femoral or axially artery.
3. Aspirate blood to the level of the syringe containing contrast to avoid air bubbles.
4. Rapidly inject 20 mL of full-strength intravenous contrast agent for the leg and 10 mL for the arm.
5. Delay x-ray exposure for 2 seconds for the proximal upper extremity and proximal thigh, 3 seconds for the forearm and distal thigh, 4 seconds for the popliteal level, and 5 seconds for the tibial vessels.
6. Fluoroscopy with the digital subtraction angiography mode may also be used.

Noninvasive Evaluation

Color flow ultrasound imaging is useful for the delayed diagnosis of chronic vascular injuries, such as a pseudoaneurysm or an arteriovenous fistula, and for the postoperative follow-up of vascular repairs. In patients with severe renal insufficiency in whom the use iodinated contrast might precipitate permanent renal failure, duplex scanning performed and interpreted by a skilled technologist or physician combined with a thorough physical examination can be used to rule out an arterial injury. The quality of the image may be reduced by hematoma, air in the subcutaneous space, and a large wound near the site of injury. If doubt remains, the calculus of harm must be assessed with respect to the risk of a contrast study versus that of an operative exploration.

Practice Recommendation for Extremity Vascular Diagnostic Evaluation

The recommended diagnostic approach is detailed in Fig. 45-2. Physical examination remains the most important

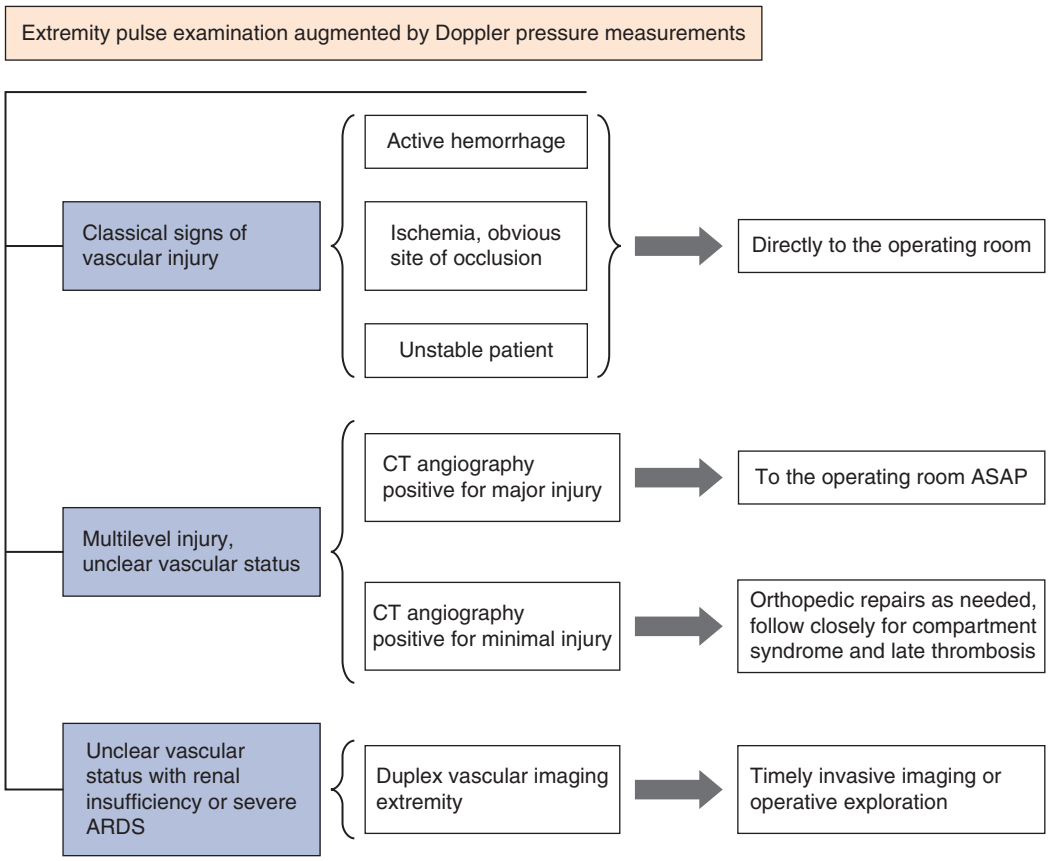

FIGURE 45-2 Diagnostic evaluation of extremity vascular injury. ARDS, acute respiratory distress syndrome; CT, computed tomography.

element of this process. Common sense dictates that patients with pulsatile bleeding, expanding tense hematoma, hemodynamic instability, or advanced ischemia go directly to the operating room to delineate and repair the injury. Expeditious imaging with either high-resolution CTA or catheter arteriography, if a possible endoluminal therapy is needed, must make sense in terms of the expense of time and the value of the results in deciding and directing the management.

GENERAL PRINCIPLES OF MANAGEMENT

Consensus-derived algorithms explaining the rationale for decision making in the evaluation and management of peripheral vascular trauma have recently been published and should be reviewed as a companion to the following information.[1,2]

Minimal Vascular Injury and Nonoperative Management

Minimal vascular injuries are those that are asymptomatic and have the potential to heal without becoming symptomatic. The diagnosis is made following imaging obtained for suspected vascular injury manifested by the soft signs. Minimal vascular injury includes intimal irregularities (eg, small intimal flap), small arteriovenous fistulae, focal spasm, and small pseudoaneurysms.[30] Progression of these lesions to produce symptoms occurs in approximately 5% to 15% of cases and usually occurs early in the postinjury course.[14] Considerable evidence suggests that nonoperative therapy of these asymptomatic lesions is safe and effective. The possibility of progression, while remote, necessitates compulsive inpatient and outpatient follow-up with repetitive physical examinations (including the API) and the liberal use of color flow imaging. Operative therapy is required for thrombosis, ischemia (including ischemic "steal" produced by an enlarging arteriovenous fistulae), and failure of small pseudoaneurysms to resolve.

Endovascular Management

The use of endovascular therapies for extremity vascular injuries is increasing. These therapies include branch coil embolization, vasodilator infusion, and the use of covered and uncovered stents. There are now several small retrospective case series and a single prospective report describing the use of covered stents for the treatment of chronic injuries, such as arterial pseudoaneurysms and arteriovenous fistula, and acute injuries with hemorrhage, dissection, and thrombosis.[5,31-33] The most common injuries treated acutely are those involving the subclavian and axillary arteries, probably due to the relative difficulty in open operative exposure of these arteries. The evidence to support endoluminal therapies for peripheral injuries remains parochial because there is no consensus on the indications (particularly in the case of minimal injury), no uniform definitions of complications, and no comprehensive long-term follow-up of the patients who have been treated.[34] Reports from large databases lack granularity to address some of these important issues.[35] As such, the decision to use an endovascular approach for treatment of acute peripheral vascular injury should be made on an individual case-by-case basis.[2,36]

Operative Management

The successful operative management of extremity vascular injuries requires prompt control of hemorrhage and expeditious restoration of adequate perfusion. These priorities must be orchestrated with the *overall management and care* of the patient. In the neurologically or hemodynamically unstable patient, other priorities will trump *definitive* vascular repair. In either case, *damage control* using a temporary intravascular shunt inserted into the appropriately prepared artery (and vein, if injured) can quickly restore perfusion in an ischemic limb,[37] whereas a tourniquet, appropriately applied (see later), can control hemorrhage.[22] Secondary considerations include adequate tissue coverage of the vascular repair, fracture stabilization, and wound management.

WHO SHOULD REPAIR INJURED BLOOD VESSELS?

Currently, trauma surgeons with general surgery specialty training perform almost 70% of complex vascular repairs of injured arteries, whereas vascular or cardiovascular surgeons perform 27% with similar rates of limb salvage (94% and 95%, respectively).[38,39] In an era of fewer open vascular procedures performed during general surgical training, the repair of extremity vascular injury in the future may not be within the capabilities of many trauma surgeons.[40] It is important that senior trauma surgeons with experience in managing vascular injury train their younger colleagues in the techniques necessary to expose and repair these injuries. Because many surgeons who perform elective vascular surgery are not sufficiently experienced in the *overall management* of a trauma patient with a vascular injury, board certification in vascular surgery does not necessarily qualify a surgeon as capable to handle these injuries, just as the lack of certification does not necessarily disqualify a surgeon. Conversely, there are many trauma surgeons who are very skilled in vascular technique by virtue of their interest and experience. Surgeons with experience in vascular techniques and management of vascular injuries, no matter what the specialty training, should be available at all trauma centers.

OPERATION

Preoperative Preparation

Broad-spectrum antibiotics and, if there is a penetrating wound or an open fracture, tetanus toxoid should be administered as soon as possible. If ischemia of the limb is apparent, greater than 3 hours have elapsed since the time of injury,

and there is no evidence of ongoing bleeding in the limb and no intracranial or intracavitary hemorrhage, consideration should be given to administering systemic unfractionated heparin (70 U/kg) as soon as possible if there is evidence of ischemia.

In controlling hemorrhage, there is no role for "blind" clamp placement in the injured extremity; it is rarely successful and frequently injures adjacent nerves. The operating room has the personnel and the equipment (including lighting and suction) necessary for effective exposure and control. A properly placed tourniquet, a Foley catheter with a 30-mL balloon inserted into the wound and inflated, or a gloved hand compressing the bleeding site during transfer to the operating room will suffice. There are a variety of commercially available disposable tourniquets that are very effective in providing temporary control. The tourniquet is placed proximal to the injury, but as distal as possible to avoid ischemia to tissues that are proximal to the injury. It should not be placed directly over joints or bony prominences because effectiveness may be reduced, and the skin directly under the tourniquet will be at risk for ischemia by direct compression. Finally, it should be applied with pressure sufficient to occlude flow. The time of placement should be recorded to accurately track the occlusion time, which should not exceed 90 minutes to avoid nerve ischemia.[41]

If there is an associated fracture or dislocation, consultation with an orthopedic surgeon will facilitate preoperative planning. The sequence of procedures and conduct of the operation should be discussed. For example, controversy can arise regarding the priority of orthopedic stabilization compared to vascular repair. The use of a temporary vascular shunt to perfuse an ischemic extremity prior to orthopedic stabilization can address both issues.[36] Shunt placement and subsequent detection of Doppler signals in the limb distal to the shunt ensure perfusion and remove the sense of urgency to perform a definitive repair. If there is extensive soft tissue loss, early consultation with a plastic surgeon will facilitate the planning of tissue coverage of the vascular repair.

Once operative priorities have been established, communication with the operating room staff is necessary to ensure the availability of appropriate instrument sets, sutures and graft material, and other ancillary equipment, such as a cell saver for blood retrieval and a patient warming device. Communication with the anesthesiologist is necessary to inform him or her of the patient's resuscitation needs, need for blood products, and estimated duration of the proposed operation.

The surgeon should be present in the operating room when the patient arrives to assist with specific operative preparation, which includes selecting suture and instrumentation appropriate to the proposed procedure[2] and provision of heparinized saline (5000 U of heparin/500 mL) and papaverine hydrochloride (a locally effective vasodilator, 30 mg/mL) for *regional* injection. The surgeon should supervise positioning, prepping, and draping. To ensure that proximal control can *always* be obtained, areas of the adjacent chest and shoulder for upper extremity injuries and the adjacent abdomen (up to and including the umbilicus) for lower extremity injuries should be prepped and draped with the *entire* injured extremity. Because the middle of the night is not the time to pull together the necessary equipment, it is prudent to assemble a standard peripheral vascular trauma set of equipment, sutures, and graft material ahead of time. It is also recommended that the surgeon wear coaxial lighting (headlamp) and 2.5× to 4× magnification loupes, depending on the diameter of the vessel to be repaired (proximal, 2.5× magnification; distal, 4× magnification).

Exposure and Control (See Atlas Figure 76)

Proximal and distal control of the involved artery should be achieved prior to exposure of the injury. The incisions for exposure are those used for elective procedures (see the later section "Management of Vascular Injuries by Anatomic Region"). In proximal extremity injuries with active hemorrhage, the site is chosen to give the fastest exposure of inflow vessel(s) for clamping. A sterile tourniquet can be exchanged for one previously applied. In the operating room, have one team member compress the bleeding site with a gloved hand and a sponge, remove the previously applied tourniquet, and prep the extremity. A sterile tourniquet for use in the operating room (ie, one that contains a bladder for inflation and a gauge for the measurement of cuff pressure) is placed proximal to the wound and inflated, and the pressure and time of inflation are documented. A 5000-U heparin bolus is then given if this is an isolated injury (no evidence of cavitary or intracranial injury). A recent retrospective analysis of the Prospective Observational Vascular Injury Trial (PROOVIT) database demonstrated no difference in either amputation or thrombosis between patients with peripheral vascular injury receiving systemic intraoperative heparinization and those who were not systemically heparinized.[42] However, the group receiving intraoperative anticoagulation contained three times as many patients with an occlusive vascular injury and over twice as many patients with prolonged preoperative ischemia (>3 hours) than did the group not receiving intraoperative anticoagulation. One would have expected higher amputation and thrombosis rates in patients with prolonged ischemia and an occlusive vascular injury.[19] A recent multicenter retrospective study containing more patients than the PROOVIT analysis found significantly improved patency of vascular repairs with no increase in bleeding.[43]

If, after proximal and distal control have been obtained, there is still ongoing hemorrhage from the wound area, an appropriately sized Fogarty balloon-tipped catheter on a three-way stopcock can be gently inserted into the artery above or below the level of injury. The catheter is advanced to the area of the injury (measured beforehand against the Fogarty using the 10-cm markers on the catheter) and the balloon inflated enough to control the bleeding. Extreme care is necessary when inflating the Fogarty balloon—as soon as any resistance to inflation is felt, inflation should stop.

Control of proximal and distal flow is best achieved by "double passing" silastic vessel loops around the vessel above and below the area of injury and gently retracting until flow

ceases. Side branches between the proximal and distal vessel loops are controlled with removable metal clips. If clamps are needed, choose the appropriately sized vascular clamp and close the ratcheted handle only as much as needed to occlude the vessel. Carefully support the clamps to avoid twisting and inadvertent stretching of the vessels.

Before initiating definitive repair of the injury, several sequential maneuvers are necessary. Carefully inspect the injury and debride the injured parts back to normal-appearing intima. Because flow has ceased with proximal and distal control, there may be proximal and distal thrombus in the vessel. Therefore, pass an appropriately sized Fogarty catheter proximally and distally to clear any thrombus. This must be done carefully because the intima can be injured by overdistention of the balloon, as previously mentioned; this is avoided by starting to retract the catheter before starting to inflate the balloon. When the slightest resistance or "drag" is appreciated, stop inflating because the balloon is now in contact with the arterial wall. At this point, continue with retraction of the catheter. Repeat catheter passes until no clot is retrieved from the proximal and distal artery. Inject heparinized saline into the proximal and distal artery using a vessel irrigator (Titus needle or olive-tipped irrigator), first aspirating blood to ensure that the tip is in the lumen. Care should be used when injecting proximally in the brachial and axillary arteries because vigorous flushing of 10 mL may force thrombus or air into the origin of the vertebral artery, potentially causing a posterior circulation stroke.

The debrided and appropriately flushed artery should then be carefully inspected to select the method of repair that should be tension free. Normal arteries in the extremities of young patients are highly elastic and can retract a substantial distance. There is a significant risk of stenosis and thrombosis if undue tension is placed on the artery in an attempt to perform a primary repair of the distracted ends. When there is doubt about tension or about the adequacy of the debridement, it is best to abandon an attempt at primary repair and proceed with interposition grafting, which is the most common type of repair in large series.[35]

Transverse or short oblique lacerations without vessel wall disruption may be repaired with simple interrupted sutures. Longitudinal and long oblique lacerations cannot be closed without compromising the luminal diameter. The injured site should be opened longitudinally for a length sufficient to inspect the intima. The injured or "questionable" intima should be debrided. A vein patch can then be used to close the arterial defect without compromising the diameter of the lumen. If suitable vein is not available, a polytetrafluoroethylene (PTFE) patch is an acceptable alternative in the common and superficial femoral arteries. If a long segment of the anterior arterial wall is debrided, leave the uninjured back wall intact. Leaving the back wall intact, rather than dividing it, prevents retraction of the arterial ends, facilitating vein patch angioplasty or interposition grafting.[20]

When there is complete vessel transection, interposition grafting is usually necessary. The vessel ends should be "spatulated" or beveled to ensure a nonstenotic anastomosis. To ensure a tension-free anastomosis, mobilize proximal and distal segments of the uninjured portion of the artery even if it means sacrificing some minor tributaries. The optimal interposition graft material is autologous greater saphenous vein harvested from an uninjured leg. Native vein graft is preferable because it has elastic properties that make it very compliant with the normal pulsatile flow of an artery. It also has a diameter that approximates that of an extremity artery and produces an adequate size match for grafting in the arm and leg. Venous intima is less likely to be thrombogenic and has superior long-term patency when compared with prosthetic material when used with smaller vessels (popliteal and tibial). When saphenous vein is unavailable, lesser saphenous vein should be used. Cephalic vein has been suggested as a suitable second choice, but cephalic vein is less muscular than the greater and lesser saphenous and will eventually dilate after it has been "arterialized." Both the cephalic vein and the lesser saphenous vein are more difficult to harvest than the greater saphenous. If time of ischemia is a concern, one can insert a temporary shunt into the injured artery and vein and proceed with the harvest.

A PTFE graft is an acceptable second choice. PTFE has a short-term patency of 70% to 90%, and infections are rare even in contaminated wounds.[44] Patency of PTFE grafts is equivalent to that of vein for injuries proximal to the popliteal artery, but inferior to vein for popliteal and more distal vessels. PTFE grafts of greater than 6 mm in diameter should be used.[45] All arterial repairs must be covered with soft tissue to prevent infection or desiccation of autogenous tissue, both of which can lead to hemorrhage or infection.

Single-vessel arterial injuries in the distal forearm and distal calf may be ligated if there is sufficient collateral flow through the remaining vessels. Observing back-bleeding through the distal injured end of the vessel indicates adequate collateral flow. Doppler signals in the hand or forefoot vessels also indicate adequate distal perfusion. When in doubt, perform an intraoperative arteriogram.

Venous Injuries

Injured small veins can be ligated without sequela. Definitive repair of major veins (ie, iliac, femoral, superficial femoral, popliteal, axillary, and subclavian) should be undertaken if the patient is physiologically stable.[46] If the patient is unstable, ligation is expeditious and effective in controlling hemorrhage.[47] A damage control approach can also be used in the unstable patient by inserting a temporary intravascular shunt into the appropriately prepared vein. The shunt should first be placed into the distal end of the injured vein to confirm proximal flow in the vein and to ensure that the distal end of the shunt has not been placed into a valve cusp; the other end is then placed into the proximal vein and flow confirmed using Doppler interrogation. Lateral venorrhaphy, best performed with a running 6-0 or 7-0 Prolene suture, is possible in most venous injuries, taking care to avoid undue tension and "puckering" due to placing stitches too far apart and creating a purse-string effect. Vein patch closure or panel graft

interposition is occasionally required. In the lower extremity, major venous ligation leads to venous hypertension, which can increase the risk for compartment syndrome. Autologous vein patch angioplasty should be considered in the more extensive injuries. The vein patch must be of a generous size to maintain adequate luminal diameter. Uncommonly, stab wounds result in a transversely oriented transaction that may be primarily repaired by simple anastomosis of the cut ends without causing significant stenosis. More extensive circumferential injuries require a saphenous vein panel graft interposition. This is performed by harvesting a long segment of saphenous vein, opening it longitudinally, wrapping it around a chest tube or other appropriate large cylindrical structure, and sewing it in a spiral fashion to create a panel graft. This large-diameter graft is a suitable conduit for venous reconstruction. This technique is tedious and requires significant vascular technical ability and experience. While preparing the panel graft, a temporary shunt should be placed into the severed ends of the vein (as described earlier).

Intraoperative Assessment of Vascular Repairs

Because technical problems can occur following repair of a vessel injury, objective assessment of the repair and the distal vascular runoff bed must occur. Palpation of the distal pulses should be performed (another reason why the *whole* extremity is prepped) followed by a handheld Doppler interrogation of the repair and the vessel immediately distal to the repair. Constant high-pitched signals indicate stenosis and should prompt imaging. Intraoperative duplex scanning is useful but requires significant training and experience to perform and interpret the images. A completion arteriogram with either single-injection radiography or fluoroscopy is useful to detect platelet ("white") thrombus or stenosis at a suture line, kinking or twisting of an interposition graft, or the presence of an intimal flap, all of which may cause early failure.

Role of Tissue Coverage

Desiccation or infection of the inadequately covered vascular repair can lead to suture line disruption followed by hemorrhage. Therefore, all repairs must be covered with healthy tissue, preferably muscle. This is typically not a problem with simple stab wounds or gunshot wounds, but tissue avulsion from automobile or motorcycle crashes or debridement of devascularized tissue as a result of blast injury can compromise adequate coverage. These often require rotation of regional muscle or local advancement of skin flaps. Early involvement of a plastic surgeon facilitates planning because a pedicled transposed muscle flap, free tissue transfer, myocutaneous flap, or fasciocutaneous flap may be indicated. However, complex myocutaneous flaps and free tissue transfer are inappropriate at the initial operation because they are time consuming and can put the patient at risk for hypothermia. These are more safely performed in a delayed fashion when the patient has recovered from the initial physiologic effects of injury. Vascular repairs can be temporarily covered by either cadaver skin graft or porcine xenograft.[48] The homograft or xenograft will adhere temporarily, provide coverage, and often can stay in place for 5 to 7 days or longer. Subsequently, split-thickness skin grafting, tissue rotation, pedicle flaps, or free tissue transfer can be performed.

In extreme cases of a severely contaminated wound, extensive tissue loss, or subsequent disruption of an inadequately covered vascular repair associated with obvious distal ischemia, an extra-anatomic bypass is required. Preferably, an autologous vein bypass can be routed through adjacent healthy tissue in the extremity. Less commonly, externally supported PTFE grafts can be tunneled around the vascular injury site to supply distal perfusion as either definitive revascularization or as a temporizing step to allow healing and later placement of a vein graft through the site of injury. Examples of useful extra-anatomic bypass routes for arterial infections are femoral-femoral bypass for iliac infections and obturator bypass for infections in the groin.

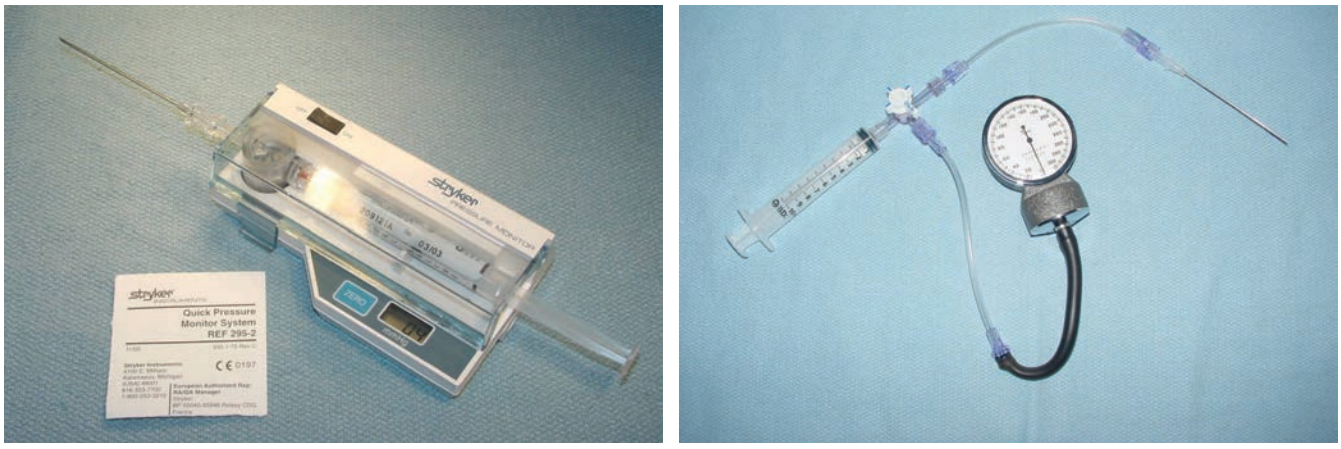
ROLE OF FASCIOTOMY

Unrecognized compartment syndrome following revascularization of an acutely ischemic limb is one of the most common causes of preventable limb loss following extremity trauma.[19] It must be remembered that compartment syndrome can be a manifestation of reperfusion injury (see the section "Pathophysiology," earlier) and may not be clinically apparent immediately after revascularization. Thus, in patients with prolonged ischemia, closed fractures, crush injury, or combined arterial and venous injury, especially if major veins have been ligated, there is a role for "preemptive" fasciotomy in which fasciotomy is performed in conjunction with the initial vascular repair.[49] In patients perceived to be at low risk for compartment syndrome (ie, no crush, no closed fracture, and revascularization in <3 hours), compartment pressure should be measured routinely in the operating room before termination of the anesthetic. A commercially available device (Stryker Surgical, Kalamazoo, MI) facilitates initial and repeat pressure measurements (Fig. 45-3A). If not available, pressure tubing on a three-way stopcock with a blood pressure cuff and monometer may be used (Fig. 45-3B). There is no consensus regarding the compartment pressure indicative of the syndrome; however, any pressure above 25 mm Hg should, at the very least, raise concern and suggest the need for repeated measurements and close observation for signs and symptoms of compartment syndrome (see the later section "Complications and Outcome").

Most trauma surgeons have experience with fasciotomy in the calf. Orthopedic surgeons more commonly perform fasciotomy in the upper arm, thigh, hand, foot, and buttocks.

Calf Fasciotomy (See Atlas Figures 80, 81, and 84)

There are four compartments in the calf to release as follows: anterior, lateral, and deep and superficial posterior



A B

FIGURE 45-3 (**A**) Stryker pressure measurement device (Stryker Surgical). (**B**) Pressure measurement device constructed of connection tubing, syringe, stopcock, and manometer from blood pressure cuff.

(Fig. 45-4). The simplest release is performed using two long incisions (double-incision fasciotomy), one each on the lateral and medial aspects of the calf. Although isolated anterior compartment syndrome occurs rarely, it is recommended to release all four compartments.

The lateral incision should be generous; it begins 2 cm anterior to the fibula and 4 cm below the fibular head to avoid the peroneal nerve and is taken distally to within 2 to 3 cm of the lateral malleolus. The fascia of both the anterior and the lateral compartments can be released through this incision. It is critical to ensure that the anterior compartment is fully released by visualizing and palpating the tibia anteriorly beneath the incised fascia. Misplacing the skin incision posterior to the interosseous membrane can lead to mistaking the lateral compartment for the anterior compartment. This results in failing to release the anterior compartment. This failure can be avoided if the tibia is palpated medially through the releasing incision (beneath the opened fascia), as described earlier, and the intramuscular septum between the anterior and lateral compartment is palpated inferiorly beneath the open fascia of the anterior compartment. If doubt exists about adequate decompression of the lateral compartment, retract the muscles of the anterior compartment and visualize the intermuscular septum separating the anterior and lateral compartment.

The medial calf incision should be made 2 to 3 cm behind the posterior margin of the tibia to avoid lacerating the greater saphenous vein. The fascia over the gastrocnemius is fully released proximally and distally. In the distal calf, the

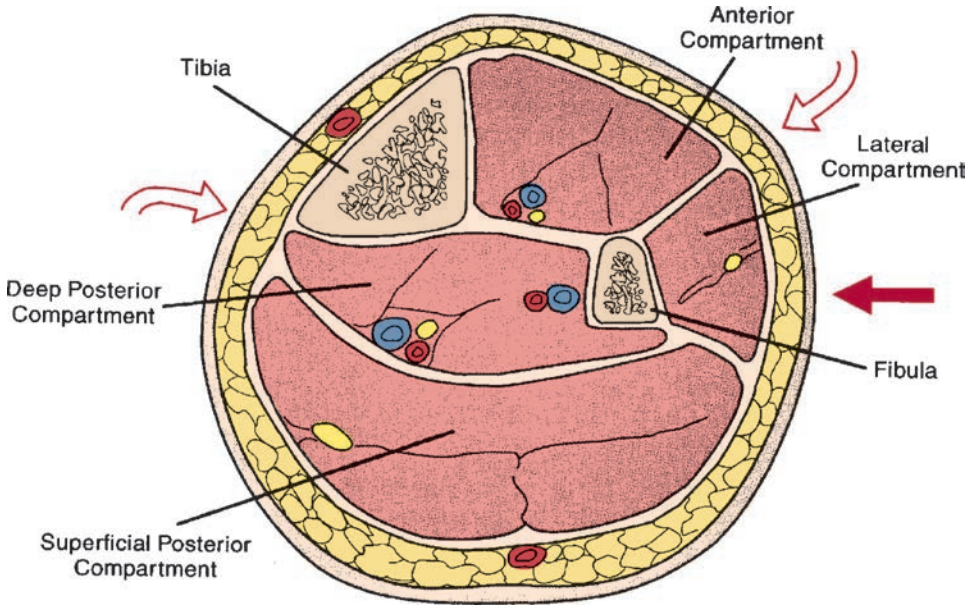


FIGURE 45-4 Cross-section of mid calf showing the four fascial compartments and their contents. Open arrows show sites of double-incision fasciotomy; closed arrow shows site of single-incision fasciotomy. (Reproduced with permission from Frykberg ER. Compartment syndrome. In: Cameron JL, ed. *Current Surgical Therapy.* 5th ed. St. Louis, MO: Mosby-Yearbook; 1995:850, Copyright © Elsevier.)

gastrocnemius and soleus muscles are then retracted posteriorly to expose the deep posterior fascia. This layer is released carefully under direct vision to avoid lacerating the posterior tibial artery.

After the four compartments are released and hemostasis is obtained, a loose dressing is applied; tight dressings will recreate the syndrome when muscle swelling occurs. Postoperatively, the extremity should remain elevated to reduce edema and facilitate wound closure, which can occur within 48 to 72 hours. Early closure can be enabled by commercially available systems (eg, negative-pressure wound therapy [KCI, Dublin, Ireland], skin stretching applications) or by applying Montgomery straps to each skin edge and daily adjusting the tension on the umbilical tapes across the wound. However, split-thickness skin grafting may be required.

Thigh Fasciotomy (See Atlas Figure 83)

Thigh compartment syndrome is less common that that of the forearm and leg. As a result, fasciotomy is only occasionally required. Nevertheless, when a closed femur fracture accompanies an arterial injury, thigh compartment syndrome deserves consideration.

There are three compartments to release: lateral, medial, and posterior, which are encased by the fascia lata. Begin with a generous lateral incision beginning at the intertrochanteric line and ending at the lateral epicondyle. After exposing the iliotibial band, it should be incised completely to release the lateral compartment. Reflect the vastus lateralis superiorly (carefully cauterizing perforating vessels) to expose the lateral intermuscular septum. Incise with a knife or scissors and extend the incision with either long Metzenbaum scissors or a fasciotome. It is worthwhile to repeat the measurement of the medial compartment pressure after release of the lateral compartment, which may be sufficient. If the pressure remains elevated, make a separate medial incision to decompress the medial compartment.

Forearm Fasciotomy (See Atlas Figure 82)

Because an intimate familiarity with the anatomy of the forearm muscles, nerves, and arteries is necessary, orthopedic surgeons or hand surgeons are often consulted to assist with decompression of the three or four forearm compartments depending on local terminology—superficial and deep volar (flexor), dorsal (extensor), and mobile wad (lateral). A dorsal incision and either a volar-ulnar or a volar-curvilinear incision are needed to decompress all compartments (Fig. 45-5). It has been demonstrated experimentally that forearm compartment pressures cannot be normalized through either of the volar approaches only.[50] Individual muscle group epimysiotomy can be undertaken for tense muscle groups, but routinely performing this does not appear to have merit. There are numerous superficial cutaneous nerves that must be carefully avoided. A thorough step-by-step description of the procedure of forearm decompression and a lucid description of the anatomy are available elsewhere.[51]

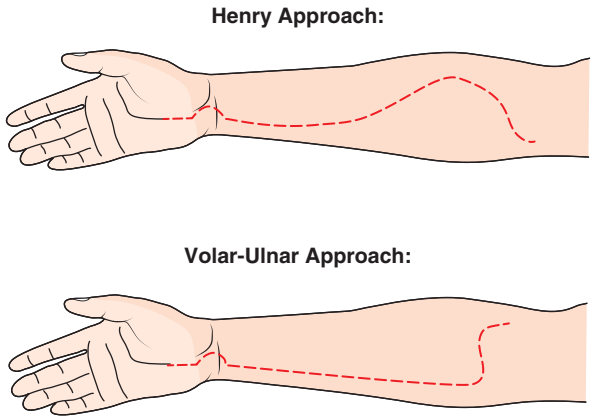

FIGURE 45-5 Curvilinear volar (Henry) and volar-ulnar incisions for decompression of a forearm volar compartment syndrome.

VASCULAR DAMAGE CONTROL

Vascular damage control is necessary when extremity vascular injury is associated with major torso injuries in an unstable patient. It involves rapid control of hemorrhage and prompt restoration of blood flow using temporary intraluminal shunts.[52,53] Fasciotomy may be part of damage control in the high-risk patient (see the earlier section "Role of Fasciotomy"). Ligation should be reserved for those arteries with adequate collateral flow. For example, in the upper extremity, injuries to either the distal radial or ulnar arteries may be treated by ligation provided there is evidence of adequate distal collateral flow assessed by either physical examination or continuous-wave Doppler interrogation. Likewise, in the lower extremity, ligation of a single tibial vessel or the peroneal can be performed following a similar assessment. If there is doubt about the adequacy of collateral circulation (eg, the patient is in profound shock), insert a temporary intraluminal shunt. Ligation of the brachial, external iliac, and superficial femoral or popliteal arteries should be avoided because ligation has a high likelihood of producing limb-threatening ischemia.

There are a variety of commercially available shunts that can be used for damage control (see Atlas Figure 72). The 10F or 12F straight carotid shunts are the most commonly used for this purpose. If these are not available, sterile intravenous tubing or endotracheal suction tubing of adequate size can be used to shunt both the artery and the vein. Venous shunt placement instead of ligation may improve extremity perfusion and lower the risk of compartment syndrome. The common femoral vein may be shunted with a pediatric chest tube.

Damage control shunt placement begins with obtaining adequate proximal and distal control. Thrombus should be cleared, as previously described, followed by the instillation of regional heparinized saline (10 U/mL). The shunt should be placed in a straight line and must be long enough to remain

safely held in place in the proximal and distal vessel with secured umbilical tapes or 2-0 silk ties. Long, looped shunts run the risk of becoming dislodged during subsequent dressing changes or procedures and should be avoided. If a patient is to be transferred to another facility, place a tie around the center of the shunt with one end of the ligature tied to the proximal and one end tied to the distal shunt ligatures that are securing the shunt in the vessel. This will ensure that the shunt is not dislodged during the transport. Securing the shunt with ligatures necessarily injures the intima at the site of their placement; those portions of the artery must be debrided at the time of definitive vascular repair. Temporary shunts have successfully been left in place ("dwell time") for greater than 48 hours. Complications of shunt thrombosis and dislodgement are low, but are likely to increase with longer dwell times.[52,53]

If there is injury to a major proximal vein of the lower extremity, it should not be ligated but should be shunted (see the section "Venous Injuries," earlier). This allows the option of repairing or ligating at a time when the patient is stable. Ligation will result in venous thrombosis, and subsequent venous repair will not be possible. However, in dire situations with a profoundly unstable patient, venous ligation may be the best option. After major lower extremity venous ligation, one should consider preemptive calf fasciotomy.

The timing of definitive vascular repair following damage control procedures is determined by the condition of the patient. Hemorrhage must be controlled and hypothermia, coagulopathy, and acidosis must be corrected prior to returning the patient to the operating room. Concern for shunt patency should not drive the decision to return to the operating room. The patency of temporary shunts used for damage control is 95%, even with protracted dwell times of up to 72 hours.[52]

COMBINED ARTERIAL AND SKELETAL EXTREMITY TRAUMA

Vascular injury complicates less than 2% of extremity fractures and dislocations, but skeletal trauma is present in 10% to 70% of patients with extremity vascular injuries.[54] In both civilian and military series, combined arterial and skeletal extremity trauma carries a substantially higher risk of limb loss than does isolated skeletal or isolated arterial injury.[19]

Successful management requires both prompt diagnosis and coordination of the efforts of both the orthopedic and vascular surgeons. Treatment priorities must be discussed; that is, should fracture fixation go before repair of arterial and venous injuries? Each case must be individualized, but concern regarding the priority of either procedure is allayed by inserting a temporary intraluminal shunt.[52] This can be done relatively quickly, and the orthopedic surgeon may then proceed with fracture fixation. Once the extremity is stabilized, the definitive vascular repair can be performed. Combined injury damage control in hemodynamically or neurologically unstable patients consists of placement of intravascular shunts, fasciotomy, and external fixation.

The Mangled Extremity

The ultimate in combination injuries of the extremity has been euphemistically termed *mangled* because it consists of severe injury to the bones, muscles, soft tissues, nerves, and vessels as a result of high-energy transfer. The amputation rate for mangled extremities remains at 20%.[55]

The grotesque appearance of these threatened limbs can be a distraction from the more severe associated injuries of the head and torso. Focus must be shifted to the initial evaluation or primary survey using ATLS guidelines (see the section "Clinical Presentation," earlier). Hemorrhage from a mangled distal extremity can be controlled with proximal tourniquet application (see the section "Preoperative Preparation," earlier). If extremity hemorrhage cannot be controlled or the patient is persistently hypotensive, proceed to the operating room where cavitary injuries can be addressed and the instrumentation and ancillary equipment necessary for extremity management are available. The complexity of this type of injury mandates collaborative evaluation with orthopedic, neurosurgical, and plastic and reconstructive surgery consultants to address management options—one of which is amputation. If skin and soft tissues are the only attachment of the mangled limb to the torso, immediate amputation is indicated.[56] A management algorithm based on the existing literature and expert opinion recommends the following general principles in the stable patient: restore anatomic alignment of fractures, perform vascular and neurologic assessments (see the section "Diagnostic Evaluation," earlier), obtain multispecialty consultation with regard to individual injury components (ie, bone, nerve, and soft tissue) in the operating room overseen by the trauma surgeon, and make a collaborative decision to attempt salvage or amputate based on that assessment.[56] If a decision cannot be made, damage control procedures should be undertaken, and a planned return to the operating room in 24 hours is scheduled. Photographs and extensive notes articulating the nature of injuries and the decision-making process are recommended at the end of the initial procedure. These are helpful for comparisons at the second operation and are useful for accurate communication with the patient and the family in the interim. The use of scoring systems to reliably predict the need for amputation has not been useful because the limb salvage rate has been consistently higher than predicted.[56]

EARLY POSTOPERATIVE MANAGEMENT

Technical problems with the vascular repair are most likely to present within the first 24 hours postoperatively. Therefore, close clinical surveillance is essential. This includes repeated pulse examination and frequent assessment of the extremity for compartment syndrome (see the later section "Compartment Syndrome"). The onset of new neurologic deficits is an important indicator of continuing ischemia and should prompt assessment of the patency of the vascular repair and the pressure within muscular compartments. Loss of a palpable pulse,

pallor replacing rubor (following ischemia, the reperfused limb should be hyperemic after rewarming), and a loss of or a change in the character of the Doppler signal (monophasic replaces triphasic or biphasic) should prompt a return to the operating room.

The use of systemic anticoagulation and antiplatelet medications in the early postoperative period is discouraged in patients with multiple injuries secondary to blunt trauma. Full anticoagulation with heparin is reserved for isolated penetrating extremity injuries with repair of small vessels.

MANAGEMENT OF VASCULAR INJURIES BY ANATOMIC REGION

The following sections provide information regarding the management of injuries to specific arteries based on their anatomic location. It is assumed that the recommendations for diagnosis and management described earlier are used since they are applicable to all regions. It is advisable to carefully review texts with detailed descriptions of the anatomy of the arteries to be discussed and the techniques used to repair them.[20]

Upper Extremity

Because of their proximity to the nerves of the upper extremity, vascular injury is frequently associated with an injury to the adjacent nerve. When combined injuries do occur, the nerve injury, rather than the vascular injury, determines the quality of the outcome in terms of function and chronic pain (see later section "Posttraumatic Pain Syndromes"). Compared to the lower extremity, the arteries of the upper extremity are less muscular, which means they must be handled with extreme care during operative repair.

SUBCLAVIAN AND AXILLARY VASCULAR INJURIES (SEE ATLAS FIGURE 69)

Subclavian injuries are the least frequent of extremity vascular injuries. The most common mechanism of injury is penetrating to either the chest, base of the neck, or shoulder; 50% of patients with a subclavian injury will be in shock. Blunt mechanisms produce contusions with intramural hematoma, laceration from shards of a fractured first rib or clavicle, or intimal disruption with thrombosis. A chest radiograph with radiopaque markers placed over any penetrating wound(s) is essential; a hemothorax, an apical cap, or an elevated hemidiaphragm (as a result of phrenic nerve injury) should arouse suspicion of a subclavian artery injury.

Exposure requires a wide prepping and draping of the ipsilateral shoulder, lower neck, chest, and arm. Proximal control on the left may require an anterolateral thoracotomy through the third intercostal space. On the right, sternotomy may be required for proximal control. Distal control may require an infraclavicular incision. The site of injury is then approached directly through a supraclavicular incision. The right subclavian is more easily approached than the left because it rises higher relative to the clavicle. An effective adjunct to proximal control in the case of a partial arterial wall laceration is the retrograde introduction of a balloon-tipped catheter through the axillary artery to the site of injury. The subclavian may then be directly approached. Surgical exposure can be difficult because of the clinically important structures closely allied with the subclavian. Division of the anterior scalene should only be done after the phrenic nerve has been identified (tracking medial to lateral across the belly of the anterior scalene) and mobilized carefully. Any direct handing of the phrenic nerve can lead to a temporary paralysis of the involved hemidiaphragm. Thus, use careful blunt dissection under the nerve and surround it with a vessel loop. If the clavicle is obstructing either the exposure or the repair, it can be divided or completely removed without sequela.[57] The subclavian artery has a thin muscular coat and it is very intolerant of heavy-handed traction, imprecise suturing, or excessive tension. The third portion of the subclavian artery (between the lateral border of the anterior scalene and the lateral border of the first rib) may be exposed by dividing the clavicle at the junction of the proximal third with the distal two-thirds and retracting it inferiorly to be reattached later or completely removed.[8]

Exposure of the axillary vessels is obtained through a transverse infraclavicular incision carried down to the pectoralis minor muscle by splitting the fibers of the pectoralis major muscle. The pectoralis minor tendon is divided at its insertion on the coracoid process; it will then retract inferiorly out of the way. The axillary artery and vein are located immediately below the muscle (Fig. 45-6). Care must be taken to avoid the cords of the brachial plexus, which are in close proximity to the axillary vessels. More distal exposure may require completely dividing the pectoralis muscle; however, this is not commonly needed.

Injuries of the subclavian and axillary vessels are rarely amenable to simple suture repair. Subclavian and axillary arterial injuries are preferentially repaired with an interposition of externally supported ("ringed") PTFE. Venous injuries may be ligated unless there is extensive soft tissue injury with disruption of collaterals. Occasionally, vein or PTFE patch repair is possible. The risk of venous hypertension is low, and ligation should be used unless the vein repair can be done expeditiously. Forearm or upper arm fasciotomy is rarely required with vascular injuries at the subclavian and axillary level. However, close follow-up is necessary.

Severe blunt trauma to the shoulder and upper extremity can cause complete disruption of the musculoskeletal support of the shoulder girdle producing what has been termed *scapulothoracic dissociation* or a *closed forequarter amputation*. A common mechanism is high-speed motorcycle crash. The diagnosis can be made from a chest radiograph that shows ipsilateral sternoclavicular dislocation and lateral displacement of the medial border of the scapula. The brachial plexus and either the subclavian or axillary artery and vein can be completely disrupted or severely stretched, producing a large hematoma and a pulseless, flaccid, and insensate upper extremity. The outcome is uniformly poor because of the neurologic injury.[58] Because of the abundant collateral circulation around the shoulder, the loss of the pulse with scapulothoracic dislocation is infrequently associated with

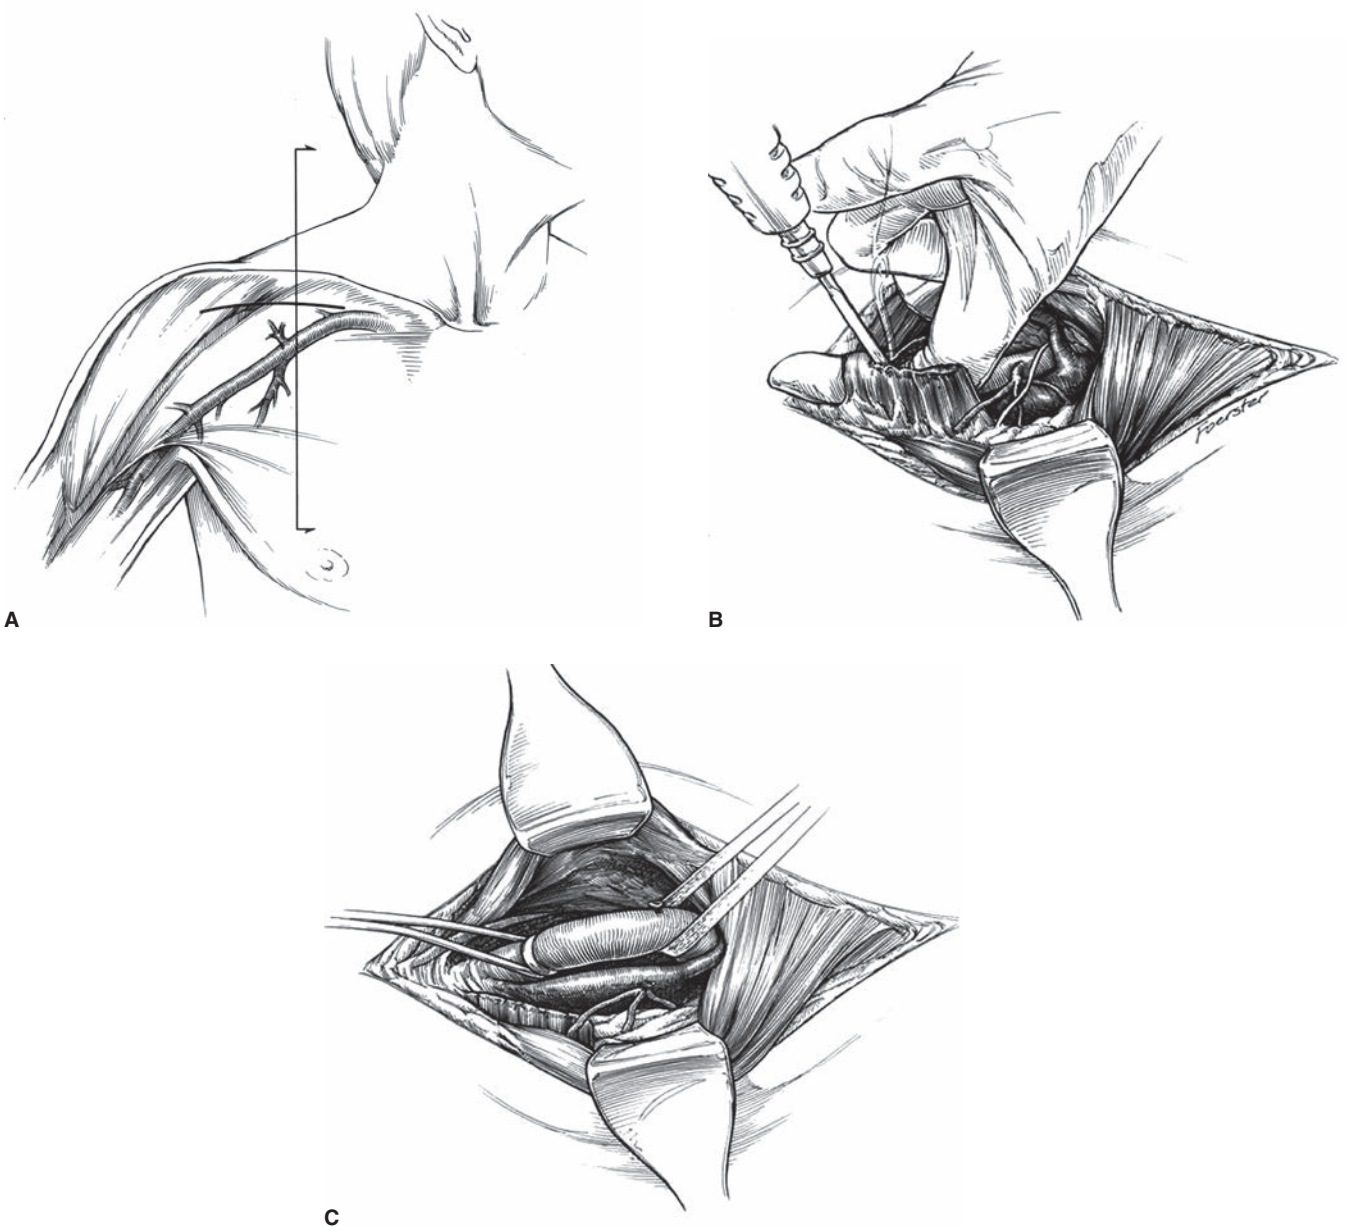

FIGURE 45-6 Approach to the axillary artery for proximal arterial control. (**A**) Location of infraclavicular incision. (**B**) Division of pectoralis minor muscle at coracoid process. (**C**) Exposure and control of axillary artery. (Reproduced, with permission, from Rutherford RB, ed. *Atlas of Vascular Surgery: Basic Techniques and Exposures.* Philadelphia, PA: WB Saunders; 1993. Copyright © Elsevier.)

limb-threatening ischemia. It may even be necessary to ligate the subclavian artery to obtain hemostasis. Recent publications have confirmed that the subclavian artery can be ligated without producing ischemia and that loss of a radial pulse following scapulothoracic dissociation has minimal risk of ischemia.[59,60] Occasionally, patients request amputation because of the burden of an insensate and paralyzed arm that is vulnerable to repeated injury and infection.

Endovascular management has been increasingly reported for axillary and subclavian injuries.[61,62] The apparent and theoretical advantages of endoluminal management include reduced morbidity and blood loss and seem particularly suited for noncompressible hemorrhage from an injury in the thoracic inlet.[61] A recent multicenter study of 223 patients with subclavian and axillary artery injuries revealed that open procedures were more common for the more severe injuries, whereas the endovascular approach was more common for pseudoaneurysms. Outcomes were equivalent with regard to limb salvage and mortality.[62]

BRACHIAL ARTERY INJURIES

Brachial artery trauma is most frequently penetrating from interpersonal violence or laceration from glass shards.

Supracondylar humerus fracture is the most commonly associated orthopedic injury.

Prepping and draping for proximal or distal injuries should include the shoulder and infraclavicular region as well as the entire arm to the fingertips; the distal arm can be draped with a sterile sleeve, which can be rolled up or cut for additional exposure or to palpate the radial pulse.

Exposure is obtained through a longitudinal incision over the course of the artery on the medial aspect of the upper arm.[20] Proximal control for high brachial artery injuries may require control of the axillary artery in the infraclavicular region. Distally, the incision can be extended with an S-shaped extension across the antecubital fossa from ulnar to radial aspect and onto the forearm to expose the origins of the forearm vessels.

Proximal control for injuries of the distal brachial artery and the forearm vessels may be temporarily obtained with a sterile pneumatic tourniquet. This adjunct, however, should be removed as soon as vessel loops or vascular clamps can be applied in order to restore collateral flow.

Simple lacerations may be treated by direct suture repair if it can be performed without tension. Saphenous vein interposition should be chosen whenever vessel injury is extensive or if primary tension-free repair is not possible. There is no role for brachial vein repair unless there is extensive soft tissue injury.

Forearm fasciotomy, particularly in the setting of prolonged ischemia, must always be considered prior at the completion of the brachial artery repair. Intraoperative compartment pressure measurements may be normal, but reperfusion edema and swelling can produce a delayed compartment syndrome. Repeated postoperative follow-up is essential to identify this delayed complication.

FOREARM ARTERIAL INJURIES

The brachial artery gives rise to the ulnar and radial arteries after crossing the antecubital fossa. The ulnar artery is larger than the radial artery in the upper arm and gives rise to the interosseous artery. Although the radial artery is more superficial and easily palpated at the wrist, the ulnar artery is the dominant blood supply to the hand in 60% of patients. Both vessels contribute to the superficial and deep palmar arches. The ulnar artery is the dominant supply to the palmar aspect of the hand, and the radial artery is the dominant supply to the dorsum. The palmar arches are incomplete in up to 30% of patients.

Prepping and draping should include the hand, wrist, and arm to the axilla. Exposure is obtained through a longitudinal incision on the volar aspect of the forearm, taking care to avoid the many cutaneous nerves in this area.[20]

Combined ulnar and radial artery injuries in the forearm require repair of at least one vessel. The larger ulnar artery in the proximal forearm is a better target for saphenous vein bypass. Distally, repair should be performed in whichever vessel is larger or less injured and more amenable to simple repair. Collateral flow should be evaluated by either completion arteriogram or Doppler interrogation, which should include the palmar arch and proper digital arteries.

Isolated ulnar or radial artery injuries can be ligated if there is absolute certainty that flow through the remaining vessel is adequate and supplies the palmar arch. Close inspection of the forearm and hand with palpation of pulses augmented by Doppler interrogation of not only the distal vessel, but also of the palm, is essential prior to ligation. Isolated forearm arterial injury may be repaired if the patient is stable and there are no other pressing management priorities.

Lower Extremity

Lower extremity vascular injuries are most commonly caused by penetrating injury. Supracondylar fractures of the femur or dislocation of the knee should be viewed with a high index of suspicion for an arterial injury. There is a role for liberal use of prophylactic compartment release following lower extremity vascular injuries when there has been prolonged ischemia.

COMMON FEMORAL VASCULAR INJURIES (SEE ATLAS FIGURES 71, 73, AND 74).

Prepping and draping should include the foot and the ipsilateral lower quadrant of the abdomen; this allows exposure of the external iliac for proximal control, if necessary (Fig. 45-7). A longitudinal incision over the common femoral vessels should be generous enough to expose the bifurcation so that both the superficial femoral and profunda femoris arteries can be controlled with encircling double-passed silastic vessel loops. Primary repair is occasionally possible, but most injuries are complex and require either a saphenous vein or PTFE interposition graft.

Femoral vein injuries require careful clamp placement for vascular control. There are numerous lateral, medial, and posterior branches that must be controlled. Vein clamping results in venous hypertension if the artery is not also occluded. Vein patch repair, saphenous vein panel interposition, or heparin-bonded, externally supported PTFE may be required. In unstable patients, venous ligation may be the best course of action. However, if there is sufficient time, shunting of the common femoral vein using a pediatric chest tube may prevent the venous hypertension associated with ligation and, with maintenance of femoral venous return, may augment cardiac filling. Calf fasciotomy should always be considered when the major veins of the lower extremity are ligated.

The profunda femoral artery is well collateralized by branches of the hypogastric (internal iliac) artery.[20] Although simple lacerations should be repaired, more extensive injuries can be ligated unless there is extensive soft tissue injury and loss of collaterals in the buttock and upper thigh. If there is a known preexisting stenosis or occlusion of the superficial femoral artery, repair of the profunda femoral artery is necessary because of its role in providing collateral flow to the leg.

SUPERFICIAL FEMORAL ARTERY AND FEMORAL VEIN INJURIES

Prepping and draping is similar to that presented for common femoral artery injuries. Exposure of the proximal superficial femoral is obtained through a longitudinal groin incision, previously described. The mid portion is located just

FIGURE 45-7 Approach to the external iliac artery in the retroperitoneum for proximal arterial control. (**A**) Location of right lower quadrant incision. (**B**) Retroperitoneal approach by retracting away peritoneum and contents. (**C**) Exposure of external iliac artery. (Reproduced, with permission, from Rutherford RB, ed. *Atlas of Vascular Surgery: Basic Techniques and Exposures.* Philadelphia, PA: WB Saunders; 1993. Copyright © Elsevier.)

behind the sartorius muscle as it travels from superior lateral to inferior medial in the thigh. The sartorius muscle can be retracted either medially or laterally to expose the superficial femoral artery and vein. The incision should be long enough to obtain both proximal and distal control. Although simple repair may be possible in some wounds, most require an interposition graft. Reversed autologous saphenous vein from the uninjured leg should be used if at all possible. The superficial femoral vein should be repaired, if possible. Consideration should always be given to calf fasciotomy in any patient with superficial femoral arterial injury and prolonged (>3 hours) occlusion and patients with ligation of the superficial femoral vein. If fasciotomy is not performed, compartment pressures should be measured before leaving the operating room and repeated frequently in the early postoperative period.

POPLITEAL AND TIBIAL ARTERY INJURIES (SEE ATLAS FIGURES 75, 77, 78, AND 79)

The popliteal artery is fixed in position at the adductor tendon proximally, the geniculate collaterals at its mid portion, and the gastrocnemius distally.[20] These points of fixation at the knee joint place the popliteal artery at risk for injury when the knee is dislocated. In full knee extension, the popliteal artery is under considerable tension. In hyperextension, it is under even more tension—as the back of the tibial plateau moves posteriorly in a dislocation, it impacts and stretches the popliteal artery, often completely disrupting it. An injury to the superficial femoral or popliteal artery occurs in less than 2% of fractures of the femur in young patients (Fig. 45-8). The popliteal vein may suffer the same fate. Because the amputation rate remains 20% to 30% following a posterior dislocation of the knee[63] and because the pulse examination may be insensitive, a CTA with three-dimensional reconstructions is reasonable for this injury.

With the patient in the supine position, prepping and draping are done from the groin to the toes. Adequate exposure requires a medial incision from the proximal popliteal space to the distal popliteal space with care not to injure the greater saphenous vein.[20] Division of the medial head of the gastrocnemius muscle and the semimembranosus and semitendinosus tendons provides a complete view of the popliteal artery and vein and the tibial nerve. This ensures adequate vascular control and the opportunity for successful repair. When closing the wound, approximation of the divided gastrocnemius muscle and semimembranosus and semitendinosus tendons with absorbable sutures will ensure an excellent functional result. Distal popliteal and proximal tibial vessel injuries are approached through a medial incision below the knee along the posterior margin of the tibia. This may be extended distally by dividing the soleus muscle over the course of the tibial-peroneal trunk and the posterior tibial vessels.[20]

Popliteal and tibial artery injuries are usually complex, and primary repair is rarely possible. Saphenous vein interposition is the best method of reconstruction. PTFE should be avoided because it has a high late failure rate when crossing the knee joint.

Empiric four-compartment calf fasciotomy should be considered when the interval of ischemia exceeds 3 to 4 hours. It should always be performed in the setting of combined popliteal arterial and venous injuries.

Some tibial vessel injuries may be ligated if there is adequate flow through the remaining vessels. Caution is advised when considering ligation of the anterior tibial artery following blunt trauma because it has been associated with a much higher rate of amputation than ligation of the peroneal or posterior tibial artery.[64] When in doubt, an intraoperative arteriogram or Doppler interrogation of the dorsalis pedis and posterior tibial arteries in the foot should be obtained. In multiple tibial vessel injuries, a saphenous vein interposition should be performed to the distal tibial vessel that best supplies the pedal arch and that can be most easily covered with healthy soft tissue.

FIGURE 45-8 Bilateral thrombosis of popliteal arteries associated with fractures of the distal femurs. Patient was trapped between wall and oncoming motor vehicle.

COMPLICATIONS AND OUTCOME

Complications following surgery for a vascular injury are those that are generic to any operation, such as a surgical site infection, and those that are parochial to the vascular repair, such as graft thrombosis, and those that may be a combination of the two, such as amputation. Each of the major complications will be discussed in that context.

Surgical Site Infection

The surgical site infection rate following interventions for extremity vascular trauma is not often reported, but some generalizations can be made. It is more common after blunt injury; of the penetrating mechanisms, it is most common after explosive injuries and shotgun wounds, both of which produce significant soft tissue trauma, moderate local contamination, and interruption of the local blood supply to the skin and subcutaneous tissue.

Preventative measures are best practice. These include preoperative broad-spectrum antibiotics with intraoperative scheduled redosing, particularly when the procedure is long (eg, combined with an orthopedic procedure) and the blood loss is substantial. Preemptive debridement of nonviable and potentially nonviable skin and soft tissue at the initial operation is paramount. For severe injuries (see the section "The Mangled Extremity," earlier), scheduled return(s) to the operating room for examination under anesthesia provides an opportunity to perform additional debridement and to assess viability of local tissues.

A surgical site infection that extends to a vascular graft or to the site of a vascular repair or anastomosis can lead to graft thrombosis or exsanguinating hemorrhage. Infection of a vascular suture line may present as a "herald bleed"—a small amount of hemorrhage from a wound considered to be stable and healing. The herald bleed abates only to be followed later with significant blood loss when the vascular repair breaks down or dehisces. Wound dehiscence or wound infection with even remote suspicion of a graft infection merits examination under anesthesia in the operating room. If the graft is not exposed and the deep layers of the wounds appear uninfected, proceed with culture of the wound, aggressive debridement of the superficial layers, wound irrigation, and packing of the open wound. After the first or second dressing change, vacuum-assisted closure can be used. In complicated wounds, a muscle flap to cover the vascular repair site is the best way to avoid infection and vessel erosion with hemorrhage. Once a repair has eroded and bled, it should be debrided back to healthy-appearing artery and ligated, the stump covered with viable tissue, and the graft replaced with an extra-anatomic bypass.

Amputation

Amputation remains the most significant of the complications following extremity vascular trauma. As has been pointed out previously, amputations of the upper extremity are less frequent, most likely because of the extensive collateral circulation around the shoulder.[20] Factors associated with limb amputation are blunt mechanism, time to reperfusion of an ischemic limb, protracted hypovolemic shock, extensive soft tissue injury (see the section "The Mangled Extremity," earlier), popliteal artery injury, failed revascularization, and unrecognized and untreated compartment syndrome (see the section "Compartment Syndrome," later).[19] Technical failures, such as a narrowed anastomosis or a twisted graft (see the section "Early Postoperative Management," earlier), can lead to amputation, but these are not common, particularly if intraoperative completion arteriography is performed (see the section "Intraoperative Assessment of Vascular Repairs," earlier).

Amputation rates during the index hospitalization can vary from 5% to 20%; higher rates are reported from military conflicts with massively destroyed limbs undergoing early amputation in theater, whereas lower rates are reported from civilian centers with mostly isolated penetrating trauma. Long-term follow-up data of patients with vascular injury are sparse, but that void is being addressed with a concurrent multicenter study.[35] The late amputation rate due to severe nerve injury producing chronic pain and allodynia is unknown.

Missile Emboli

Intravascular migration of bullets, shotgun pellets, and other foreign bodies is uncommon and occurs in less than 1% of extremity vascular injuries.[65] The most common occurrence is the migration of small-caliber shotgun pellets from the proximal extremity veins through the right side of the heart and into the pulmonary circulation. Larger bullets may enter arteries and embolize to distal vessels causing ischemia. Bullets that enter the great veins may embolize proximally to the heart or, by the force of gravity, travel in a retrograde fashion into the lower extremity veins.

Diagnosis requires a high index of suspicion and a thorough peripheral vascular examination. Entrance wounds without exit wounds or associated fragments, pellets, or bullets on radiographs of the injured limb should raise the alert that "missile" embolism may have occurred. Arterial obstruction by an offending missile embolus producing acute limb ischemia requires prompt operation for bullet retrieval. In the absence of limb threat, angiography and snare deployment under fluoroscopy can be successful for missile retrieval. A cut-down under local anesthesia at the snare introduction site is usually required to remove the retrieved bullet. Asymptomatic small-caliber shotgun pellets in the extremities are best left alone.

Compartment Syndrome (See Previous Section on Fasciotomy)

All muscle compartments in the extremities are vulnerable to intracompartmental hypertension that can eventually produce a compartment syndrome, leading to nerve and muscle necrosis. A compartment syndrome can be caused by hemorrhage from direct trauma or reperfusion following ischemia (see the section "Pathophysiology," earlier). Compartment syndrome results from swelling of muscle in a confined space (ie, bound by rigid structures, such as fascia and bone). This swelling increases the tissue pressure within the confined space or "compartment," compressing both venous and lymphatic outflow and, eventually, arteriolar inflow, further increasing tissue pressure and reducing perfusion and ultimately resulting in ischemic neuropathy and myonecrosis if not treated promptly. Compartment syndrome occurs most commonly in the muscle compartments of the lower leg. It may be life threatening because of the systemic effect of rhabdomyolysis with subsequent myoglobin-induced renal failure and hyperkalemia.

The anterior compartment of the leg is the most vulnerable. Acute complete traumatic occlusion or ligation of the popliteal vein will increase tissue pressure enough to cause compartment syndrome, particularly in the anterior compartment. The upper extremity has more extensive venous drainage and is less prone to develop compartment syndrome than the lower extremity following venous occlusion or ligation.

Compartment syndrome follows less than 10% of brachial artery injuries and is not a complication of upper extremity venous ligation unless there is extensive soft tissue injury.

Thrombosis of a Graft in an Artery

Despite meticulous techniques, some grafts fail. They fail because of problems with the inflow, the conduit, or the outflow. Intraoperative completion angiography will detect most conduit problems (eg, kinking or a 360° twist of a tunneled vein) but may miss inflow and outflow problems. For this reason, compulsive repeat examinations of the runoff bed are mandatory. A patient who had a palpable distal pulse in the cold operating room but has no palpable pulse in the warm recovery room should raise concern for a technical problem. In this case, check the patient's blood pressure; if the patient is hypotensive and has lost the pulse in the contralateral extremity, the issue is inflow and is systemic and not local. Proceed with resuscitation and investigation of the cause of hypotension. If the contralateral pulse returns with resuscitation but the ipsilateral does not, the problem is local and the patient should be returned to the operating room. If the patient did not have a pulse in the cold operating room and had a satisfactory completion arteriogram and biphasic continuous-wave Doppler signals in the runoff bed, use the Doppler and physical examination to follow the distal circulation. Often a palpable pulse will return and the previously ischemic runoff bed will be hyperemic in the normothermic patient. Postoperative vascular checks must be performed frequently. If there is any doubt about patency, the patient should be returned to the operating room for direct inspection of the repair. If there is no pulse in the graft or distal artery, catheter thrombectomy followed by completion angiography is necessary.

The most common causes of early failure are technical errors. These include intimal flaps, kinking, undue tension, and stenosis at the site of repair or anastomosis. Less commonly, platelet thrombus accumulates on a technically adequate repair. This may occur from the systemic platelet activation associated with injury. It is often associated with extensive muscle or crush injury. Less commonly, it is a manifestation of a heparin allergic reaction, which instigates the process of heparin-induced thrombocytopenia. Low-molecular-weight dextran (40,000) should be given as a 40-mL bolus and then infused at 40 mL/h for 24 hours. Once the thrombus has been removed by thrombectomy, the patient should be followed closely for recurrent occlusion and the cause of heparin-induced thrombocytopenia should be investigated.

Postoperative anticoagulation is not usually helpful in arterial repairs for vascular trauma. However, it may have a role in venous repairs and should be considered in otherwise stable patients.

Posttraumatic Pain Syndromes

The ultimate outcome from extremity vascular injury is largely determined by the associated musculoskeletal and neurologic injuries. The neuropathic or insensate extremity will severely limit functional capacity, not only of the limb, but also of the patient. Complex regional pain syndromes (I and II, previously termed *reflex sympathetic dystrophy and causalgia*, respectively) are disabling neuropathic syndromes that can occur following mild to severe injury. Patients may complain of hyperalgesia or allodynia that may become so severe that they will not touch or move the limb. If the diagnosis is suspected, a diagnostic sympathetic block should be performed. If successful (moderate to complete relief of pain), the patient should be offered a sympathectomy. The earlier this is done in the course of the disease, the more likely sympathectomy will produce long-term benefit. Undiagnosed and untreated neuropathic pain syndromes can lead to a patient-requested amputation.

Ambulatory Venous Hypertension

Late sequelae from venous injuries can be more troublesome than those of arterial injuries. Thrombosis following venous repair is not uncommon, but the vein will usually recanalize, the process of which can lead to valvular dysfunction, venous insufficiency, and ambulatory venous hypertension. If untreated, postphlebitic syndrome occurs, which can be disabling. Compressive support stockings should be given to all patients following venous repair. Because patient compliance with wearing support hose is very poor, patient education is critical in gaining their cooperation.

Pseudoaneurysm and Arteriovenous Fistula

Late development of either a pseudoaneurysm or an arteriovenous fistula is very uncommon due to improved modalities of diagnosis of arterial injury in the acute phase of care. These complications may occasionally be missed or may become apparent weeks to months after injury. For these reasons, patients who have had complex vascular repairs should be followed after discharge with duplex ultrasound. Arteriovenous fistulae and pseudoaneurysms are amenable to either open or endovascular treatment, with endovascular treatment becoming more common.

Endovascular Commentary to Chapter 45: Peripheral Vessels

Todd E. Rasmussen

Disclaimer: The viewpoints expressed are those of the authors and do not represent official positions of the University of Michigan, the United States Air Force, or the Department of Defense

It is impossible to overlook the large amount of work and level of expertise that converged in the writing of this chapter on peripheral vascular injury. Dr. Shackford did a masterful job of providing a comprehensive update on all aspects of presentation and management of extremity vascular injury as well as addressing "hot button" topics, such as who is best suited to manage this injury pattern, the greater reliance on computed tomography (CT) imaging for diagnosis, and damage control surgical approaches. Like many types of trauma, the understanding of vascular injury has been advanced from experience and study during the recent wars in Iraq and Afghanistan.[1,2] The sections of this chapter reinforce these lessons learned and make note of a number of still unsettled topics for which our understanding is evolving.

The use of catheter-based, endovascular tools for extremity vascular injury is limited, partly because of the increased use of contrast-enhanced CT angiography (CTA). For decades, traditional catheter-directed angiography has been the gold standard for the diagnosis of vascular trauma. The technique remains useful in some settings, such as the occasional "on the table" angiogram in the setting of an injured extremity. The ubiquitous presence, speed, and ability of CTA to provide a plethora of diagnostic information, however, has allowed it to replace invasive arteriography as the new de facto diagnostic standard. In this era, invasive catheter-based angiography is mostly reserved for instances in which an endovascular procedure (eg, a stent graft or coil embolization) is planned.[3,4]

Endovascular treatment of peripheral injuries is also uncommon and reserved for anatomic locations or patient scenarios in which open exposure and repair are more complicated or morbid. For example, the use of covered stents (ie, stent grafts) has been shown to be particularly useful in the management of select axillo-subclavian artery injuries.[5] In many of these situations, open exposure and repair would be associated with significant blood loss and morbidity due to a combination of incisions and/or working near the brachial plexus. Improved vascular access, imaging, and stent graft technologies now allow for many of these injuries to be crossed and repaired from a transfemoral or transbrachial (ie, retrograde) approach.[3-5]

Most peripheral injuries distal to the thoracic outlet and the inguinal ligament are best managed using open repair techniques. One exception is the use of catheter-directed coil embolization to treat traumatic extremity arteriovenous fistulae. In these cases, if the fistula is large or symptomatic and there are no other indications for an open operation,

arteriography can be performed with an eye toward coiling the inflow vessel as a means of treatment. There are also reports of the effective use of covered stents to treat popliteal artery trauma resulting from a posterior knee dislocation. Unless there are circumstances in which endovascular therapy may provide a particular advantage (ie, morbidly obese patient or need for catheter-directed thrombolytic therapy), however, open repair of this injury pattern is still advised in most cases.

Alcohol and Drugs

Grace F. Rozycki • Laura S. Johnson

KEY POINTS

- Because excessive alcohol consumption and/or opioid pain reliever abuse are frequently observed in injured patients, trauma surgeons should know the common substances abused and the interventions to help the patient.
- An estimated 16 million people in the United States have alcohol use disorder, and an estimated 623,000 of them are adolescents.
- American College of Surgeons Levels I and II trauma centers are mandated to have protocols in place to assess and screen patients who are at risk for alcohol use disorder.
- Prescription opioid overdoses and a recent surge in illicit opioid overdoses (heroin and illegally made fentanyl) are interconnected trends that have fueled America's opioid overdose epidemic.
- Most illicit drugs exert their initial reinforcing effects by activating reward circuits in the brain similar to those involved in alcohol addiction. Continued drug use impairs brain function by interfering with the capacity to exert self-control over drug-taking behaviors.
- Treatment for opioid use disorder includes the following medications: methadone, a synthetic opioid agonist that eliminates withdrawal symptoms and relieves drug cravings; buprenorphine, a partial opioid agonist that has weaker activation of opioid receptors but is well tolerated; and naltrexone, an opioid antagonist that blocks the activation of opioid receptors.
- Surgeons write 36.5% of outpatient prescriptions for opioids, and, therefore, we are uniquely positioned to effect change in the opioid crisis at the local, state, and national levels.

INTRODUCTION

The health consequences of alcohol abuse and nonmedical use of prescription opioid pain relievers are significant. Recent reports indicate that excessive alcohol consumption is responsible for 88,000 deaths annually, making alcohol use the third leading preventable cause of death in the United States. In 2016, 10,497 people died in alcohol-impaired driving crashes, accounting for 28% of all traffic-related deaths in the United States.[1]

Equally concerning is that public health authorities have noted an unprecedented increase in the morbidity and mortality associated with opioid pain relievers. Between 1999 and 2016, more than 630,000 people died from a drug overdose in the United States. In addition, in 2016, a record number (63,632) of drug overdose deaths occurred, a rate of 19.8 per 100,000 persons.[2] These alarming statistics are consistent with the dramatic rise of opioid pain reliever use over the past 15 years. Even the lay press is replete with articles and books documenting this major public health challenge.[3-5]

An integral part of substance abuse, whether alcohol or drugs, is addiction. According to the National Institute on Drug Abuse, drug addiction is a "chronic disease characterized by compulsive, or uncontrollable, drug seeking and use despite harmful consequences and changes in the brain, which can be long lasting."[6] The Centers for Disease Control and Prevention (CDC) cites that 48.5 million persons in the United States, or 18% of persons 12 years of age or older, reported the use of illicit drugs or the misuse of prescription drugs in the past year.[2]

Considering the growing number of people with substance abuse problems and/or addiction, it is likely that trauma surgeons will frequently encounter these patients in the trauma bay or intensive care unit, on the ward, and in the clinic. In order to provide the best care, the surgeon should be aware of an array of medications or substances abused, how to test for them, expected mental status changes, and, in the case of chronic use, the abnormal findings on blood tests and

imaging. Further, the surgeon should understand the need for and application of interventions and their efficacy in helping the patient. Given the magnitude of these major public health challenges, the CDC, the Substance Abuse and Mental Health Services Administration, the National Institute on Drug Abuse, and the National Institute on Alcohol Abuse and Alcoholism have devoted considerable effort to collecting and reporting data on "alcohol-related harms" and "prescription drug overdose" in an effort to better assess the problems, identify trends, and potentially provide solutions. The following sections discuss the substance disorders relative to the scope of the problem, pathophysiology, treatments, screening, and interventions.

ALCOHOL USE DISORDER

Overview of the problem

According to the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), alcohol use disorder is a "chronic relapsing brain disease characterized by an impaired ability to stop or control alcohol use despite adverse social, occupational, or health consequences."[7] The DSM-5 provides criteria for the diagnosis of alcohol use disorder and its levels of severity (Table 46-1). This classification provides some consistency to a wide range of conditions and helps clinicians with the diagnosis, treatment, and follow-up of patients.

An estimated 16 million people in the United States have alcohol use disorder, and an estimated 623,000 of these people are adolescents. According to the National Institute on Alcohol Abuse and Alcoholism, an alcohol-impaired driving fatality involves a driver or motorcycle rider with a blood alcohol concentration (BAC) of 0.08 g/dL or greater.[8] Although a good marker for acute intoxication, the BAC may vary with the patient's age, sex, race, weight, and food and drugs ingested. Hence, the metabolism of alcohol is no longer considered to be zero-order kinetics. A BAC level of 0.08 g/dL exceeds the legal limit of alcohol for driving and typically occurs after four drinks for women and five drinks for men (of average size and weight) within about a 2-hour period.[9] Mental and physical impairment increases as BAC increases, with the most severe level of intoxication being alcohol poisoning (BAC ≥0.31), a life-threatening impairment characterized by stupor, vomiting, seizures, hypoventilation, and hypothermia (Fig. 46-1).[8] Alcohol poisoning death rates vary substantially by state with a low of 5.3 per 1 million population in Alabama to 46.5 per 1 million population in Alaska. On average, six persons, mostly adult men, die from alcohol poisoning each day in the United States.[10]

Regardless of how much alcohol is consumed, a person can still experience alcohol withdrawal syndrome after abstinence. A major focus of the treatment is the prevention of

TABLE 46-1: *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Criteria for Alcohol Use Disorder[7]

In the past year, have you:

1. Drank too much or longer than intended
2. More than once tried to cut down but could not
3. Spent a lot of time drinking or getting over aftereffects
4. Wanted a drink so badly you could not think of anything else
5. Found that drinking interfered with responsibilities
6. Continued to drink even though it caused trouble with relationships
7. Gave up activities in order to drink
8. More than once were in situations while drinking that increased risk of harm
9. Continued to drink even though it made you depressed
10. Had to drink much more than you did to get the effect
11. Found that you had withdrawal symptoms when alcohol effects wore off

The presence of two or more symptoms indicates alcohol use disorder: mild = 2 to 3 symptoms, moderate = 4 to 5 symptoms, and severe = 6 or more symptoms.

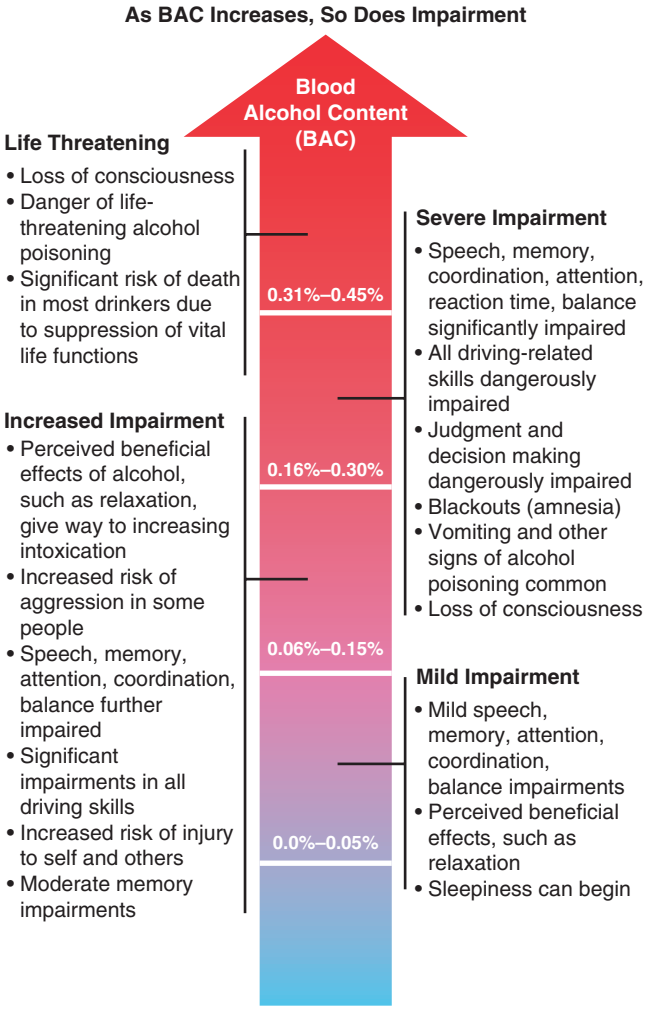

FIGURE 46-1 Signs and symptoms associated with blood alcohol concentration levels.[8] (Reproduced from National Institute on Alcohol Abuse and Alcoholism. Alcohol facts and statistics. https://www.niaaa.nih.gov/alcohol-health/overview-alcohol-consumption/alcohol-facts-and-statistics. Accessed August 21, 2018.)

TABLE 46-2: Spectrum of Alcohol Withdrawal Syndromes[18]

Minor alcohol withdrawal	Alcohol hallucinosis	Alcohol withdrawal seizures	Delirium tremens
Tremor, anxiety, nausea, headache, diaphoresis, palpitations	Visual hallucinations	Seizures	Hallucinations, disorientation, tachycardia, hypertension, fever, agitation, diaphoresis Key manifestation: rapid change in consciousness over short time
Onset within 6–36 hours of abstinence of alcohol	Onset within 12–24 hours of abstinence of alcohol	Onset within 12–48 hours of abstinence of alcohol	Onset within 48–96 hours of abstinence of alcohol

Because of the short action of ethanol, withdrawal symptoms usually begin within 8 hours after blood levels decrease, peak at about 72 hours, and are markedly reduced by days 5 to 8 of abstinence.

delirium tremens, which, if untreated, has about a 15% mortality rate. Table 46-2 lists the spectrum of alcohol withdrawal syndrome, its adverse consequences, and approximate times of onset. In addition to these alterations, recent evidence has focused on the effects of acute alcohol intoxication on coagulation (ie, impaired clot formation and inhibition of fibrinolysis). Identification of this bidirectional effect of alcohol has encouraged caution in interpreting viscoelastic testing and early recognition and treatment of alcohol withdrawal syndrome to prevent adverse coagulation outcomes.[11,12]

Pathophysiology

Understanding the pathologic changes that occur due to alcohol ingestion has relevance in the current and future treatment of alcohol use disorder. In general, alcohol is a central nervous system depressant, but various alterations in neurotransmitters are responsible for the changes that occur following alcohol absorption and during the periods of abstinence. The major neuroinhibitory transmitter of the central nervous system is γ-aminobutyric acid (GABA). Acutely, alcohol inhibits the flow of ions through *N*-methyl-D-aspartate (NMDA)-type glutamate receptors and enhances the activity of GABA receptor channels, producing an overall inhibitory effect on neurons. However, in chronic alcohol use and after abstention from alcohol, GABA receptors are downregulated, contributing to many of the symptoms of alcohol withdrawal. The activity in the glutamate neurotransmitter system, the major excitatory neurotransmitter in the central nervous system, produces many of the signs and symptoms of alcohol withdrawal syndrome. Also, chronic alcohol use increases dopaminergic transmission, which may be responsible for hallucinations.[13,14] Other pathophysiologic processes associated with alcohol abuse include oxidative stress, inflammation, acetaldehyde generation, decreased gut barrier function, impaired anabolic signaling, upregulation of catabolic processes, fibroblast activation, mitochondrial injury, and cell membrane disturbances.[15]

Treatment

The spectrum of alcohol use disorder presents challenges for treatment, as the following factors need to be considered: amount of alcohol ingested per time, chronic abuse, age of the patient, comorbidities, and a history of relapse. For example, a recent study found that age of 55 years or older and severe brain injury (Abbreviated Injury Scale ≥3) were independent predictors of the progression of alcohol withdrawal to delirium tremens.[16] The Clinical Institute Withdrawal Assessment for Alcohol, revised version (CIWA-Ar), is a 10-item scale for the assessment of patients with alcohol withdrawal syndrome.[17] Scores range from 0 to 67, and if the patient's score is less than 8, it indicates mild withdrawal symptoms that rarely require any medications. Scores from 8 to 15 are consistent with moderate withdrawal symptoms and usually respond to benzodiazepines. However, a score greater than 15 indicates severe symptoms and signs and requires that the patient be closely monitored, usually in the intensive care unit. The validity and reproducibility of CIWA-Ar are well documented, and it provides an objective way to monitor the treatment for alcohol withdrawal syndrome.[14,18,19] A key point is the avoidance of delirium tremens with its spectrum of signs and symptoms, including hyperthermia, cardiac dysrhythmias, seizures, hallucinations, and medical disorders, all of which increase the mortality rate.[18] The National Institute on Alcohol Abuse and Alcoholism and the Substance Abuse and Mental Health Services Administration jointly convened a consensus panel of experts to review current evidence on the effectiveness of medications for the treatment of alcohol use disorders. Table 46-3 provides a summary of their findings.[19] When treating alcohol use disorder, the clinician should consider the patient's past experience with medications, level of motivation of abstinence, medical status, and contraindications to the medications. Although the optimal length of treatment is unknown, guidelines for monitoring the patient are provided by the National Institute on Alcohol Abuse and Alcoholism.[19]

Special Groups

THE PREGNANT PATIENT

Simply stated, pregnant patients should not drink alcohol. Avoidance is the best plan because the consequences for the mother and her unborn child are devastating. Alcohol can disrupt fetal development at any stage during a pregnancy

TABLE 46-3: Medications for Treatment of Alcohol Use Disorder[19]

	Disulfiram	Naltrexone	Acamprosate
Frequency of administration	Daily	Daily (oral) Monthly (extended release)	Three times per day
Principal action	Deterrent to drinking alcohol as it causes severe nausea and vomiting when alcohol is ingested	Blocks opiate receptors involved in rewarding effects of drinking	Reduces symptoms of protracted abstinence by counteracting the imbalance between glutamatergic and GABAergic systems associated with chronic alcohol withdrawal
Clinical uses	Patients who are dependent on alcohol who completed alcohol withdrawal	Patients who can discontinue drinking for several days before treatment initiation	Patients who are dependent on alcohol and are abstinent at treatment initiation

and is a leading preventable cause of birth defects and neurodevelopmental abnormalities in the United States. The resulting developmental, cognitive, and behavioral problems can manifest at any time during childhood and last a lifetime. Fetal alcohol spectrum disorders include fetal alcohol syndrome (including partial fetal alcohol syndrome), alcohol-related neurodevelopmental disorder, and alcohol-related birth defects.[20]

Treatment of alcohol use disorder in the pregnant or nursing patient remains a challenge because the medications used to treat the disorder have not been shown to be safe in this population. Pregnant or nursing patients should be referred to an addiction specialist who has experience managing patients with high-risk pregnancies.[21]

OLDER ADULTS

The number of older patients with alcohol use disorder continues to rise. Han et al[22] reported that the number of adults age 50 years or older with substance use disorder is projected to double from 2.8 million (2002–2006) to 5.7 million in 2020.[22] These patients present unique challenges because they frequently have comorbidities that complicate their treatment, increase hospital length of stay, and delay placement to a rehabilitation center. Unique to this age group is the intense shame that they feel about alcohol dependence, and consequently, they will go to great lengths to hide it. Especially in this age group, alcohol dependence may be confused with other medical problems, and so it should be in the differential diagnosis of someone who presents with signs and symptoms of depression or dementia.[19]

ADOLESCENTS

The Federal Uniform Drinking Age Act of 1984 set the minimum legal drinking age to 21 years.[23] Although states follow this law, each state has some latitude on the specifics, such as allowing people younger than 21 years of age to drink with their parents present. According to the 2015 National Survey on Drug Use and Health, an estimated 623,000 adolescents (age 12–17 years) had signs and symptoms of alcohol use disorder.[24] This survey also reported that 5.1 million people age 12 to 20 years admitted to binge drinking in the past month. Underage college drinking (<21 years) is common and takes a toll on the intellectual and social lives of students. An extreme version of excessive drinking on campus occurs when fraternity members "haze" new recruits by encouraging them to consume large amounts alcohol within a short period of time. Recently, hazing has garnered increased public awareness because, in 2017, three college students died from alcohol poisoning in hazing rituals.[25,26] In addition to the tragic loss of life in this young age group, there is also an average of 60 years of potential life lost and hence a tremendous loss to society. Regardless of age, the development of serious medical problems and the consequences of alcohol-related injuries provide incentive for clinicians to assess and screen patients for alcohol abuse in the hope of reducing excessive drinking among adults.

Screening and Assessing Patients

BRIEF INTERVENTIONS

Because alcohol abuse is a significant risk factor for injury, American College of Surgeons (ACS) Level I and II trauma centers are mandated to have protocols in place to assess and screen patients who are at risk for alcohol use syndrome. These time-limited counseling strategies are designed for use in high-volume settings and focus on changing behavior and increasing treatment compliance. Gentilello et al[27] demonstrated a 50% reduction in trauma recidivism when brief alcohol interventions are used. Trauma surgeons have a unique opportunity to capitalize on the teachable moment associated with injury and, hence, implement screening and brief interventions. The screening process contains three steps: (1) identifying the target population and then screening those patients; (2) conducting the brief intervention to assess the patient's understanding of how alcohol contributed to the injury (this may be initiated by informing the patient about his or her admission BAC); and (3) offering professional advice so that the patients can set realistic goals about treatment.[28]

TABLE 46-4: Description of Screening Instruments Adapted from the American College of Surgeons Committee on Trauma Quick Guide[29-31]

	AUDIT[a]	Consumption + CAGE[b]	CRAFFT[c]
Description	10 questions	3 consumption + 4 dependence questions	6 questions about behaviors that are reliable indicators of consumption and risk
Use	Identifies: 1. Unlikely to be at risk 2. At risk; drinks excessively 3. Had problems related to alcohol 4. Likely to have alcohol dependence	Identifies: 1. Likely to be at risk of having alcohol problems 2. Likely to have alcohol dependence	Identifies adolescents likely to have alcohol or drug problems
Score	Ranges from 0–40 16–19: severe alcohol problems ≥20: alcohol dependence	Considered positive if number of drinks per week exceed recommended amount or patient answers "yes" to ≥2 CAGE questions	≥2 positive answers indicate possible problem
Advantages	Sensitive to a wide range of drinking problems Well validated	Provides information on consumption and possible dependence	Designed for adolescent screening Includes alcohol and drug screening

[a]AUDIT: Alcohol Use Disorders Identification Test.
[b]CAGE:
1. Have you ever felt that you should **C**ut down on your drinking?
2. Have people **A**nnoyed you by criticizing your drinking?
3. Have you ever felt bad or **G**uilty about your drinking?
4. Have you ever had an **E**ye-opener first thing in the morning to steady your nerves or get rid of a hangover?

[c]CRAFFT:
1. Have you ever gotten into a **C**ar driven by someone who was high or had been using alcohol or drugs?
2. Do you ever use alcohol or drugs to **R**elax or fit in?
3. Do you ever use alcohol or drugs while you are by yourself (**A**lone)?
4. Do you ever **F**orget things that you did while using alcohol or drugs?
5. Do your **F**amily or **F**riends ever tell you that you should cut down on drinking or drugs?
6. Have you ever gotten into **T**rouble while you were using alcohol or drugs?

In addition to the trauma setting, the Screening, Brief Intervention, and Referral to Treatment (SBIRT) has been shown to be effective in primary care practices, in emergency departments, and among adolescents. Table 46-4 contains a description of three commonly used screening instruments with references for more information.[29-31]

A variation in the traditional screening and brief intervention instruments is the Electronic Screening and Brief Intervention (eSBI). It is conducted using electronic devices, such as computers and mobile devices, and the advantages include the following: (1) the service may be performed across different venues including health care systems or within a community; hence, it expands the reach of the intervention; (2) the delivery of the components may be fully or partially automated, thus overcoming time constraints as a common barrier to implementation; (3) the electronic component facilitates delivery and potentially reduces costs; and (4) individuals may be more likely to participate, especially those who are reluctant to discuss alcohol problems face to face with a physician. A review of 31 investigations on the effectiveness of eSBI showed that in nearly all studies it reduced excessive alcohol consumption and related harms.[32] These studies had the limitations of self-reporting alcohol use and variations in the methods of data acquisition, but according to the Community Guide rules of evidence, eSBI was shown to be an effective screening method.[33]

SCREENING ADOLESCENTS

Because alcohol abuse among adolescents remains a public health and safety problem, the implementation of an age-appropriate screening tool for the early detection of risky behavior can be effective in decreasing alcohol-related deaths and potential years of life lost. The National Institute of Alcohol Abuse outlines a four-step process for alcohol screening and brief intervention for patients age 9 to 18 years. The process includes asking the two screening questions, guiding the patient, assessing the risk, advising the patient, and providing follow-up and support. The uniqueness of this tool is that the questions are simple and direct and that they vary slightly depending on whether the patient falls into the elementary, middle, or high school age group. Also distinctive about this screening tool is that it includes the topic of "friends' drinking," which may be a less intimidating way of approaching the topic.[34] For adolescents, brief motivational interviewing, even a single session, seems to be more successful than other types of interventions.[35] Additionally, a meta-analysis also supported the effectiveness of motivational interviewing–type interventions for adolescents who abuse alcohol or drugs, thus showing promise for this technique in clinical settings.[36] Based on the positive results of these studies, the American Academy of Pediatrics recommends that clinicians who work with children and adolescents regularly

TABLE 46-5: Biomarkers of Alcohol Exposure or Ingestion[38]

Marker	Time to return to normal limits	Type of drinking
γ-Glutamyl transferase	2–6 weeks of abstinence	70 drinks/week for several weeks (a standard drink is equal to 14.0 g or 0.6 oz of pure alcohol)
Aspartate aminotransferase	1 week	Unknown, but heavy
Alanine aminotransferase	Unknown	Unknown, but heavy
Macrocytic volume	Unknown	Unknown, but heavy
Carbohydrate-deficient transferrin	2–4 weeks of abstinence	4 drinks/day

screen for current alcohol use and employ brief intervention techniques during office visits.[37]

Biomarkers

Biomarkers are objective indicators of alcohol exposure or ingestion (Table 46-5). The most commonly known biomarker is the BAC, which is highly sensitive and specific, but only for acute alcohol ingestion. Other biomarkers, although not as specific, may reflect the presence of chronic and/or high-level use of alcohol and may be used as outcome measures to evaluate the effectiveness of medications and behavioral interventions and as evidence of abstinence.

Carbohydrate-deficient transferrin (CDT) is a newer indirect alcohol biomarker. Although the mechanism responsible for the elevation of CDT is not clearly understood, moderately heavy alcohol consumption for about 2 weeks can cause the transferrin molecule to be lacking in the carbohydrate residue in some of its terminal chains.[38] The particular advantage of CDT over γ-glutamyl transferase is that fewer factors other than alcohol use can cause its elevation.

OPIOIDS

Overview of the Problem

The facts surrounding opioid abuse are staggering. Drug overdose deaths, especially those associated with opioids, continue to increase in the United States and globally (Fig. 46-2). The number of deaths from drug overdoses continues to rise among men, women, all races, and adults of nearly all ages. Of the 62,632 deaths due to a drug overdose in 2016, 42,249 of them were due to an opioid.[2] Also in 2016, 2.14 million people age 12 and older had an opioid use disorder, including 153,000 adolescents.[39] From the same report, during the period of July 2016 to September 2017, opioid overdoses increased 30% in 45 states and 70% in the Midwestern area of the United States. On average, 115 Americans die every day

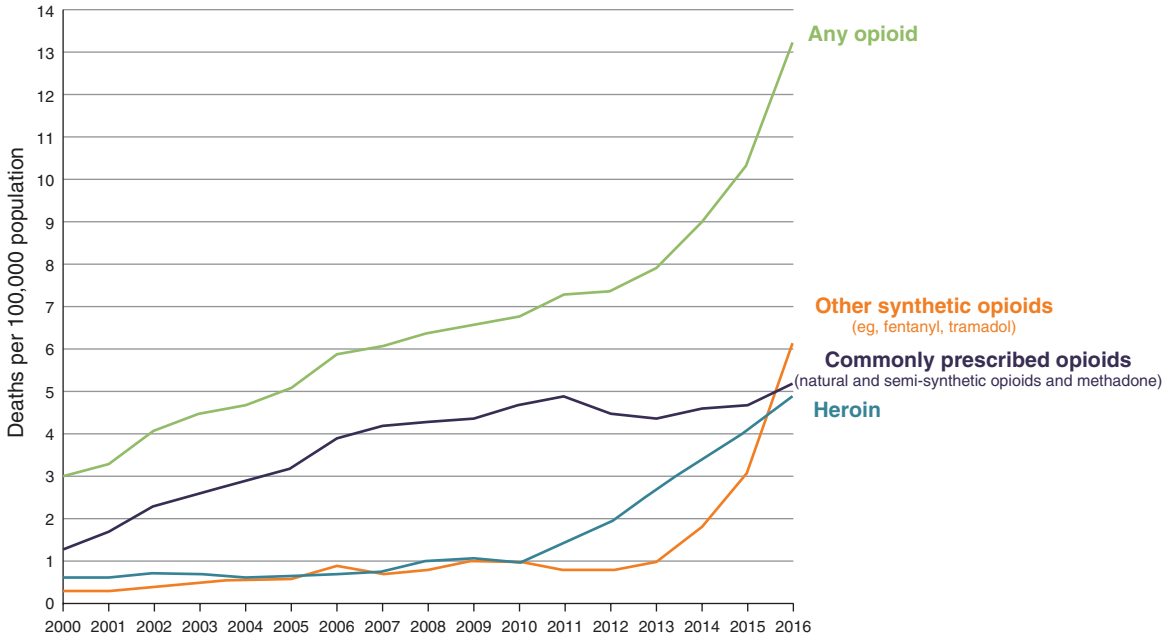

FIGURE 46-2 Overdose deaths involving opioids, by type of opioid, United States, 2000-2016. (Reproduced from the Centers for Disease Control and Prevention.[2])

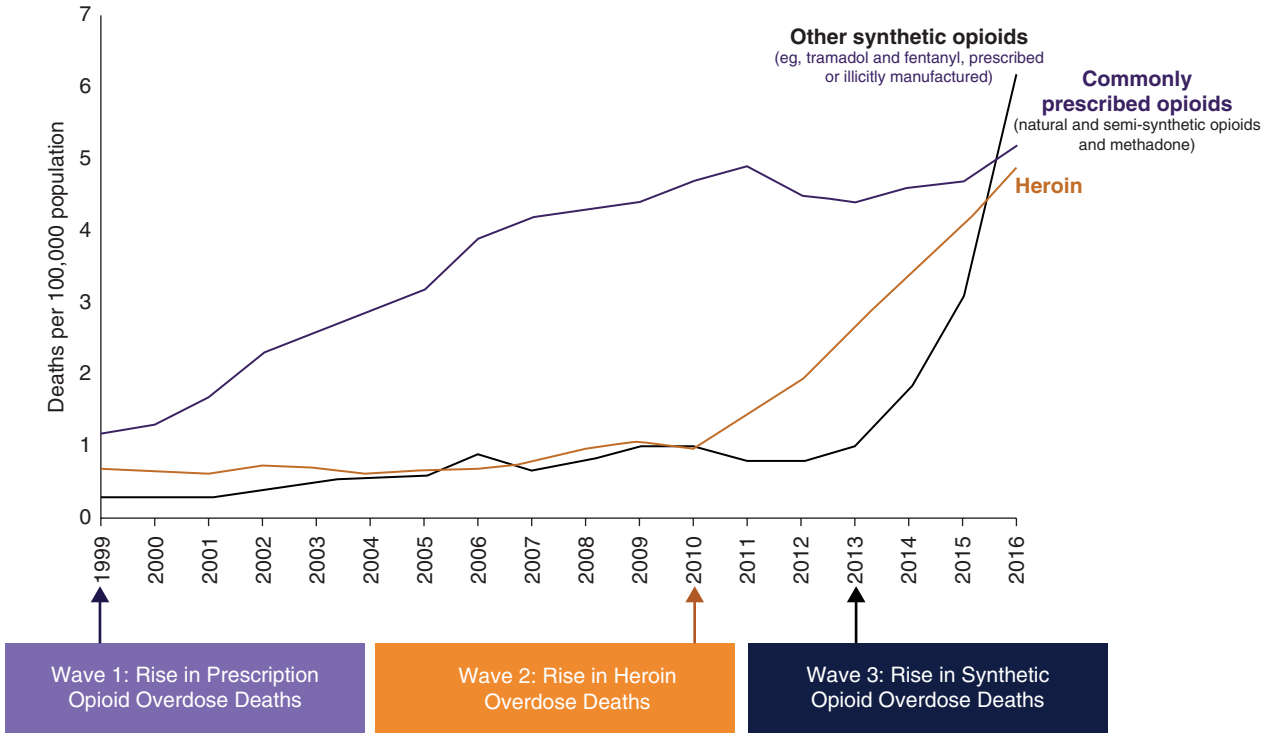

FIGURE 46-3 Three waves of the rise in opioid overdose deaths. (Reproduced from the Centers for Disease Control and Prevention.[40])

from an opioid overdose.[40] These alarming data are consistent with the terms *national crisis* and *public health emergency*.

In order to appreciate the statistics and trends documented by the CDC, it is helpful to understand the following definitions:

1. *Drug poisoning or overdose deaths* include deaths resulting from unintentional or intentional overdose of a drug, being given the wrong drug, taking a drug in error, or taking a drug inadvertently.
2. *Natural and semisynthetic opioids (prescription opioids)* include morphine, codeine, hydrocodone, and oxycodone.
3. *Synthetic opioids* other than methadone include fentanyl, fentanyl analogs, and tramadol.
4. Common *prescription opioids* include:
   - Hydrocodone (Vicodin), oxycodone (OxyContin, Percocet)
   - Oxymorphone (Opana)
   - Morphine (Kadian, Avinza)
   - Codeine
   - Fentanyl

How Did We Get Here? Milestones in the Opioid Crisis

The CDC describes the rise in opioid overdose deaths in the following three "waves": the 1990s—increased prescribing of opioids with overdose deaths involving prescription opioids; 2010—rapid increases in overdose deaths involving heroin; and 2013—significant increases in overdose deaths involving synthetic opioids, especially illicitly manufactured fentanyl (Fig. 46-3).[41] These three "waves" show that interconnected trends are driving America's opioid overdose epidemic (ie, a several-decades-long increase in deaths from prescription opioid overdoses and a recent surge in illicit opioid overdoses driven mainly by heroin and illegally made fentanyl).

In addition to these waves, it is helpful to be aware of the factors that contributed to the evolution of the opioid crisis in order to appreciate how initially good intentions about pain control led to adverse outcomes.[41]

In the mid-1800s, Civil War soldiers used opium tinctures as medicine to treat diarrhea and painful wounds. Considering the soldiers' great demand for pain medication, pharmaceutical companies began producing synthetic opioids in the late 1800s, and about that time, heroin also became available. Later, opium derivatives were recognized as addictive substances, and the United States restricted their import to medical uses only.[42] In the early 1900s, federal restrictions were placed on morphine (International Opium Convention) and, later, heroin (the Heroin Act), prohibiting the manufacturing, importation, and possession of heroin, even for medical purposes.[43] However, opium problems continued as veterans were given opioids for acute pain and many continued to use and misuse opioids after the acute crisis ended. By the 1970s, other opioids such as oxycodone and hydrocodone were developed and marketed for the relief of acute and cancer-related pain. However, a major change occurred in 1980, when a short letter entitled "Addiction Rare in Patients Treated

with Narcotics" was printed in the *New England Journal of Medicine*.[44] Citing their own results but not analyzing any data, the authors of this five-sentence letter stated that only 4 of 11,882 patients became addicted to opioids. Subsequently, this letter was cited over 600 times in support of using opioids to treat chronic pain, although no evidence supported that opinion.[44] Further support of this practice came from a paper describing the treatment of 38 patients with chronic pain who were treated with opioid pain relievers.[45] Despite the small number of patients in that study, the authors concluded that opioid pain relievers could be prescribed safely on a long-term basis. That study was also cited numerous times to support the expanded use of opioids for chronic noncancer pain. In 1995, Purdue Pharma introduced OxyContin (oxycodone hydrochloride), which was a "game changer" in that it was an extended-release formulation of oxycodone. Between 1996 and 2002, Purdue Pharma funded more than 20,000 pain-related educational programs and launched a campaign to encourage the long-term use of opioid pain relievers for chronic noncancer pain. Purdue provided financial support to organizations, and in turn, they advocated for aggressive identification of the treatment of pain, especially using opioid pain relievers. A number of physicians and pain organizations, including the World Health Organization, began advocating for more aggressive use of opioids for chronic pain.[46] Subsequently, between 1997 and 2002, prescriptions for OxyContin increased from 670,000 to 6.2 million.

Another major contributing factor to the prolific use of opioid pain relievers was the 1995 American Pain Society Presidential Address, "Pain as the Fifth Vital Sign."[47] Soon after Dr James N. Campbell delivered his Presidential Address, this concept was endorsed by the US Department of Veterans Affairs and The Joint Commission. Later, the American Academy of Pain Medicine and the American Pain Society issued a consensus statement endorsing opioid pain relievers for chronic noncancer pain. Subsequent legislation included state laws such as the Intractable Pain Act, which removed sanctions for physicians who prescribed long-term opioid therapy.[41] The other initiative that contributed to the opioid crisis was the development of the Hospital Consumer of Healthcare Providers and Systems Survey.[48] This 25-question patient satisfaction survey, endorsed by the Centers for Medicare and Medicaid Services and the Agency for Healthcare Research and Quality, incorporated three questions about pain control. That portion of the survey was intended to measure how well hospital providers managed patients with pain. Unfortunately, there was no evidence that equated the patients' perceptions with quality of care. In addition, hospitals encouraged patients to participate in this survey as full annual reimbursement was directly tied to a high score for pain management. Hence, hospital leadership ensured that the "fifth vital sign" was addressed regularly and that the patient's pain was kept to a minimum.

It should be noted that trends began to emerge regarding opioid abuse and investigations ensued. In 2007, the manufacturer of OxyContin and three senior executives pleaded guilty to federal criminal charges that they misled regulators, doctors, and patients about the risk of addiction associated with the drug.[49]

Pathophysiology

Current evidence shows that most illicit drugs exert their initial reinforcing effects by activating reward circuits in the brain similar to those described earlier in the section on alcohol addiction. Continued drug use impairs brain function by interfering with the capacity to exert self-control over drug-taking behaviors and rendering the brain more sensitive to stress and negative moods. Fig. 46-4 shows the stages of the addiction cycle (ie, binge and intoxication, withdrawal and negative effects, and preoccupation and anticipation or craving).[50]

Treatment of Opioid Use Disorder

Studies show that people with opioid use disorder who follow detoxification with complete abstinence are likely to relapse.[51] This setback is an anticipated step on the path to recovery, but it can also be life threatening. Therefore, an important way to support recovery and maintain abstinence from the addictive drug(s) is through the use of medications that reduce the negative effects of withdrawal and cravings without producing the euphoria that the original drug of abuse caused. The following are commonly used drugs to support that goal.

OPIOID AGONIST

Methadone is a synthetic *opioid agonist* that eliminates withdrawal symptoms and relieves drug cravings by acting on opioid receptors in the brain—the same receptors that other opioids such as heroin, morphine, and opioid pain medications activate. Although it occupies and activates opioid receptors, it does so more slowly, and in an opioid-dependent person, treatment doses do not produce euphoria.[52] It has been used successfully since 1947 to treat opioid use disorder. A comprehensive Cochrane review in 2009 compared methadone and psychosocial treatment to a placebo and psychosocial treatment. The authors found that methadone treatment was effective in reducing opioid use and that patients were 4.44 times more likely to stay in treatment than controls.[52] However, careful follow-up of these patients is needed because, in 2016, 3373 persons in the United States died from drug overdoses involving methadone.[2]

OPIOID PARTIAL AGONIST

Buprenorphine is a *partial opioid agonist*. Although it binds to opioid receptors, its activation of those receptors is less strong. Like methadone, it can reduce cravings and withdrawal symptoms in a person with an opioid use disorder without producing euphoria, and patients tolerate it well.[53]

OPIOID ANTAGONIST

Naltrexone is an *opioid antagonist* (ie, it works by blocking the activation of opioid receptors). Instead of controlling withdrawal and cravings, it treats opioid use disorder by preventing

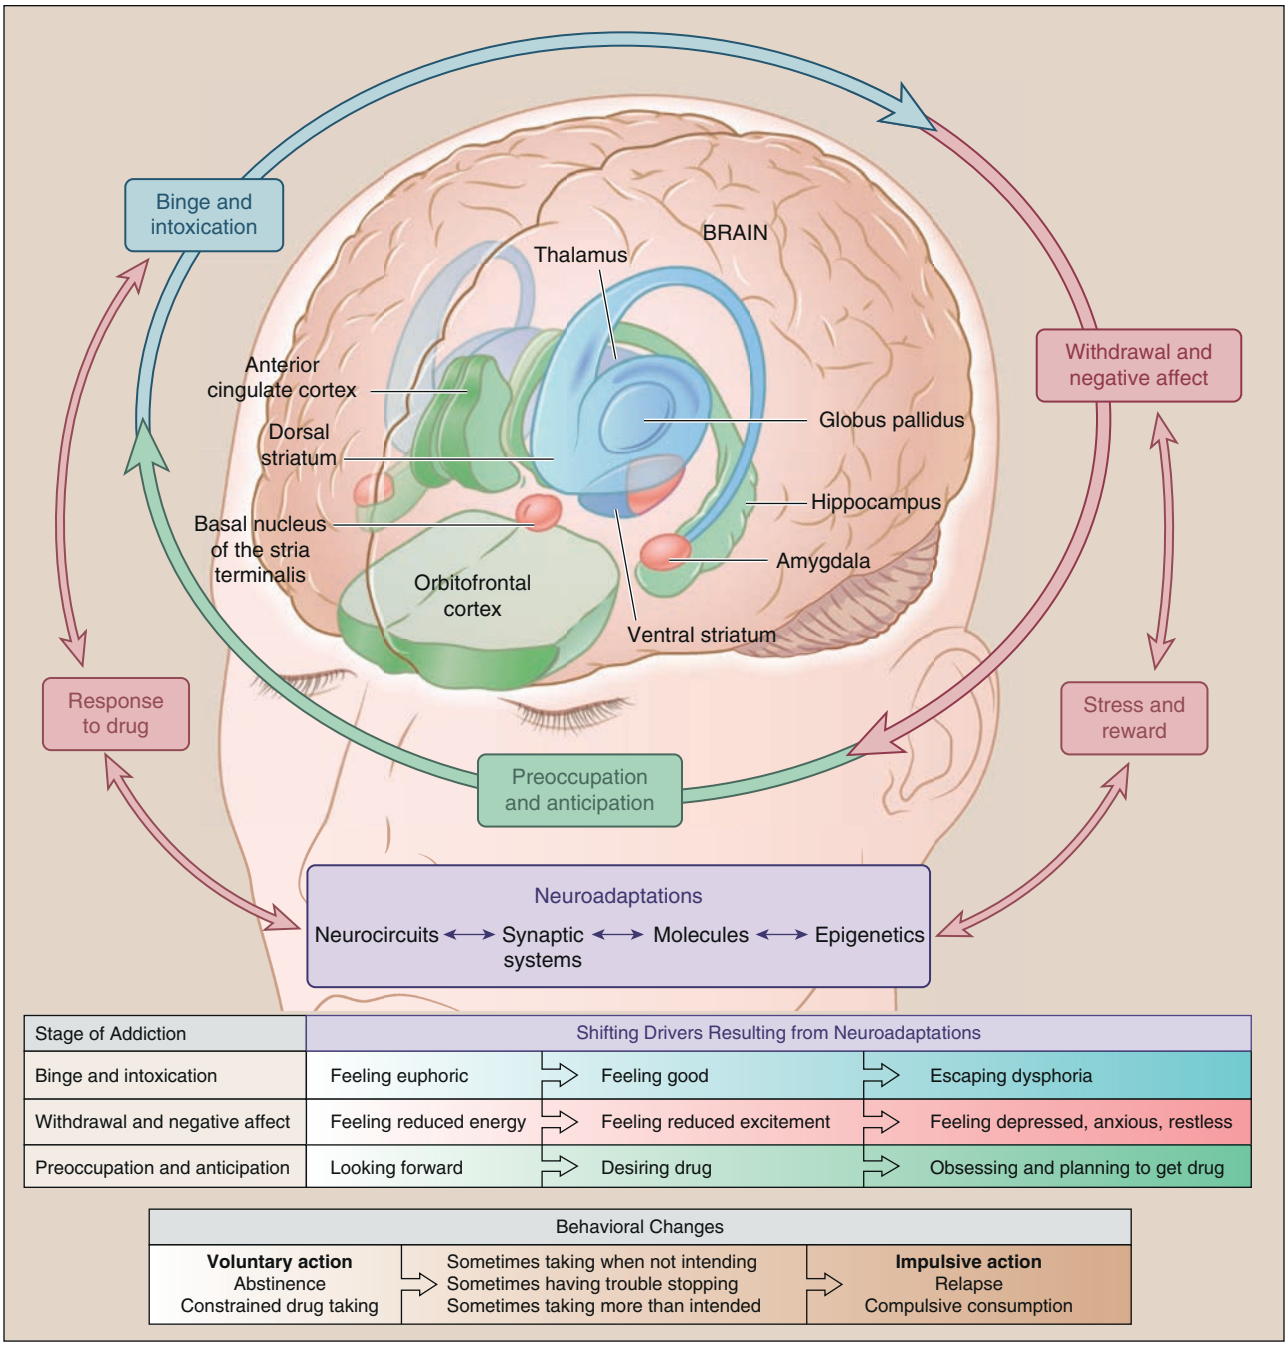

FIGURE 46-4 Stages in the addiction cycle.[50] (Reproduced with permission from Volkow ND, Koob GF, McLellan AT. Neurobiologic advances from the brain disease model of addiction. Review. *N Engl J Med.* 2016;28:374. Copyright © 2016 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

any opioid drug from producing rewarding effects such as euphoria. Its use for ongoing opioid use disorder treatment has been somewhat limited because of poor adherence and tolerability by patients. An injectable, long-acting form of naltrexone (Vivitrol) has been recommended for those who do not have ready access to health care or who struggle with taking their medications regularly. This extended-release injectable form of naltrexone has promise for treating opioid and alcohol dependence but requires full detoxification to be effective.[52]

SYNTHETIC DRUG ABUSE

A particular challenge to clinicians is the identification and treatment of patients with synthetic drug abuse. First, in the United States, it is estimated that five new synthetic drugs are introduced monthly. Second, some of the drug components are available in various forms as over-the-counter medications and thus are easily accessible to the general population. Two of the common over-the-counter drugs that are abused include

TABLE 46-6: Synthetic Illicit Drugs[54]

Type	Common names	Effects
Synthetic cannabinoids	Spice, K2	Seizures, violent behavior, cerebral emboli
Synthetic cathinone	Bath salts, Bliss, Ivory Wave, Vanilla Sky	Insomnia, seizures, tachycardia
3,4-Methylenedioxy-methamphetamine (MDMA)	Ecstasy, Molly	Hallucinations, long-lasting depression
N-Bomb	Smiles, 25i	Hallucinations, seizures, rhabdomyolysis
Ketamine	Cat Valium, Jet, Special K	Hallucinations, amnesia
N-Methylamphetamine	Meth, Ice, Glass	Violent behavior, psychosis
Methadone	Saliva, Waver, Amidone	Cerebellar edema
Fentanyl	King Ivory, Jackpot, Apache	Gait impairment, neurologic deficits
Anabolic androgenic steroids	Pumpers, Gear, Juice	Increased aggression and cognitive impairment
Methcathinone	Ephedrone, Cat, Jeff	Hypertension, tachycardia, ataxia, dysarthria
Desomorphine	Krokodil, Russian Magic	Extreme skin ulcerations, gangrene (Fig. 46-5)

dextromethorphan (contained in cough syrup, antihistamines, and decongestants) and loperamide, an antidiarrheal. Third, the internet is replete with information about how to make synthetic drugs, and they are pharmacologically similar to traditional illicit drugs, such as cocaine, methamphetamines, and marijuana. Many of the drugs are addictive stimulants, and their repeated use causes long-term or irreversible damage to the dopaminergic, adrenergic, and serotonergic pathways in the brain. Some of the severe life-threatening adverse effects include seizures and cardiac dysrhythmias. In fact, illicit drugs should be considered in the differential diagnosis of new-onset seizures.[54] Table 46-6 provides information about synthetic drugs, including their common "street" names.

COMMONLY USED ILLICIT DRUGS

The following is a discussion of some of the drugs that have been found to be associated with fatal injuries.[55] In addition to the testing challenges for illicit drugs previously mentioned in this chapter, a positive drug test could represent an inactive drug metabolite resulting from past use (ie, not proximate to the injury time).

1. As of 2018, marijuana or Δ-9-tetrahydrocannabinol (THC) has been approved for recreational use in eight states. In addition, in 30 states including the District of Columbia, laws exist that legalize THC in some form. Because its recreational use is not fully approved in all states, THC remains the most commonly used illicit drug in the United States. It is made from the dried leaves of the *Cannabis sativa* or *Cannabis indica* plant and is highly lipophilic. Because of this property, it is stored in adipose tissue, liver, muscle, and the spleen and is redistributed into the bloodstream long after ingestion. Hence, marijuana can cause highly potent mental, physical, and toxic effects that are hard to control or predict.[56,57]
2. Cocaine is a powerfully predictive stimulant made from the leaves of the coca plant native to South America. Cocaine increases dopamine in the brain and prevents its recycling. This adverse process causes a buildup of dopamine between neurons, hence inhibiting normal communication. Tachycardia, hyperthermia, and dysrhythmias are among the most serious adverse effects of cocaine. Treatment for cocaine addiction (as well as for heroin) includes those medications discussed in the opioid section.[58]
3. Heroin is an opioid drug made from morphine, a natural substance taken from the seed pod of opium poppy plants. It is highly addictive and can cause serious organ damage, especially cardiac valvular disease. From 2013 to 2014, there were 10,574 heroin-related deaths, a 26% increase. Of note, the strongest risk factor for heroin addiction is opioid abuse.[59]
4. Hallucinogens are a very diverse category of drugs. Common hallucinogens include ayahuasca (hoasca, aya, dimitri), dimethyltryptamine (DMT), D-lysergic acid diethylamide (LSD), peyote (mescaline), 4-phosphoryloxy-*N,N*-dimethyltryptamine (psilocybin), and phencyclidine (PCP). Many of these substances have a wide variety of mind-altering effects including paranoia and psychosis. There is no specific medication to treat addictions to hallucinogens, and so treatment currently relies on behavioral and supportive methods.[60]

FIGURE 46-5 Hand with gangrenous changes secondary to Krokodil injections. (Reproduced with permission from Alves E, Grund J, Afonso C, et al. The harmful chemistry behind krokodil (desomorphine) synthesis and mechanisms of toxicity. *Forensic Sci Int.* 2015;249:207-213.)

DRUG AND ALCOHOL CRASH RISK

Driving under the influence of drugs is dangerous as side effects include slowed reaction time, impaired judgment, decreased coordination, drowsiness, and even hyperactivity. Any of these impairments can lead to reckless driving, automobile crashes, and/or injury to a pedestrian. According to the 2016 National Survey on Drug Use and Health, 11.8 million people admitted to driving under the influence of drugs.[61] Unlike BAC, there is no universal or single test for illicit drugs because they often contain multiple preparations and may be taken via several routes (intravenous, oral, inhalation) over different periods of time. Hence, the metabolism of these drugs may involve several organs and different kinetic orders. The National Highway Traffic Safety Administration conducted a study on the crash risk of alcohol-positive, drug-positive, and alcohol-plus-drug-positive drivers using a case-control design.[62] Drugs included over-the-counter, prescription, and illegal products. The study used data from crash-involved and non–crash-involved drivers from Virginia Beach, Virginia, over a 20-month period. They found that drivers who drank alcohol were 2.07 times more likely to crash than drivers who drank no alcohol. The drug odds ratios were adjusted for sex, age, race/ethnicity, and BAC, but the presence of drugs did not increase the risk of a crash. A potential explanation for this finding is that some drugs have a long half-life, and although the patient may test positive for the drug, the drug effects have long dissipated. Another study conducted in nine European Union countries showed the highest crash risk was for drivers with high alcohol concentrations, and those positive for marijuana were estimated to be at an elevated risk.[63] Similar results were noted from a study using the Fatality Analysis Reporting System in which the investigators found that during the period 1999 to 2010, the proportion of fatally injured drivers testing positive for narcotics and THC had tripled.[55] These studies and others suggest that driving under the influence of drugs and alcohol is a growing concern and a substantial cause of motor vehicle fatalities.

WHAT IS BEING DONE AND WHAT CAN WE DO?

According to a study examining opioid prescriptions by specialty, surgeons write 36.5% of outpatient prescriptions for opioids.[64] Hence, surgeons are uniquely positioned to effect change in the opioid crisis at the local, state, and national level (Table 46-7). A good starting point for surgeons is to

TABLE 46-7: What Is Being Done and What Can Be Done

Federal government	States	Health insurers	Health providers	Patients
Educating about pain management, addiction, overdose, and providing guidance on safe pain management	Implementing prescription drug monitoring programs	Reviewing programs to address improper prescribing and use of opioids	Using opioids only when benefits are likely to outweigh risks	Considering nonopioid options for pain management
Equipping states with resources to implement and evaluate safe prescribing practices	Implementing and evaluating programs to improve prescribing practices	Increasing coverage for treatments to reduce pain, especially nonopioid pain medicines	Starting with the lowest effective dose of immediate-release opioids	Storing prescription opioids in a secure place
Improving access to addiction treatment and recovery services	Using data to identify and address high-risk prescribing	Covering clinicians' time when they are conducting activities that improve quality and safety of pain management and addressing addiction	Reassessing benefits and risks when considering dose increases for opioids	Disposing of medications properly
Increasing access to overdose-reversing drugs	Enhancing the use of best practices for prescribing	Reducing barriers (eg, prior authorization) to the use of nonopioid pain relievers	Prescribing only the number of days that acute pain is expected to be severe enough to require opioids	Participating in local hospital and community efforts to address the opioid crisis
Tracking opioid-related trends and supporting research on pain management and addiction	Increasing access to medication-assisted treatment	Working closely with hospital systems to develop data bases to track high-risk patients	Using state-based prescription drug monitoring program to identify patients at risk of addiction or overdose	Getting help Substance Abuse and Mental Health Services Administration Helpline: 800-662-HELP (4357)[74]

become familiar with their local hospital and state initiatives. For example, health care executives are assembling teams to develop best practices for their institutions and then collaborating with other hospitals within their regions to ensure that patients do not go from one hospital to another in search of opioids. The physicians at Gundersen Health System have been taking steps toward decreasing opioid abuse for over 10 years. A pain medicine specialist ensured that Gundersen physicians understood the nuances of treating patients with chronic pain, and they implemented guidelines for prescribing narcotics. They formed a committee to address these issues, and much of their success is based on a continuous reassessment of progress as medication standards and patient populations change.[65] In addition to health care providers and hospital leaders strategizing about how to tackle the opioid crisis, the patient needs to be an integral part of the process. Gundersen Health System includes all stakeholders, including the patient, as members of its Chronic Pain Committee. The inclusion of the patient was also helpful in developing their Chronic Pain Registry. Another way that surgeons can contribute to diminishing the opioid problem is to set prescription guidelines for postoperative pain. Orthopedic surgeons at the Mayo Clinic developed opioid prescription guidelines for patients undergoing several common orthopedic procedures. The researchers compared the well-matched groups in the preguideline (1822 patients) and postguideline (751 patients) periods. They found that the median prescription dropped from about 95 pills of 5-mg oxycodone to approximately 50 pills, an overall 48% decrease.[66]

The CDC has published recommendations for prescribing opioids for chronic pain outside of active cancer, palliative, and end-of-life care (Table 46-8). Many of the best practices at hospitals are based on these guidelines, and the reader is referred to the CDC website for the complete publication.[67] Some of these guidelines are supported from studies on the use of opioid pain relievers prescribed for postoperative pain. For example, Waljee et al[68] reviewed the opioid prescriptions given to 296,452 adults who underwent common upper extremity surgical procedures. They found that patients who previously received opioids were more likely to fill a postoperative opioid prescription and renew prescriptions more often.[68] Another study, conducted among the acute care hospitals in Ontario, Canada, found that taking benzodiazepines preoperatively was a risk factor for the prolonged use of opioid pain relievers.[69]

Suggestions made by the ACS include the following: (1) promote the use of prescription drug monitoring programs; (2) encourage research and training developed in collaboration with specialists in pain management for safe prescribing; (3) recognize and address issues specific to veterans; (4) change the direct relationship between provider reimbursement and patient pain control; and (5) support patient safety legislation.[70] Additionally, the ACS published an educational tool for patients regarding opioids so that the patient can understand the importance of his or her role in this addiction crisis.[71] Table 46-9 offers suggestions for multimodal pain management. Other leading organizations, such as the US Food and Drug Administration (the agency that ensures that drugs used by the US public are safe), published

TABLE 46-8: Centers for Disease Control and Prevention Recommendations for Prescribing Opioids for Chronic Pain Outside of Active Cancer and Palliative and End-of-Life Care[65]

1. Prescribe nonpharmacologic and nonopioid therapy for chronic pain.
2. Establish treatment goals with the patient.
3. Discuss with the patients the risks and realistic benefits of opioids.
4. Prescribe immediate-release opioids, not extended-release.
5. Initially prescribe the lowest effective dose.
6. Prescribe as per the expected duration of pain.
7. Evaluate benefits and harms regularly.
8. Evaluate continuation of therapy at appropriate intervals.
9. Review patient's history of controlled substance prescriptions.
10. When prescribing opioids for chronic pain, consider urine drug testing annually.
11. Avoid prescribing opioids and benzodiazepines concurrently.
12. Offer evidence-based therapy for patients with opioid use disorder.

TABLE 46-9: Multimodal Pain Management[75,76]

Preoperative	Intraoperative or after injury	Postoperative or after injury
Appropriate goal setting to target "functional" and not "pain free"	Regional anesthesia	Targeted opioid utilization
Identification of high-risk individuals	Neuraxial anesthesia	Continuous regional nerve blocks
		Nonnarcotic pain management strategies: Gabapentinoids Acetaminophen NSAIDs
		Early rehabilitation
		Cognitive therapy for pain management (guided imagery, relaxation techniques, music therapy)
		Management of psychological disease impact on pain manifestation

NSAIDs, nonsteroidal anti-inflammatory drugs.

a special report outlining their plans to deal with this opioid misuse crisis.[72] All of these initiatives presented convincing evidence that legislative efforts are needed to counter the addiction crisis. An example is H.R. 6, the Substance Use-Disorder Prevention That Promotes Opioid Recovery and Treatment for Patients and Communities Act, passed on June 22, 2018, with substantial bipartisan support. This legislation will help to advance treatment and recovery initiatives, improve prevention, protect communities, and bolster efforts to curb the production of deadly illicit synthetic drugs.

Finally, there is some relatively good news to report. From 2012 to 2017, the overall national opioid prescribing rate declined. In 2017, this rate was the lowest it had been in 10 years, at 58.7 prescriptions per 100 persons, about 191 million total opioid prescriptions. Overall, these numbers are still too high, and some counties had rates that were seven times higher than the overall average, indicating that progress is being made but there is still much work to be done.[73]

SUMMARY

The growing number of people with substance abuse problems and/or addiction qualifies as a national crisis and a major public health problem. Trauma surgeons will frequently encounter these patients in a variety of settings and are uniquely positioned to achieve a positive change toward this crisis. Early screening, assessment, and treatment are important steps in the treatment of alcohol use disorder and the prevention of the high mortality disease, delirium tremens. Underage drinking requires special tactics relative to screening and treatment, especially since years of potential life lost are greatest in this group. Deaths due to drug overdoses continue to rise, and multifaceted strategies such as prescription drug monitoring programs, prescription guidelines, pharmaceutical treatments, counseling, legislative efforts, and patient engagement are essential components of the resolution. Clinical outcomes and basic science research are also necessary components of the solution. The surgeon's responsibility includes becoming aware of the resources on substance abuse and minimizing the patient's pain while addressing the imperative to avoid improper prescribing.

Social Violence

Amy M. Kwok • James W. Davis

KEY POINTS

- The Centers for Disease Control and Prevention estimate that 12.7 million women and men have been affected by intimate partner violence.
- The World Health Organization reported that 35% of woman worldwide have experienced physical or sexual violence.
- The HITS (Hurt, Insult, Threaten, Scream) questionnaire has been validated for screening for intimate partner violence.
- Older people with cognitive impairments, physical disabilities, or mental health problems are at higher risk for elder abuse.
- Fractures in places besides the hip, vertebrae, or wrists and spiral fractures are suspicious for elder abuse.
- The Elder Abuse Suspicion Index is a six-question screening tool validated in the ambulatory care setting.
- The United States has the highest rate of youth homicides out of all the industrialized nations.
- A gun in the home is associated with a 40-fold greater chance of killing a family member or acquaintance.
- Individuals who participate in gangs are more likely to be involved in fights, take weapons to school, and use drugs or alcohol at school.

INTRODUCTION

Trauma care is, by definition, tertiary prevention or treatment. Understanding the root causes of the injury may aid in better comprehension and treatment of the trauma victim. Improvements in trauma care should incorporate consideration of the psychosocial aspects of such injuries as well as the impact on the larger health care system.

Patients who are victims of family and community violence may have relatively simple traumatic injuries but often have complex psychosocial issues that affect their response to injury. Simply treating the injuries and not intervening with the underlying causes makes recidivism of these patients the likely end result. Early detection and efforts at prevention of interpersonal violence must be part of the trauma center's prevention program.

Violence may be defined as "the intentional use of physical force against another person or against oneself, which results in or has a high likelihood of resulting in injury or death."[1] Its frequency is documented by the following facts:

- Suicides and homicides are the second and third leading causes of death among children and youth under the age of 21.[2]
- Overall, injury and violence remain the leading cause of death for persons age 1 to 44.[2]
- One person dies every 4 minutes as a result of intentional injury.[3]
- Intimate partner violence is the most common cause of injury to women in the United States, causing nearly 2 million injuries a year.[4-7]

The literature is replete with studies identifying risk factors for interpersonal violence.[2,8-10] Despite this potential knowledge base, physicians are often hesitant to use this information.[11-13] Early recognition and intervention may prevent future incidents and decrease rates of complications such as posttraumatic stress disorder.[13-15] The statistics on death and injury from intentional violence are only the tip of the iceberg. The cost to society of violent behavior also includes the price of legal battles, incarceration, and the economic effects on the health care system as a whole, as well as the psychological stress to victims and the families of victims.[3,4]

The purpose of this chapter is to provide practicing surgeons with some basic information on intentional violence with a focus on intimate partner and community violence, so that they may be better providers of care for these patients with special needs.

INTIMATE PARTNER VIOLENCE

Intimate partner violence (IPV), also known as domestic violence, refers to those acts of interpersonal violence resulting in physical or psychological injury to members of the same family or household or to intimate acquaintances in heterosexual or same-sex relationships. According to the Centers for Disease Control and Prevention (CDC), IPV constitutes physical, emotional, or psychological harm in the form of physical or sexual violence, stalking, and/or psychological aggression.[2] Other reports have acknowledged that child[16,17] and elder abuse may also be included in the spectrum of domestic violence.[18] IPV and elder abuse will be covered here, and child abuse will be addressed in the chapter on pediatric trauma.

IPV is not new; it has long plagued mankind. A 15th-century scholar argued that a man should beat his wife "not in rage but out of charity and concern for her soul."[19] English Common Law established "the Rule of Thumb" in 1895, stating that a husband could not beat his wife with a switch greater in diameter than the width of his thumb.[20] The legal right of men to beat their wives was not abolished until 1871 in the United States.[21] Until the 1970s, assaults on wives were considered misdemeanors, when an equal assault against a stranger would have been considered a felony.[22] In 1992, it became a requirement of The Joint Commission that all accredited hospitals have policies and procedures in their emergency departments and ambulatory care facilities for identifying, treating, and referring victims of abuse.[22]

Public awareness campaigns such as No More (nomore.org) have heightened awareness on this issue. Multiple medical professional organizations recognize IPV as a public health problem not limited to specialties. The responsibility resides with all the treating physicians and surgeons to diagnose and aid in providing resources to the victim.[23-25]

Incidence and Prevalence

The actual incidence of IPV is unknown because definitions and estimates vary widely. However, the estimated statistics are alarming. Currently, the CDC estimates more than 12.7 million women and men have been affected by IPV.[26] IPV affects 24 people every minute.[26]

The National Intimate Partner and Sexual Violence Survey from the CDC and National Institute of Justice and Department of Defense estimates that more than 27% of women and 11% of men in the United States experienced physical violence, rape, and/or stalking by an intimate partner in their lifetime. The rates of IPV were highest for persons age 18 to 24 years.[27] Women are more likely to experience rape, stalking, and physical violence, whereas men are more likely to experience physical violence alone.[28] Nearly 1 in 5 women (19.3%) and 1 in 59 men (1.7%) have been raped in the United States.[26] In addition, 51.5% of female rape victims reported being raped by their intimate partner.[28]

These rates are similar to those reported by the World Health Organization (WHO). They found worldwide that 35% of women have experienced physical or sexual violence, with 30% involving IPV.[29] In effect, one out of three women around the world has been beaten, coerced into sex, or otherwise abused during her lifetime.[30]

One report from the National Institute of Justice and the CDC estimated that 1.5 million women are physically assaulted or raped by an intimate partner in the United States annually.[31] The National Violence Against Women Survey also estimated that 5.3 million IPV incidents against women occur annually, with more than 550,000 requiring medical attention, loss of 8 million days of paid work, and loss of 5.6 million days of household productivity.[24] The estimated cost of this violence is more than $8.3 billion.[32,33]

The incidence of IPV in the lesbian, gay, bisexual, transgender, and queer (LGBTQ) community is significantly understudied. However, prevalence rates are estimated to be similar or even higher than in the heterosexual community. The CDC found that LGBTQ persons experienced higher rates of IPV, with a 61% lifetime prevalence in bisexual women compared to 44% of lesbian and 35% of heterosexual women. IPV rates were lower in men when compared to women but still affected 37% of bisexual men, 26% of gay men, and 29% of heterosexual men. Gay and bisexual men also had higher rates of IPV than heterosexual men, with 25% of gay men and 37% of bisexual men experiencing some form of IPV, including rape, physical violence, and/or stalking.[34] Rates of sexual violence were higher in the LGBTQ community compared to heterosexual men and women. Almost half of bisexual men (47%) and 40% of gay men have been victims of sexual violence, compared to 21% of heterosexual men. Bisexual survivors are more likely to experience physical and sexual violence, whereas transgender victims are more likely to experience physical violence. Gay men were more likely to experience IPV in the forms of intimidation and harassment, and the homicide rate is highest among gay men (76.2%) in the LGBTQ community.[34,35]

The *cumulative lifetime prevalence* of domestic violence of women seen in the emergency department is 40% to 60%, and 12% to 25% of visits by women to the emergency department are from domestic violence.[31,36] IPV is responsible for 30% of trauma center admissions for women.[37] Severe physical violence is experienced by 24.3% of women by an intimate partner, including being slammed against something or assaulted with fists or hard objects.[28]

A WHO multicountry study and US studies on domestic violence found that those who reported IPV had a wide range of physical problems, were twice as likely to experience depression and alcohol abuse, and had a 4.5-fold increased risk of suicide attempts.[29,38] In some regions, women were 1.5 times more likely to acquire HIV.[29,30]

Victims are more likely to have long-term health and mental problems such as depression, posttraumatic stress disorder, and drug and alcohol abuse than nonvictims.[24,26] Physical abuse occurs as well in 7% to 20% of pregnancies. IPV continues to be a significant risk factor for violence in pregnant patients, specifically adolescent pregnant patients.[39,40]

In the United States, 17% of all homicides involved IPV. Of these cases, 77% of the victims were female, and 62% of

the female homicide victims were murdered by their intimate partner.[41,42] This averages to four to five women murdered every day by their partner.[43] The Violence Policy Center found that of all murder–suicides, 72% of cases involved an intimate partner and 94% of the victims were female.[41] Worldwide, 38.6% of female homicides were committed by an intimate partner.[38] The majority of female homicides (52%) are committed with guns.[42]

Women are 3.6 times more likely to be shot by a spouse or ex–significant other than by a stranger.[44] Women are six times more likely to be killed if a gun is in the house in IPV homicides.[42] In addition, marital violence is a significant predictor of physical child abuse. In one study, the probability of child battering increased from 5% with one act of marital violence to near certainty with 50 or more acts of wife battering.[45]

Child battering occurs in 59% of the homes with spousal abuse and may be as high as 77% with severe wife abuse.[46,47] The victim is frequently demoralized and is so lacking in self-esteem that it is difficult to leave the situation.[48] Additionally, the threats of retaliation, injury to children or pets, and death increase the victim's fears and helplessness. Indeed, the risk of physical violence actually increases after moving out.[49]

Identifying Intimate Partner Violence

A three-phase cycle has been described for battering. The first phase involves a gradual buildup of tension and then escalation with name calling, intimidation, and mild physical abuse. The second phase involves an uncontrollable discharge, with verbal and physical attack and frequently injury. In the third phase, the abuser apologizes and asks for forgiveness and promises that it will not recur. With repeated cycles, the first phase increases in length, the violence may become more acute, and the third phase decreases. Again, the victim is frequently demoralized and is so lacking in self-esteem that it is difficult to leave the situation.[48]

The second cycle for victims of domestic violence involves the failure to make the diagnosis even after the patient arrives in the emergency department. In a study of battered victims presenting to the emergency department, 23% had presented 6 to 10 times previously and 20% had 11 prior emergency department visits.[50] In 40% of cases with known domestic violence, physicians made no response at all, and in 92% of cases, physicians made no referral for the abuse.[51] Victims of domestic violence view physicians as least effective in helping them compared to women's shelters, social services, clergy, police, and lawyers.[51]

There are some characteristics of injury type and location in domestic violence. Injuries tend to be central (face, head, neck, breast, and abdomen) versus the more peripheral injuries seen in accidents. In one study of injury locations, the head, face, and neck were significantly more frequently injured in victims of domestic violence than in accident victims (P <.001), and an unwitnessed injury is a significant marker for IPV.[52,53]

Because victims of IPV may be fearful or ashamed, nontraumatic complaints predominate as reasons for the physician visit. In one study, 78.4% of IPV victims had medical complaints and 72% were never identified as victims of abuse.[54] Even after a violent episode, only 23% had injury-related complaints. Domestic violence victims rarely volunteer information; after battering, only 13% of victims either told staff or were asked about the possibility of abuse.[55] However, domestic violence victims were not offended when asked about abuse in a nonjudgmental manner.[56] Further, the failure of health care providers to ask about domestic violence may be perceived as evidence of a lack of concern and add to feelings of entrapment and helplessness.[57]

In 2015, a Cochrane review found that routine screening increased identification of women experiencing IPV by nearly threefold.[58] Joseph et al[59] found the prevalence of IPV to be 5.7 cases per 1000 trauma center discharges, with an overall mortality of 6%. He concluded that a mandatory IPV screening should be done in all trauma patients and that a national intervention focus is a necessity.[59] The use of a specific screening tool for domestic violence has been shown to be more effective than routine social services evaluation.[56] Screening for IPV should be approached in a quiet environment, separate from the partner, with a nonjudgmental opening such as, "Because we see a lot of patients coping with abusive relationships, we now ask about IPV routinely."

There are a number of screening tools that have been validated for IPV screening. The Hurt, Insult, Threaten, Scream (HITS) screening tool questionnaire consists of four questions. Answering one or more questions affirmatively indicates a positive screen.[60]

1. Does your partner physically **h**urt you?
2. Does your partner **i**nsult you or talk down to you fairly often?
3. Does your partner **t**hreaten you with harm?
4. Does your partner **s**cream or curse at you fairly often?

The US Preventive Services Task Force (USPSTF) recently updated their recommendations to screen asymptomatic women of childbearing age for IPV and provide referral services to those who screen positive. The USPSTF found adequate evidence that screening can identify abuse, and other studies have found that effective interventions can reduce violence.[61,62] The American College of Surgeons, American College of Physicians, American College of Obstetricians and Gynecologists, American Academy of Orthopedic Surgeons, American Medical Association, Eastern Association for the Surgery of Trauma, and the Western Trauma Association all recommend screening for IPV.[18,23-25]

Treatment and Referral, Documentation, and Reporting

Once the diagnosis of IPV has been made, the responsibilities are to treat the patient, reassure the patient about safety, and make the appropriate referral to social services. It is important to carefully document the injuries in the medical record. Regardless of the legal requirement to report IPV, failure to do so may have lethal consequences. In several studies of women murdered by their spouses or boyfriends, the majority

had accessed the health care system within a year or two of their deaths, most for injury, and even when the diagnosis was made, there was no referral for the abuse.[63,64]

Summary of Intimate Partner Violence

IPV is common and commonly undiagnosed. As recommended in the position statement by the American College of Surgeons, all trauma patients should routinely be screened for IPV.[25] The use of a specific screening tool without the partner present is strongly recommended. Trauma centers and trauma surgeons should have ongoing education about domestic violence to improve the recognition and management of this epidemic problem.

ELDER ABUSE

Elder (>60 years old) abuse is a single or repeated act, or lack of appropriate action, occurring within any relationship where there is an expectation of trust, that causes harm or distress to an older person; elder abuse can involve physical abuse, psychological or emotional abuse, financial or material abuse, sexual abuse, and neglect.[65] Elder abuse and neglect is suspected to be greatly underreported, which may stem from lack of professional awareness, victim reluctance, or even cognitive impairments in reporting.[66,67] One in 10 elders in 2008 reported some form of elder abuse, including emotional, sexual, or physical abuse or potential neglect from caregivers, friends, and/or family.[67]

Health care professionals tend to underestimate elder abuse, and when detected, approximately 50% of elder abuse cases are reported.[66]

Incidence and Prevalence

Similar to IPV, the exact incidence of elder abuse is unknown because it is largely underreported. Recent reports estimate a 7.6% to 10% incidence of elder abuse.[67-69] In one study, 88.5% of abused elders experienced psychological abuse, whereas 19.7% reported physical abuse and 29.5% experienced neglect.[70]

Older people with cognitive impairments, physical disabilities, or mental health problems were found to be at higher risk of being abused.[71-73] Alarmingly, 34% to 62% of caregivers were found to abuse elders with dementia.[70,72,74]

Elder abuse is found to be most common in women and persons older than 75 years of age. A family member is identified as being the abuser in 90% of the reported cases.[75-77] Cultural differences and language barriers in vulnerable groups may hinder identification of abuse, especially in Latino, Asian, and Pacific Islander elders.[78,79]

Worldwide, the incidence of elder abuse is predicted to increase as the global population is expected to more than double to approximately 1.2 billion in 2025.[80] A WHO review found a 4% to 6% combined rate of elder abuse in developed countries.[81] The highest prevalence rate of elder abuse is found to occur in more developed countries rather than developing countries.[77]

The rates of elder abuse in nursing homes are alarming. One study found that over half of the nursing home staff reported physical violence, neglect, and mental abuse of their elderly patients. The majority of these cases involved neglect.[82] Previous studies from 1999 to 2001 found that one-third of nursing homes in the United States were cited for abuse violations.[83]

There is a significant association between elder abuse and risk of morbidities such as depression, increased rates of hospitalization, increased emergency service use, and mortality.[73,84-87] One study found that elder abuse, especially neglect, was associated with significantly increased risk of mortality.[85] One prospective cohort study found a threefold increase in mortality for persons age 65 years and older who were referred to Adult Protective Services for mistreatment and a 1.7-fold increase for those with self-neglect.[88]

Diagnosis

Some of the findings of elder abuse are similar to other forms of abuse (eg, skin injury and tears and bruising). Fractures in the elderly are unfortunately common, but fractures in places besides the hip, vertebrae, or wrists, or spiral fractures may be suspicious of abuse. Malnutrition and dehydration may be signs of neglect in a dependent elder.[89,90]

As with IPV, there are a number of screening tools that may be used for assessment of elder neglect and/or abuse. The Elder Abuse Suspicion Index is a six-question screening tool validated in the ambulatory care setting.[91] The first five questions are answered by the patient and the last question by the physician. Any affirmative response to questions 2 to 6 is considered a positive screen.

1. Have you relied on people for any of the following: bathing, dressing, shopping, banking, or meals?
2. Has anyone prevented you from getting food, clothes, medication, glasses, hearing aids, or medical care or from being with people you wanted to be with?
3. Have you been upset because someone talked to you in a way that made you feel shamed or threatened?
4. Has anyone tried to force you to sign papers or to use your money against your will?
5. Has anyone made you afraid, touched you in ways that you did not want, or hurt you physically?
6. Elder abuse may be associated with findings such as poor eye contact, withdrawn nature, malnourishment, hygiene issues, cuts, bruises, inappropriate clothing, or medication compliance issues. Did you notice any of these today or in the past 12 months?

The American Medical Association recommends elder abuse screening directed at both the elder patient and caregiver.[77] Questions directed toward the caregiver include the following: Are your elder's needs more than you are able to handle? Are you worried that you might hit your elder? Have you hit your elder? When screening the elder patient, questions asked include: Has anybody hurt you? Are you afraid of anybody? Is anyone taking or using your money without

your permission? The responses might lead to further questions, and additional information may need to be obtained.

Treatment and Referral

When elder abuse is suspected, as in IPV, medical treatment comes first. If there is reason to believe that an elder is suffering from abuse, neglect, or exploitation, referral for possible elder abuse should occur. Reporting elder abuse is required in most states. Documentation of injuries on the medical record should be meticulous.

Summary of Elder Abuse

Elder abuse is less common than IPV (7.6%–10%) but continues to trend upward. It is associated with significant morbidity and mortality. Seniors with risk factors should undergo brief screening questions, as listed earlier. If elder abuse or mistreatment is suspected based on answers to the screening questions or physical findings, further assessment is indicated. If there is reason to believe that there is abuse or neglect, reporting and careful documentation are essential.

COMMUNITY VIOLENCE

History of the Problem

The issue of interpersonal violence as a public health problem has gained significant national and worldwide attention. Worldwide, violence causes more than 1.3 million deaths each year and is the fourth leading cause of death for people age 15 to 44 years.[92] The United States significantly exceeds all other high-income nations in violent death.[92] The United States also has the highest youth homicide rate out of all the industrialized nations.[93,94] In 2013, the National Research Council and Institute of Medicine found that US males and females had shorter life expectancies than other economically developed countries, with homicide and suicide accounting for about a quarter of the years of life lost for US men.[94]

Gunshot suicide deaths account for 51% of violent deaths and occur 17 times more frequently in the United States than in Great Britain.[95-98] Young men in the United States age 16 to 19 years are five times more likely and males age 20 to 24 years are seven times more likely to die from violence.[94] Worldwide, more than 500 young adults are murdered daily.[92]

Over 2.4 million emergency department visits are due to violent injury annually in the United States.[99] In 2010, the total cost associated with fatal and nonfatal injuries due to gun violence was estimated to be at least $174 billion.[100] Most violence occurs not between strangers but among intimate partners, friends, and acquaintances.[101-103]

Risk Factors

Injuries resulting from violence occur when people have learned to use force to "solve" problems. Most age and population groups in the United States are actually at relatively low risk. A number of risk factors have been identified for community violence and related injury, including age, socioeconomic status, race, access to firearms, alcohol and other drug use, gang involvement, exposure to domestic violence and child abuse, and media violence. The most significant risk factors are male gender, being an adolescent or young adult, and low socioeconomic status.[92,95] Men younger than 65 years old were fourfold more likely to be murdered than women or people over 65 years of age.

Homicide is the second leading cause of death for men between 15 and 24 years old and the leading cause in African American men between 15 and 24 years old in the United States.[94,95] Sixty-six percent of all homicides involve the use of firearms.[94]

Increased concerns about violence have led to more Americans obtaining and carrying firearms for protection,[104] but this actually leads to increased risk of firearm injury or death. It is estimated that 40% to 50% of American households have guns.[105,106] A gun in the home is associated with a 40-fold greater chance of killing a family member or acquaintance (homicide, suicide, or accidental) than an intruder in self-protection.[107]

Alcohol and drug use are also associated with an increased risk of violence.[108] In one study, individuals who began drinking before age 14 years were significantly more likely to have been in an alcohol-related fight than those who began drinking after age 21.[109] Alcohol is involved in one-half to two-thirds of homicides, half of serious assaults, and more than 25% of all rapes.[110] Approximately 36.7% of homicides involved alcohol, where the majority of victims had a blood alcohol content of 0.08 g/dL or higher.[95]

Gang Violence

A national survey of youth gangs reported more than 30,000 gangs with 850,000 members in 2012, an increase of 20% from the previous year.[111] More than 85% of cities with a population greater than 50,000 have street gangs. Gangs were involved in approximately 16% of all homicides.[111] Individuals who participate in gangs are more likely to be involved in fights, take weapons to school, and use drugs or alcohol at school.[112,113]

The media's glamorized version of violence is seen by millions daily. The use of violence is an acceptable, if not the preferred, method of dealing with conflict and used by heroes as well as villains. A longitudinal study of young adults demonstrated that those with childhood high violence television viewing were significantly more likely to have grabbed, pushed, or shoved their spouses and that the men in this group were three times more likely to be convicted of crimes.[114]

Surgeon's Role

Physicians are in a key position to impact the lives of victims of interpersonal violence.[115] The timing and proximity of our contact with the patient are crucial components of the formula for successful intervention.

There are barriers to intervening, but despite these barriers, physicians can and should address the issue of intentional violence. Many professional organizations have published position statements and/or guidelines. Most guidelines advocate for the routine incorporation of questions regarding safety and exposure to interpersonal violence into the history. Alpert et al[116] have made a list of age-specific screening questions that can be easily covered. The value of this routine questioning is partly about identifying individual victims but also represents an opportunity to improve overall health care. Routine screening provides physicians with opportunities to express concern for the patient and to express the antiviolence message.[117] Indeed, when patients were given an opportunity to tell physicians how to intervene in family conflict, the overwhelming majority thought physicians should ask.[13]

SUMMARY

Violence in our society represents a complex, multifaceted problem. In many ways, violence is like a chronic disease. This "disease" is related to both lifestyle and environment. Sims et al[118] at Henry Ford Hospital found that trauma is a recurrent disease, with 44% having recurrent injury, and the overall 5-year mortality rate of 20% clearly demonstrates that this "disease" should not be ignored.

The enormity of this problem requires an ordered, disciplined approach such as that developed by the public health community to address infectious diseases.[1] This approach should include event surveillance, epidemiologic analysis, intervention design and evaluation, and a focus on prevention. Our educational efforts should be based on clear competencies,[119] and interventions should be evidence based.

Pediatric Trauma

Denis D. Bensard

KEY POINTS

- Injuries are the leading cause of death in the United States for persons age 1 to 19 years and the fifth leading cause of death for newborns and infants age less than 1 year.
- The Broselow emergency tape or Pediatric Advanced Weight Prediction in the Emergency Room (PAWPER) provide estimated weight of a child using length-based estimation without (Broselow) or with (PAWPER) adjustment for body habitus.
- The Shock Index, Pediatric Age-Adjusted (SIPA) identifies injured children with high injury severity, need for blood transfusion within the first 24 hours, and increased in-hospital mortality.
- Criteria to activate a massive transfusion protocol in injured children may include 20 mL/kg of packed red blood cells in the first hour or anticipated blood loss greater than one-half blood volume in 12 hours or greater than one blood volume in 24 hours.
- The motor component of the Glasgow Coma Scale (GCS) alone identifies a child with a serious traumatic brain injury.
- In general, the presence of free fluid on a focused assessment with sonography for trauma (FAST) examination is an indication for computed tomography imaging in a stable injured child.
- Spinal cord injury without radiologic abnormality is particularly hazardous because children may only present with transient neurologic findings, but then go on to develop neurologic deficits hours to days after the initial injury.
- Children with two or more rib fractures are more likely to require a thoracostomy tube, thoracotomy, thoracoscopy, and/or laparotomy.
- For a child with an injury to a solid organ in the abdomen, the success of nonoperative management approaches 95%.
- Suspicion of child abuse should be raised if there is a discrepancy between the history and the extent of injury, if there are explanations that do not fit, or if the amount of time between the incident and presentation for medical attention is significant.

INTRODUCTION

Early in the last century, little distinction was made in the care of children from adults. William E. Ladd, a general surgeon, observed this firsthand as he cared for severely burned children in the Halifax disaster of 1917. "Dr. Ladd was distressed by the quality of surgical care offered to these small patients and was determined to improve it."[1] He and Dr. Robert E. Gross in the mid-20th century pioneered a new field of surgery specific to children, illuminating features of children that merited special attention. They and others recognized that although the care of children shared some similarities to that of the adult, there were distinctly different anatomic and physiologic characteristics and surgical conditions in children that made them unique. In 1962, the first pediatric trauma unit opened at the Kings County Hospital Center in Brooklyn. Yet, the lack of dedicated care and clinical protocols persisted in the United States until the early 1970s. The first designated pediatric shock trauma unit in the United States opened at the Johns Hopkins Children's Center and became incorporated into the statewide University of Maryland Institute of Emergency Medical Systems.[2] In the years that followed, the American College of Surgeons (ACS) Committee on Trauma (COT) established the treatment of pediatric injury as an important component of all regional trauma centers, integrated pediatric trauma into the Advanced Trauma Life Support (ATLS) course, and established minimum requirements for pediatric trauma center designation. As of 2018, the number of ACS designated Level I/II pediatric centers is 109, over twice the number of

43 in 2010. The importance of designated trauma centers for children cannot be overemphasized. Myers et al[3] found that injured children treated at a Level I pediatric trauma center were more likely to survive when compared to those treated at a Level I trauma center. Similarly Notrica et al[4] reported that mortality (20.6/100,000) in states without verified pediatric trauma centers exceeded mortality in the states with Level I/II verified pediatric trauma centers (15.3/100,000) or Level I verified pediatric trauma centers only (12.9/100,000).

C. Everett Koop, a former pediatric surgeon and US Surgeon General, declared, "If a disease were killing our children at the rate unintentional injuries are, the public would be outraged and demand that this killer be stopped." Worldwide, every year, nearly a million children are killed. Nonfatal injuries affect the lives of between 10 million and 30 million more. Each year in the United States, more than 12,000 children die from unintentional injuries, and nearly a million children are treated in emergency departments (EDs) for nonfatal injuries.[5] The cost of unintentional injury can be measured in dollars, permanent disability, and potential lost years in productivity or life. The estimated cost of all injury in the United States in 2013 was $671 billion. Of those costs, which include total estimated lifetime medical and work-loss costs, $6.8 billion and $22.4 billion were a result of fatal and nonfatal injury, respectively, in children age 0 to 14 years. Sadly, these figures do not include the cost associated with future work lost and quality of life, which would be most pronounced in the very young.[6,7]

Injuries are the leading cause of death in the United States for persons age 1 to 19 years and the fifth leading cause of death for newborns and infants age less than 1 year (Fig. 48-1). The death rate for males is almost two times the rate for females. Pediatric trauma patients demonstrate a lower mortality than adults. Children demonstrate differing injury patterns by age, and patterns differ from those observed in adults. By adolescence, however, patterns of injury mirror those seen in adults. The mechanisms of injury affecting each age group are largely influenced by developmental stage. Two peaks in deaths are observed: the toddler years (age 1–4 years) and adolescence (age 15–18 years). Infants are at highest risk of death from inflicted trauma. Strikingly, intentional injury from abusive trauma accounts for more deaths in infants than unintentional injury. Toddlers often suffer injury from falls due to their immature motor and cognitive skills coupled with their higher center of gravity. From ages 5 to 9 years, pedestrian injuries are the leading cause of death, reflecting greater mobility and, thus, risk. Motor vehicle occupant injuries predominate in the 10- to 14-year-old age group. Adolescent death is most often due to a motor vehicle crash as the driver or occupant. This age group is particularly at risk of serious injury or death due to greater autonomy, poor judgment, and alcohol or drug use. Injury death rates for teenagers are significantly higher than for all other age groups. Although penetrating injury is relatively uncommon in young children, it becomes more prevalent in adolescence. Homicide is the second leading cause of death in those older than age 15 years, but in African American youths, it is the leading cause of death. Firearm homicides account for nearly 14.5% of years of potential life lost before age 65 among black males compared to 1.2% among white males.[8]

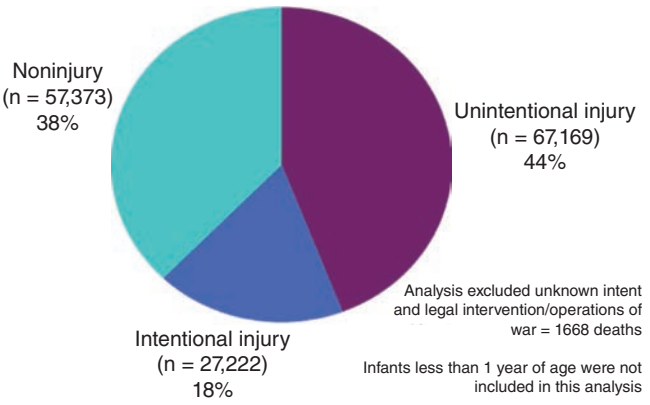

FIGURE 48-1 Cause of death by injury status and intent among children age 1 to 19 years, United States, 2000 to 2005.

An estimated 17.4 million children do not have access to a pediatric trauma center within 60 minutes.[9] In fact, 90% of injured children receive care in facilities other than pediatric trauma centers.[10] Dictated largely by geography and pediatric specialist limitations, most injured children are initially cared for by adult specialists with variable pediatric-specific training or resources. Therefore, it is incumbent on all providers of trauma care to have knowledge in the unique needs of children, recognizing that *children are not just little adults*.

INITIAL ASSESSMENT

The initial evaluation of children does not differ from that in adults. The assessment should proceed in a systematic approach based on the principles of the ATLS program published by the ACS-COT. There are unique characteristics of children that differ from adults that must be considered during the assessment (Table 48-1).

The most common cause of preventable prehospital deaths is airway obstruction or brain apnea.[11] Examining prehospital death and preventability, Oliver et al[12] found that more than 50% of patients suffered a potentially preventable death. Of interest, 76% suffered a neurologic injury, and 19% had evidence of airway obstruction on autopsy. A bystander was present in half the cases; most called emergency medical services, but fewer than half attempted a lifesaving intervention prior to their arrival.[12] Early death (<6 hours) from trauma most often results from lethal traumatic brain injury (TBI) or hemorrhage.[11,13] The Hartford Consensus Conference concluded that the leading cause of preventable death is bleeding and that simple interventions that "stop the bleed" can be lifesaving.[14] Prehospital cardiopulmonary resuscitation (CPR) portends a poor prognosis in the absence of easily reversible airway obstruction, tension pneumothorax, or hemorrhage. In 169 injured children requiring prehospital CPR, 28 survived to discharge, including 16 with full neurologic recovery. Of patients who had prehospital CPR that

TABLE 48-1: Age-Based Vital Signs from Infancy to Adolescence

Age group (years)	Weight range (kg)	Heart rate (bpm)	Blood pressure (mm Hg)	Respiratory rate (breaths/min)	Urinary output (mL/kg/h)
Infant (0–1)	0–10	<160	>60	<60	2.0
Toddler (1–3)	10–14	<150	>70	<40	1.5
Preschool (3–5)	14–18	<140	>75	<35	1.0
School age (6–12)	18–36	<120	>80	<30	1.0
Adolescent (>12)	36–70	<100	>90	<30	0.5

continued upon arrival to the ED, all died.[15] Fallat[16] has suggested that if a child has arrested, resuscitation time exceeds 30 minutes, and the nearest facility is more than 30 minutes away, transport may be futile. Despite current evidence that suggests either death or a poor outcome is inevitable, many children undergoing prehospital CPR will still be transported to the nearest hospital and, if pediatric capability is limited, will be transferred to the pediatric trauma center despite little chance of survival.

Additional factors at presentation alert the physician to a child with life-threatening injury. Low Glasgow Coma Scale (GCS) score, prehospital intubation, and shock have traditionally been used to identify high-risk patients. Falcone et al[17] performed an analysis of 29 commonly used trauma team activation criteria including the six minimum criteria of the ACS-COT for highest trauma team activation. The most predictive of requiring a high-level resource were gunshot wound to the abdomen, blood given before arrival, traumatic arrest, tachycardia/poor perfusion, pre-trauma center IV fluid volume resuscitation greater than 40 mL/kg, age-appropriate hypotension, airway compromise, and GCS score less than 8. Nearly one-half of the injured children who met these criteria needed at least one high-level resource during their ED resuscitation; nearly 25% required two to three resources. The criteria used for trauma team activation not only identify children at risk of life-threatening injury, but also identify those who will likely require one or more emergent interventions.[17] It is in this high-risk group that adequate preparation, skills, and age-appropriate equipment are essential. Team failure is most likely to occur in high-acuity pediatric trauma activations, those without prior notification, or penetrating injury.[18]

In young children (<40 kg), dosing of medications and fluids is weight based. The Broselow emergency tape and Pediatric Advanced Weight Prediction in the Emergency Room (PAWPER) tape are simple tools that provide estimated weight using length-based estimation without (Broselow) or with (PAWPER) adjustment for body habitus. These tools can guide providers in recommended fluid administration, drug dosing, and normal ranges of vital signs by age and guide appropriate size of necessary equipment. However, these tools have limitations. The length-estimated weight tapes appear to accurately estimate ideal body weight but may incorrectly estimate weight in the under- or overweight child. Underdosing of medications in the overweight child or overdosing in the underweight child can occur.[19] Adjusted dosing or redosing of medications may become necessary in some children. Despite their limitations, these tools may be helpful to providers who treat injured children infrequently.

The Primary Survey

AIRWAY

Ensuring an adequate airway is the first priority in trauma resuscitation. In analysis of preventable deaths in the state of Montana, Esposito et al[20] found that most of the preventable deaths occurred in the subgroup of children less than or equal to 14 years of age. Inappropriate trauma care was highest in the ED phase of care and primarily resulted from errors in management of the airway.[20] Similar findings were reported in a subsequent study by Sanddal et al[21] of preventable pediatric deaths in Utah. Among patients surviving to a hospital, the preventable death rate was 11%. Issues with care were again mainly in management of the airway, fluid resuscitation, chest injury diagnosis, and management.[21]

Infants and young children have a prominent occiput that tilts the head forward when supine; in combination with a short neck, floppy epiglottis, and increased lymphoid tissue, upper airway obstruction is common, particularly in the unconscious child. A simple maneuver, the jaw thrust or chin lift, can relieve obstruction caused by the tongue, facilitate bag-mask ventilation, and allow time to prepare for endotracheal intubation (ETI). Children have an increased metabolic rate and oxygen consumption. They have diminished functional residual capacity. Together, this results in a propensity for rapid oxygen desaturation. With little intrapulmonary oxygen reserve, they become hypoxic more precipitously than adults. Supplemental oxygen or oxygen with bag-mask ventilation helps to minimize this characteristic of young children.

After simple support of the airway and administration of oxygen, the need for intubation should be assessed. In spontaneously breathing children, basic airway maneuvers can establish airway patency and restore adequate respirations. Unconsciousness, combativeness, declining GCS, and shock are the most common indications for a definitive airway in an injured child and identify a seriously injured subset of children with an increased risk of death.[22] Nasotracheal

intubation is rarely performed in children. The child is preoxygenated, and rapid sequence intubation (RSI) drugs are administered. ETI generally proceeds orally with direct visualization of the glottis and in-line stabilization of the neck. A neck injury should always be assumed to be present. Standard direct laryngoscopy (DL) is usually performed.

Video laryngoscopy (VL; Glidescope) to facilitate successful intubation in the difficult airway has increased since the introduction of the device. In a meta-analysis of 14 studies by Sun et al,[23] although VL improved glottis visualization in pediatric patients, an increase in time to intubation and number of failures was observed. The use of VL in trauma remains unproven. In a simulation of pediatric trauma patients with cervical spine immobilization, 23 children age less than 10 years underwent DL and VL. The use of VL resulted in a less optimal view of the glottis and required 21 seconds, compared to 7 seconds for DL.[24] These data suggest that DL is not inferior to VL when performed by those experienced in ETI, and caution is warranted before application of VL in the injured child.

The narrowest point of the airway is the cricoid cartilage not at the level of the vocal cords. Therefore, selection of the correct size endotracheal tube (ETT) is essential to successful intubation. Inappropriate size and multiple attempts can lead to laryngospasm and inability to maintain the airway. Oxygen desaturation and laryngospasm are two of the most common complications observed in attempted ETI placement in children. The third most common complication is right mainstem intubation due to the relative short length of the airway. The physician should have some idea of the appropriate depth of the ETT. A general rule of thumb is three times the diameter of the ETT should be the measurement at the lip indicated by the markings on the ETT.

RSI is a commonly used adjunct in trauma emergency airway management.[25] RSI maximizes the chances for success while minimizing the adverse physiologic effects of intubation.[26] The most feared complication of the technique is the inability to intubate and subsequently ventilate the patient. RSI requires familiarity with airway management techniques, sedation agents, neuromuscular blocking agents, supplemental agents, and postintubation management techniques.[27] Children exhibit an exaggerated vagal response to hypoxia, succinylcholine, laryngoscopy, and intubation.[28] To attenuate the physiologic effects of ETI, especially in children with a TBI, preinduction medications (eg, lidocaine, fentanyl, atropine) may be administered.[29] A sedative induction agent (eg, thiopental, ketamine, propofol, fentanyl, or etomidate) is given, followed by a rapidly acting neuromuscular blocking agent (eg, succinylcholine), resulting in unconsciousness and motor paralysis.

Cricoid pressure is applied, and intubation follows. Overcompression can easily occur due to the compressibility of the pediatric airway. Once the ETT is placed, a colorimetric device that measures exhaled or end-tidal carbon dioxide ($EtCO_2$) is connected. A color change from purple ($EtCO_2$ <0.5%) to yellow ($EtCO_2$ >4%), symmetric chest rise, and auscultation of bilateral breath sounds suggest successful intubation. In the child suffering circulatory arrest, a color change may not be observed until the circulation is restored.

If ETI is unsuccessful, there are several rescue maneuvers available. The first and perhaps easiest is the placement of a laryngeal mask airway (LMA) designed for use during anesthesia. The LMA is easy to insert and requires less training than ETI but does not protect against aspiration. Successful use after failed emergency ETI has been reported.[30] When basic interventions or ETI fail, particularly in the paralyzed patient, an emergent surgical airway becomes necessary. Cricothyroidotomy, needle cricothyroidotomy, or translaryngeal jet ventilation offers the last options in securing the airway. Although there is ample literature concerning these techniques in adults, their use in children has been limited, emphasizing the importance of expertise in emergency pediatric airway management.[31]

BREATHING

The first step in assessment of breathing is the rate and quality of respirations. The infant may breathe normally up to 60 times per minute, young children up to 40 times per minute, and older children 20 to 30 times per minute. Young children primarily use the diaphragm to breathe; they have underdeveloped musculature, rendering them prone to muscle fatigue and less likely to be able to maintain a sustained high respiratory rate. Ineffective movement of air may result from poor effort, parenchymal injury, pneumothorax, or airway obstruction. Signs of respiratory distress include stridor, chest retractions, paradoxical motion of the diaphragm, and grunting. When these signs are present, support of respiration becomes necessary.

Pulse oximetry is a noninvasive measure of hemoglobin saturation that correlates well with arterial Pao_2 and is a measure of blood oxygen saturation. At readings of less than 80%, correlation with Pao_2 is lost and severe hypoxemia may be present. Oximetry can provide indirect evidence of ventilation, but objective evaluation requires measurement of arterial Pco_2 or $EtCO_2$. If it is determined that ventilation is inadequate, it becomes necessary to give supplement breaths or assume all ventilation. Breaths should be delivered every 2 to 3 seconds with adequate chest rise. Full ventilation will require adequate sedation and often paralysis. For mechanical ventilation, a tidal volume of 6 to 8 mL/kg is used to reduce the risk of barotrauma, and the FiO_2 is titrated to below 60% to minimize the harmful effects of hyperoxemia. Measurement of end-tidal capnography is useful to guide the rate of assisted breaths. Significant hypocarbia or hypercarbia is deleterious in the brain-injured patient due to the effects on cerebral circulation. Current guidelines suggest that an $EtCO_2$ of 35 to 40 mm Hg is optimal. In a study of children with severe TBI (GCS <8) from Level I pediatric trauma centers, children with an admission $Paco_2$ between 36 and 45 mm Hg had greater discharge survival compared with those with both admission hypocarbia ($Paco_2$ ≤35 mm Hg) or hypercarbia ($Paco_2$ ≥46 mm Hg).[32] Excessive ventilation with low $EtCO_2$ can be minimized with capnography.[33] Inadequate

ventilation or high peak inspiratory pressure (>30 mm Hg) with ventilation may be due to unrecognized pneumothorax. In this setting, evidence of pneumothorax requires rapid decompression with chest tube placement. The Broselow tape or palpation of the intercostal space can guide selection of the appropriate size chest tube. In the absence of pneumothorax or hemothorax, significant pulmonary contusion or aspiration may account for the impaired ventilation, but the treatment remains largely supportive.

The child's chest is highly compliant and poorly muscularized, and the ribs are less ossified, leaving the intrathoracic contents susceptible to injury. External signs of trauma may be absent or minimal. The mediastinum is mobile, and pneumothorax can rapidly deteriorate to tension pneumothorax, especially if positive-pressure ventilation is required. Rib fractures are uncommon in blunt-injured children for these reasons. Rib fractures suggest a significant blunt force injury. Kessel et al[34] found that children with rib fracture were more likely than adults with rib fracture to suffer brain injury, hemothorax/pneumothorax, and spleen and liver injury.

Ventilation may also be compromised by inadequate gastric decompression. The distended stomach interferes with diaphragmatic excursion, especially in the very young (Fig. 48-2). Therefore, an orogastric tube should be placed in any injured child requiring prolonged bag-mask ventilation or ETI. A nasogastric tube should not be placed in any child with signs of basilar skull fracture or facial trauma, so a policy of orogastric tube placement simplifies decision making and reduces the risk of malplacement.

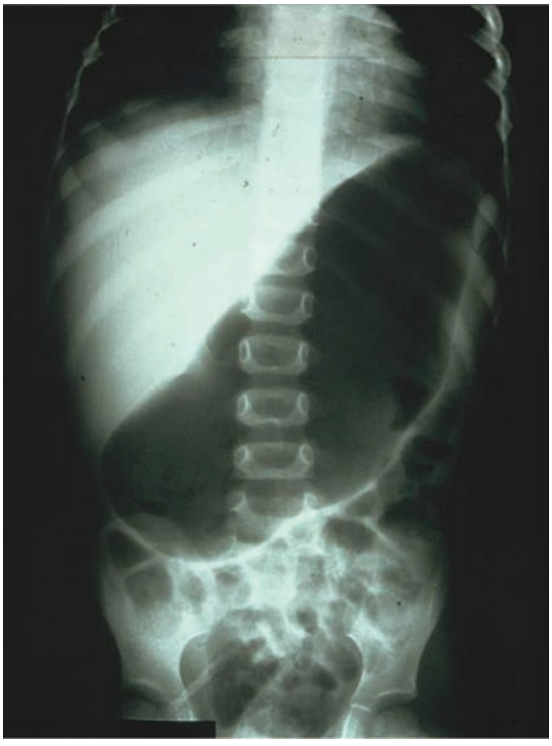

FIGURE 48-2 Acute gastric dilatation in an injured child.

CIRCULATION

Infants and young children have a limited ability to meet increased cardiac output demand. Stroke volume is generally fixed. Thus, an increase in cardiac output requires an increase in heart rate. Compensation for the loss of intravascular volume results in an increase in both heart rate and systemic vascular resistance with shunting of blood to vital organs. In a classic experiment of hemorrhagic shock, puppies were subjected to continuous hemorrhage calculated at 1% blood volume per minute. The response to hemorrhage was gradual and compensated until nearly a third of the blood volume was lost. With continued blood loss, the fall in mean arterial pressure and cardiac output accelerated, followed by death.[35] Children have robust compensatory mechanisms for mild to moderate shock. However, once a critical threshold is passed, decompensation occurs rapidly, emphasizing the need for early recognition.

Assessment of the circulation begins with the examination of the level of consciousness, skin color, heart rate, blood pressure, and peripheral pulses. An adequate blood pressure may be falsely misleading. The assessment of capillary refill allows an estimate of the degree of vasoconstriction and compensation present. Delayed (>2 seconds) capillary refill in the absence of hypothermia suggests that blood pressure is maintained by an increase in vascular resistance and that the child is significantly hypovolemic. A rapid assessment should be made for any external signs of bleeding that can be controlled by direct pressure or a tourniquet. The efficacy of tourniquets to control blood loss in military and civilian adults is well described; however, less is known regarding their efficacy in children. In a large study of prehospital interventions for children injured in Afghanistan, Sokol et al[36] found that tourniquet or hemostatic dressing application for extremity vascular injury or amputation was the most effective intervention and safe. Based on the military experience in both adults and children, if there is major hemorrhage from an extremity or amputation, a tourniquet should be applied. The pelvis should be examined for stability. If a pelvic fracture is suspected in conjunction with signs of shock, the pelvis should be wrapped in a sheet to provide compression that can reduce ongoing bleeding.

Signs of decompensated shock in children include altered mental status, mottled or cyanotic skin, cool pale extremities, weak peripheral pulses, and delayed capillary refill. Review of age-based normative values for heart rate and blood pressure demonstrate changes that occur from infancy to adolescence (Table 48-1). In general, respiratory rate and heart rate are normally higher, whereas blood pressure is lower in the young, but by age 12 years, they approach the normative values of the adult. Mortality is increased in children suffering traumatic injury and hypotension. Gunst reported 2% mortality in hypotensive injured children.[37] Hypotension, even brief episodes, substantially increases mortality in children suffering from TBI.[38]

Injured children generally suffer from one of three types of shock: hemorrhagic, cardiogenic, or distributive. Hemorrhagic and distributive shock are the most common;

TABLE 48-2: Shock Index, Pediatric Age-Adjusted (SIPA) Used to Rapidly Identify Traumatic Shock in an Injured Child

Vital signs by age with calculated cutoff values				SIPA
Age (years)	**HR (bpm)**	**SBP (mm Hg)**		**SIPA cutoff value**
1–3	70–100	90–110		1.2
4–6	65–110	90–110	HR/SBP = SIPA	1.2
7–12	60–100	100–120		1.0
>12	55–90	100–135		0.9

Note: SIPA is easily calculated by dividing heart rate (HR) by systolic blood pressure (SBP). In younger children, the cutoff value is higher due to higher normal HR and lower normal blood pressure. With increasing age, these values approximate those of adults, and thus, after age 12, the SIPA cutoff (0.9) is equivalent to the adult shock index cutoff (0.9).

cardiogenic shock is rarely the cause of primary traumatic shock in children and, if present, suggests that death is imminent. Although hemorrhage should always be assumed as the source of traumatic shock, it must be remembered that severe central nervous system (CNS) injury in young children can produce hypotension in the absence of hemorrhage.[39] A simple calculation, the Shock Index (SI; heart rate/systolic blood pressure [SBP]), can quantify the degree of shock, stratify the risk of death, and direct triage of injured patients to a trauma center. Cannon et al[40] demonstrated in adults that the risk of death is 16% when the SI is greater than 0.9 compared to a 6% risk of death when the SI is less than 0.9. An increase in SI from the field to the ED nearly doubles mortality.[40] The applicability of an uncorrected adult SI to children is limited given the relatively high values of normal heart rate and low values of normal of SBP in children relative to adults, leading to a falsely elevated SI (>0.9). To correct for age-based normative values, we examined the Shock Index, Pediatric Age-Adjusted (SIPA) in injured children (Table 48-2). We found that, like observations in adults, once SI is adjusted for age, SIPA identifies injured children with high injury severity, blood transfusion within the first 24 hours, high-grade solid organ injury requiring blood transfusion, and increased in-hospital mortality.[41] In a review of the Trauma Quality Improvement Program (TQIP) database of 22,344 children age 1 to 16 years, Nordin et al[42] demonstrated that SIPA was a strong predictor of transfusion needs, injury severity, admission to the intensive care unit (ICU), ventilator use, and mortality for both blunt and penetrating trauma. A rapid SIPA calculation can be derived by simply dividing heart rate by SBP regardless of age-based norms. In any child following injury, a value greater than 1.2 suggests traumatic shock and the likely need for one or more interventions.

Among the most difficult challenges in the care of children is vascular access. Smaller veins coupled with increased subcutaneous fat in children make both palpation and visualization of veins more difficult. Peripheral vein collapse due to hypovolemia, vasoconstriction from hypothermia, failed attempts with resultant hematoma or bruising, and extremity fractures all further complicate attempts at successful peripheral intravenous (IV) access. Ideally, access is obtained with placement of two peripheral IV catheters in the upper extremities. The Broselow emergency tape guides selection of an appropriate IV catheter size. What may appear to be an inadequate catheter size in an adult may be suitable for rapid fluid infusion in a child. The saphenous vein at the ankle is an excellent option for peripheral IV access if attempts in the upper extremity fail.

Pediatric Advanced Life Support (PALS) and ATLS now recommend placement of an intraosseous (IO) line if IV access cannot be established within three attempts or 90 seconds, whichever is sooner.[43] In children, IO placement is generally first attempted in the proximal tibia. Other potential sites include the distal tibia, the proximal humerus, and the distal femur. IO avoids many of the problems associated with central venous access. IO placement with a battery-operated device (eg, EZ IO) is rapid, requires little training, and provides reliable access in which most drugs, fluids, and blood achieve the central circulation in seconds (Fig. 48-3). Complications are low, but IO placement should be avoided in a fractured extremity due to the risk of fluid extravasation and resultant compartment syndrome.

Historically, if peripheral venous access failed, then central venous access using the Seldinger technique based on anatomic landmarks was attempted. This practice has largely been abandoned but remains an option when all other measures fail. Usually attempts are made to access the femoral vein first followed by the internal jugular vein or subclavian vein. Ultrasound is readily available in most EDs, is easy to learn, and permits visualization of the femoral vein or internal jugular vein, facilitating central venous catheter placement. In a randomized trial of children undergoing planned central venous access, ultrasound reduced the number of cannulation attempts with a greater success rate relative to the landmark approach.[44] Regardless, central venous access carries the risk of serious complications and delay and, because of the suboptimal conditions in the ED, requires early catheter removal to avoid central line–associated bloodstream infection. Therefore, central venous access should only be considered if peripheral IV and IO access have failed.

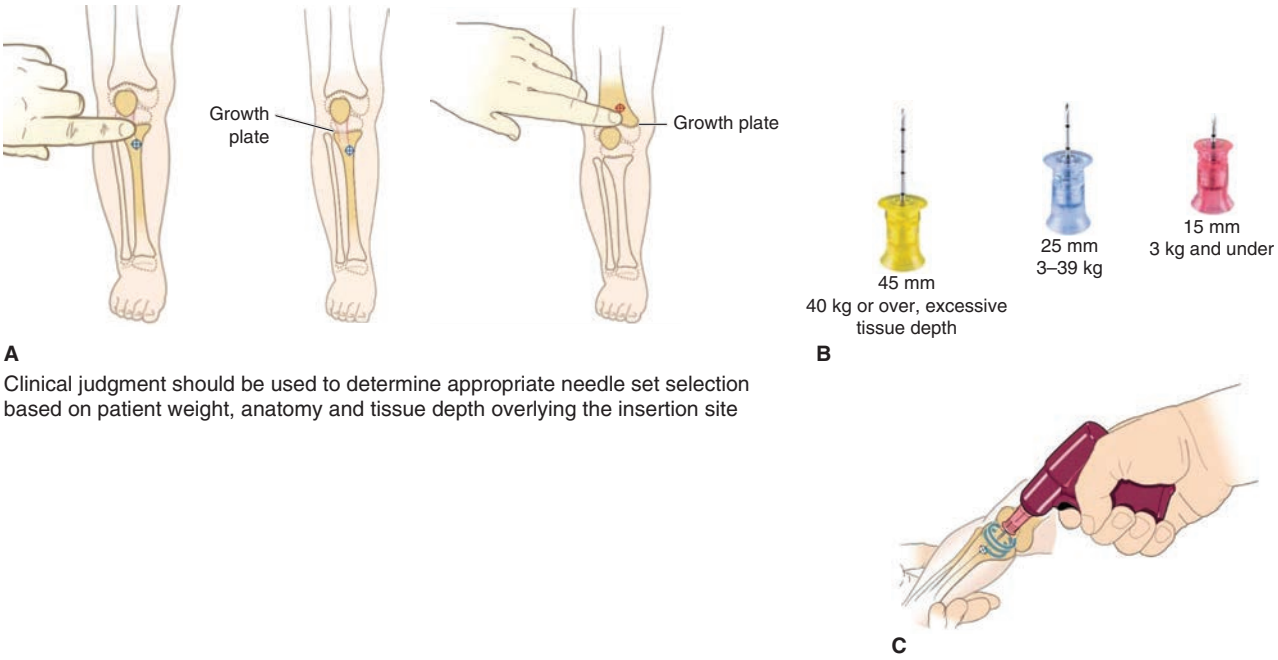

FIGURE 48-3 (**A**) Preferred sites of IO placement in infants and children. (**B**) Recommended weight based EZ IO needle length guide. (**C**) Depiction of correct technique in a child. (Images courtesy of Teleflex Incorporated. © 2020 Teleflex Incorporated. All rights reserved.)

Once IV access is obtained, a 20 mL/kg bolus of 0.9% normal saline (NS) or lactated Ringer's solution is administered. Due to the risk of non–anion gap metabolic acidosis, lactated Ringer's is favored over 0.9% NS. In patients with a TBI, early administration of hypertonic saline (3% or 7.5%) rapidly restores blood volume and may be beneficial in treatment. Two recent randomized trials in patients older than age 15 years, however, failed to demonstrate any benefit of prehospital hypertonic saline over 0.9% NS in patients with either hypovolemic shock (SBP <70 mm Hg or SBP 71–90 mm Hg and heart rate >108 bpm)[45] or TBI (GCS <8).[46] Colloid solutions for the resuscitation of traumatic shock fail to demonstrate consistent benefit. A meta-analysis by the Cochrane Review found no evidence from randomized controlled trials that resuscitation with colloids reduces risk of death compared to resuscitation with crystalloids in patients with trauma. Moreover, the use of the colloid, hydroxyethyl starch, may increase mortality.[47] For now it appears that 0.9% NS or lactated Ringer's should remain the initial resuscitative fluid unless blood transfusion becomes necessary. If the patient does not respond or only transiently responds, a second 20 mL/kg bolus of isotonic crystalloid may be given, but contemporary damage control resuscitation emphasizes early blood and product administration in lieu of repeated crystalloid administration. Blood samples for arterial blood gas, lactate, hemoglobin, coagulation (thromboelastography or prothrombin time/partial thromboplastin time), and type and cross should be obtained.

Under- or overresuscitation with fluids is likely deleterious in trauma patients. The optimal amount of fluid needed in the first 24 hours to adequately resuscitate injured patients remains unclear. However, most patients dying of shock or TBI die within 24 hours from either hemorrhage or lethal brain injury. Most deaths occur despite ongoing resuscitation.[48] In adults, investigators from the Glue Grant found that ventilator days, ICU and hospital length of stay (LOS), risk of acute respiratory distress syndrome, multiple organ failure, bloodstream and surgical site infections, and abdominal/extremity compartment syndromes were all increased in a dose-dependent fashion with aggressive crystalloid administration.[49] In contrast, we reported that high-volume early resuscitation in children, defined as greater than 60 mL/kg/24 h, did not demonstrate an increased risk of acute respiratory distress syndrome, multiple organ failure, abdominal compartment syndrome, or bloodstream infections, but like the Glue Grant investigators, we observed an increase in ventilator days, ICU LOS, anemia, and thrombocytopenia.[50] Edwards et al[51] reported similar findings to both studies in a cohort of pediatric combat causalities. They observed that the adverse effects of crystalloid became most pronounced when greater than 150 mL/kg was administered in the first 24 hours, but administration of 50 to 150 mL/kg was not associated with increased mortality. Not surprisingly, underresuscitation (<50 mL/kg/24 h) led to increased mortality, but this may simply reflect survival bias (ie, children who died prior to hemorrhage control and ongoing fluid resuscitation). Injured children should be judiciously resuscitated, but adequate fluid should be given to ensure adequate tissue oxygenation and cerebral perfusion regardless of the amount of crystalloid needed in the early resuscitative phase. While adult studies have suggested benefit to permissive hypotension, Hughes et al[52] warns that there is no evidence to support permissive hypotension strategies in pediatrics.

In the absence of a sustained response to 40 mL/kg of isotonic crystalloid fluid bolus, ATLS advises the administration of blood. Blood component administration is the resuscitative

fluid of choice in the bleeding patient until hemorrhage control is achieved. The decision to begin blood transfusion must be balanced against its potential delayed adverse effects,[53,54] including a potential negative effect on outcome in children suffering TBI.[55] Injured children requiring early blood administration represent a seriously injured subset. Early blood transfusion (<6 hours) is associated with up to 50% mortality, in stark contrast to the low mortality in those who do not receive blood or undergo delayed blood transfusion.[54] Interestingly, most children who received early blood in this series died of lethal injury to the brain rather than hemorrhage. It may be that the brain-injured child in shock and without hemorrhage might benefit from an alternate resuscitative strategy utilizing vasopressors, as suggested by Di Gennaro et al.[56]

An ongoing requirement for blood suggests noncompressible intracavitary hemorrhage, and massive transfusion becomes more likely. A focused ultrasound examination for pericardial and intra-abdominal fluid (focused assessment with sonography for trauma [FAST]) demonstrating free fluid can assist in directing the child to emergent laparotomy to achieve hemorrhage control.[57] Like traumatic shock, the need for massive transfusion is associated with an increased risk of death in children. Neff et al[58] found in combat-injured children that once a threshold of 40 mL/kg/24 h of blood products is given, critically injured children are more than 2.5 times more likely to suffer early in-hospital death.[58] Similar findings are reported in civilian pediatric victims.[54] Current evidence in adults suggests that in this setting blood components should be transfused in 1:1:1 or 1:2:1 ratio (packed red blood cells to fresh frozen plasma to platelets) until hemorrhage is controlled and there is no evidence of ongoing bleeding.[59] In contrast, in a study of pediatric casualties in Iraq and Afghanistan, Edwards et al[51] found that balanced component resuscitation did not improve outcomes and was associated with higher mortality when all transfused patients were considered. Further studies are needed to reconcile this apparent difference in children from adults.[52,60]

The decision to transfuse blood is based on vital signs, injury patterns, anticipated major bleeding, or risk of continued bleeding after surgical control. In a prospective study of injured adults, Sisak et al[61] found that 9% required early blood transfusion and nearly half had activation of a massive transfusion protocol (MTP). Injury pattern, vital signs, lactate, and anticipated major bleeding were the best predictors of MTP in this cohort, which demonstrated a high rate of emergency surgery (86%) and mortality (14%).[61] Less is known in children. In children, most protocols recommend that MTP be activated in children with signs of bleeding. Criteria may include greater than 20 mL/kg of packed red blood cells in the first hour or anticipated blood loss of greater than one-half blood volume in 12 hours or greater than one blood volume in 24 hours. The Assessment of Blood Consumption (ABC) score consists of four variables (heart rate >120 bpm, SBP <90 mm Hg, positive FAST, and penetrating torso injury) each assigned 1 point. Validated in adults, a score of greater than 2 triggers an MTP and correctly classifies most bleeding adult patients in need of MTP.[62] The ABC score may not be applicable in children due to differing normal values of heart rate and BP with age. In a pilot study using a modified ABC score using SIPA (ABC-S), the authors found that an ABC score of greater than 2 poorly predicted the need for MT, but an ABC-S score of 1 or greater improved prediction of MTP, with sensitivity increased from 29% to 65% and comparable specificity.[63] Although it is evident that MTP results in earlier delivery of blood components, it remains unclear whether it improves outcome in children.[60,64,65]

In the child who presents with signs of life and loses vital signs while in the ED, resuscitative thoracotomy may be considered. First, reversible causes of pulseless electrically activity such as tension pneumothorax or hypovolemia should be excluded. Unfortunately, the outcome in children with blunt injuries who have a cardiac arrest and ED thoracotomy is dismal.[66] The results are more favorable in adolescent patients suffering penetrating injury and witnessed cardiac arrest, particularly those suffering stab wound to the heart.[67] ED thoracotomy may be warranted in children suffering penetrating torso injury who lose vital signs in the ED or have short transport time with prehospital CPR less than 15 minutes.

DISABILITY

The child's level of consciousness, pupillary examination, and neurologic exam define disability. The aim of the neurologic assessment is to identify severe head injury or spinal cord injury that may require urgent neurosurgical intervention. A rapid assessment can be determined using the Alert/Pain/Verbal/Unconscious (APVU) scale. APVU appears to correlate well with the GCS: alert, GCS of 15 (interquartile range [IQR], 15); pain, GCS of 13 (IQR, 12–14); verbal, GCS of 8 (IQR, 7–9), and unconscious, GCS of 3 (IQR, 3).[68] GCS is more typically used and shows good performance in preverbal children compared to older children with blunt head injury. Receiver operator characteristic curves demonstrate good correlation of GCS with brain injury confirmed by computed tomography (CT) or requiring acute intervention.[69] Concerns remain that calculation of the GCS can be difficult in children, is compromised by the need for ETI, and suffers significant interrater variability. Ultimately, the goal is to ascertain quickly which children require an urgent CT scan and perhaps neurosurgical intervention. This has led others to examine the use of abbreviated GCS scales or one of the three components of the GCS to rapidly identify at-risk children.[70] We found that the motor component of the GCS alone identifies children with serious TBI and the elimination of the eye and verbal components did not adversely affect the performance of the tool.[71]

If after assessment by one of the previously described tools the child is felt to have a serious brain injury, the eye examination should be repeated to determine if there is evidence of impending transtenorial brain herniation suggested by unilateral dilation of a pupil. This or rapid progressive neurologic deterioration implies critical intracranial hypertension. If present, temporizing measures such as brief hyperventilation ($EtCO_2$ 25–30 mm Hg), 3% hypertonic saline IV bolus (1–6 mL/kg), or IV mannitol (0.25–1 mg/kg) should be considered until definitive neurosurgical care

is available.[72] Mannitol should not be administered to a child with hypotension or shock. Unlike mannitol, hypertonic saline, a volume expander, can be used in the setting of hypotension. The child is examined for evidence of a spinal cord injury. Respiratory failure and/or shock can be the first signs of injury to the spinal cord but are only attributed to this once all other potential causes are excluded. Symmetric flaccid paralysis of the extremities indicates spinal cord injury, and spinal immobilization should continue.

EXPOSURE

Children are susceptible to hypothermia, more so than adults. Hypothermia can lead to arrhythmias, abnormal coagulation, and metabolic acidosis, with the latter two drivers in the lethal triad of trauma death. Review of the National Trauma Data Bank (NTDB) demonstrated that of those trauma patients in whom temperature was measured, 2% had a core temperature as low as 32°C. Comparison of core temperature versus mortality revealed that as temperature decreased, the mortality rate increased, reaching approximately 39% at 36°C.[73]

The trauma room temperature should be maintained at greater than 80°F. Wet clothes should be removed, the child covered with warm blankets, and exposures for procedures minimized. All IV fluids and blood products should be warmed using fluid warmers. Active external rewarming with a convective air blanket (eg, Bair Hugger) should be initiated when the core temperature falls below 36°C. Despite the importance of exposure and environmental control during pediatric trauma resuscitation, compliance is poor. In children with TBI or requiring ETI where the duration of exposure is prolonged, Kelleher et al[74] found hypothermia to be common. Sundberg et al[75] remind us that a hypothermic patient is 9.2 times more likely to die than a normothermic patient when adjusting for seasonal variation. Therefore, children who are prone to hypothermia or arrive hypothermic must be rewarmed and kept warm. There is no role for hypothermia in the acute setting of trauma despite reports of hypothermia used in cardiac arrest or management of TBI.

THE SECONDARY ASSESSMENT

The secondary assessment begins only after all elements of the primary assessment are satisfied. Periodic review of vital signs, pulse oximetry, $EtCO_2$ capnography, fluid administration, and GCS alerts the surgeon to significant change and the need to interrupt the secondary assessment. Chest and pelvis radiographs are obtained if indicated. The examination generally proceeds systematically from head to toe, as in adults. At this time, a brief medical history, current medications, and immunization status are obtained. For penetrating wounds, it may be necessary to administer tetanus toxoid and/or immunoglobulin depending on the immunization status. At this point, if the child is hemodynamically stable with evidence of external injury or in pain, an analgesic should be given that will address the pain and facilitate the remainder of the examination. In children, pain is considered the fifth vital sign but is often overlooked.[76]

Bleeding from scalp lacerations should be controlled with pressure, surgical staples, or injection of local anesthetic containing epinephrine. Due to the frequency of head injury in children, the child should be examined for bleeding from the ear, bruising posterior to the ear, or orbital ecchymosis—findings that suggest basilar skull fracture. The chest is examined for crepitus, rib fractures, bruising, or penetrating wounds, and the chest auscultated. One or more of the following in children increases the odds of significant chest injury following blunt trauma: low SBP, elevated respiratory rate, abnormal thoracic examination, abnormal chest auscultation, femur fracture, and a GCS score of less than 15.[77] If there is evidence of pneumothorax, tube thoracostomy is performed.

Increased risk of abdominal injury in children is present when examination reveals low SBP, abdominal tenderness, or femur fracture. Abdominal tenderness confers a sixfold increased risk of significant intra-abdominal injury, but the reliability of absent abdominal tenderness to exclude intra-abdominal injury decreases with declining GCS.[78,79] Another important finding in children is bruising of the abdomen from either a seat belt[80] or handle bar.[81] When present, these findings should raise concern for a significant intra-abdominal injury. Lutz et al[82] reported that, among restrained children involved in a motor vehicle crash, those with a bruise were 232 times more likely to have a significant intra-abdominal injury when compared with children without bruising of the abdominal wall. Pelvic fracture is uncommon in children.[83] Nevertheless, the pelvis should be palpated for tenderness and instability. If either is present, an x-ray should be obtained; however, the routine use of pelvic x-ray in the evaluation of blunt-injured children is discouraged.[84,85] As in adults, if a pelvic fracture is present, the meatus in males and the vaginal introitus in females should be examined for blood. In postmenarche females, a urine pregnancy test should be obtained to identify an unknown pregnancy and the potential for fetal compromise. Routine rectal examination, like routine urinary catheterization, is not indicated in children.[86]

When examining the extremities, it is important to remember that children may have fractures with minimal displacement, known as greenstick fractures. Tenderness with or without hematoma, bruising, and displacement should prompt imaging. For displaced fractures, the pulses should be assessed distally, and the fractured extremity splinted to reduce pain and bleeding. It may be necessary to attempt reduction to restore flow if a distal pulse is absent.

The FAST examination, although a diagnostic test, is considered a component of the secondary assessment. In special circumstances, it may be performed earlier, particularly in the child in cardiac arrest or profound shock. In this situation, FAST permits examination of the heart and abdomen that can direct emergent interventions or discontinuation of resuscitative efforts if cardiac activity is absent. In stable children, the FAST cannot be solely relied upon to rule out intra-abdominal injury due to its low sensitivity.[87] Thirty to fifty percent of children with negative FAST will have a solid organ injury.[88] In general, the presence of free fluid on FAST is an indication for CT imaging in the stable child. Some

believe that the utility of FAST to direct CT imaging can be improved if integrated with additional supportive findings, such as elevated hepatic transaminases,[89] a scoring system,[90] or perhaps a step-up approach where imaging is only indicated if additional clinical factors are present.[91] Until these novel approaches that combine FAST with adjunctive findings, tests, or as an element of a scoring scale are validated, FAST should only be relied upon to direct intervention in a child with shock.

The utility of routine laboratory studies in the evaluation of trauma patients to aid in diagnosis of injury is limited and has been largely abandoned. The tests rarely result in a change in management and add unnecessary cost to care.[92] Capraro et al[93] showed that, in children with confirmed abdominal injury by CT, no routine laboratory test demonstrated good sensitivity, specificity, positive predictive value, or negative predictive value, leading the authors to conclude that routine "trauma panels" are not indicated as a screening tool in children with blunt trauma. Selective testing for suspected injury to the liver (aspartate aminotransferase), pancreas (lipase), or kidney (urinalysis) is not unreasonable but may lead to unnecessary CT imaging that only reveals injuries not requiring surgical intervention.[94] Laboratory studies are most helpful in assessing the metabolic state of the patient,[95] degree of acute blood loss anemia, and degree of trauma-induced coagulopathy. Keller et al[96] found that over half of children with severe TBI (GCS 3–8) had abnormal coagulation studies but few needed an intervention.[96] Arterial blood sampling provides valuable information regarding the metabolic condition of the critically injured patient. The degree of blood loss or the need for blood transfusion can be aided by hematocrit measurement,[97] although acute values may be falsely elevated.[61] Serum lactate, a byproduct of anaerobic metabolism, is useful to quantify the degree of metabolic derangement, is prognostic, and can guide resuscitation.[98]

The Environmental Protection Agency reports that nearly half of all radiation in the United States is attributable to medical imaging (Fig. 48-4). The overall average radiation of the US population has doubled in the past 25 years and is largely due to increased utilization of diagnostic CT scanning.[99] The radiosensitive pediatric population is most at risk. Brenner et al[100] predicted that although pediatric patients only represented 4% of all CT imaging, they account for 20% of all CT-related cancer deaths. In 2013, Miglioretti et al[101] quantified the risk of developing a future malignancy based on a child's age at the time of the CT scan. The authors estimated that 1 in 570 to 6130 scans will lead to the development of a new cancer depending on the child's age, sex, and type of scan.[101] In 2007, CT imaging was predicted to cause 29,000 new cases of cancer, of which 15% would result from imaging children. The theoretic prediction of cancer from CT imaging has been validated. A linear relationship between the dose of radiation delivered during a CT scan and the relative risk of developing leukemia and brain cancer was reported in a large cohort of European children.[102] Similar findings were reported in a study of Australian children in 2013.[103] Although the estimated

Among the prescribed remedies are improved preventive efforts, speedier surgery and further research. *Sci Am*. 1983;249(2):28-35.)

future risk of cancer is low, these studies represent only a relatively short period of observation following exposure. Moore et al[104] speculated that if real, late deaths due the effects of ionizing radiation could emerge as the fourth peak in trauma-related mortality, albeit many years later (Fig. 48-5).

Given our increasing knowledge of the risks associated with radiation, a CT scan should only be ordered when the results are likely to influence the care of the patient. To raise awareness and reduce radiation dosing during pediatric medical examination, the Alliance for Radiation Safety in Pediatric Imaging launched the Image Gently campaign in 2008. These and other efforts are intended to decrease the amount of radiation from imaging through specific steps[105] or by eliminating unnecessary imaging. Among the "five things that physicians and patients should question," the ACS advises to avoid the routine use of whole-body diagnostic CT scanning in patients with minor or single-system trauma. Clarifying which patients can safely forgo CT scans to minimize radiation exposure without missing clinically important injuries is critical. Children who suffer blunt trauma and have a normal chest radiograph do not benefit from chest CT.[106] Great vessel injury is rare in children, and typically, an abnormal silhouette on chest radiograph is reported. CT will detect more injuries than a conventional chest radiograph, but management rarely changes. For example, children, like adults, with an occult pneumothorax detected by CT but not seen on plain films do not require treatment but are simply observed.[107] Fenton et al[108] has demonstrated that although children are frequently imaged with CT, few will require a surgical intervention. In a cohort of injured children undergoing evaluation for blunt trauma, no child imaged on the basis of mechanism of injury alone had a significant or life-threatening injury. These children averaged 1.7 CT studies with a radiation exposure nearly three times the accepted annual limit for environmental sources. In contrast, in children with abnormal GCS (<15), abnormal vital signs, or abnormal physical examination, nearly one-fourth of studies were positive for significant or life-threatening injury.[104] Children should not be imaged based on mechanism of injury, but rather, imaging should be directed by findings of the primary and secondary survey.

In an effort to reduce CT utilization, clinical decision rules to identify children at low risk for clinically important injuries requiring intervention have been developed. The use of these decision instruments can effectively reduce unnecessary imaging of minor head injury, the cervical spine, and the abdomen. In the absence of a GCS score less than 14, altered mental status, loss of consciousness of greater than 5 seconds, vomiting, severe mechanism of injury, or skull fracture, children can be observed safely rather than imaged by CT. When studied, the prediction rule demonstrated a negative predictive value of 100% in children over the age of 2 years.[109] In the National Emergency X-Radiography Utilization Study (NEXUS), a decision rule was examined in a prospective, multicenter study. The investigators found that the decision rule correctly identified all pediatric patients with cervical spine injury and correctly designated 20% of patients as low risk, for whom imaging could have been eliminated.[110] The Pediatric Emergency Care Applied Research Network (PECARN) examined a clinical decision rule composed of seven history and physical exam factors (abdominal wall bruising, GCS <14, abdominal tenderness, thoracic trauma, complaints of abdominal pain, decreased breath sounds, or vomiting) that successfully identified children at low risk of clinically important abdominal injuries; 5.4% of children with a seat belt sign or GCS <14 underwent an abdominal intervention (Fig. 48-6). In contrast, if none of the criteria were present, the risk of an abdominal intervention was 0.1%.[111] Although the decision instrument can reduce imaging, the specificity of 42.5% demonstrates that over half of the studies remain negative for clinically significant injury. These data support the opinion that pan-scanning or nonselective imaging of children is unwarranted.

The primary and secondary assessments in children demonstrate subtle differences from those in the adult, but the principles remain largely the same. Seriously injured children typically suffer multisystem injury, and if shock is present, the risk of death is increased. Conversely, many children suffer single-system injury, with a low frequency of needing a craniotomy, thoracotomy, or laparotomy. Careful examination, selective laboratory studies, and the use of decision

instruments can lead to directed imaging with few missed injuries.

MANAGEMENT OF SPECIFIC INJURIES

Neurologic Injury

TBI is a leading type of childhood injury according to the Centers for Disease Control and Prevention. In the United States alone, children age 0 to 14 years make almost half a million ED visits for TBI annually.[112] TBI resulting from unintentional trauma constitutes the primary cause of death among children and young adults. Fortunately, most brain injuries are mild,[113] but even this level of injury is associated with ongoing problems.[114] TBI is a significant financial burden on the economy of the United States. Charges for TBI-related hospital visits are more than $1 billion per year in the United States.[115] Neuropsychological sequelae associated with pediatric TBI can influence key developmental processes, such as learning, emotional awareness, and social functioning.[116] Injury costs for children are often greater than those for adults, because they include expenditures for acute treatment, long-term rehabilitation, and loss of productivity for the parent or guardian.

Children less than age 1 year are at increased risk of abusive head injury. In toddlers (age 1–4 years), head injury most often occurs due to fall. By adolescence, head injury because of a motor vehicle crash is most frequent. Children suffering unintentional serious head injury often have concomitant multisystem injury due to significant blunt force mechanism. Nearly 80% of all trauma deaths in children have associated TBI. Consequently, TBI is the most common cause of disability and death in childhood. Based on the current best estimates, severe pediatric TBI has a 20% mortality, and over half of those who survive demonstrate an unfavorable 6-month outcome.[117] As the severity of injury increases, the risk of death, vegetative state, or decreased functional status rises.

At birth, the head is one-fourth the total body length, whereas in the adult, it is one-seventh (Fig. 48-7). The head is proportionally large and the legs proportionally short during childhood. The center of gravity in an infant and toddler is more cephalad.[118] The skull of the infant is thin and soft, and the closure of sutures is not completed until age 3 years. This heavier head mass, coupled with a higher center of gravity and weak neck, may in part account for the propensity for children to strike the head in a fall and the higher frequency of head injury. The volume of cerebrospinal fluid is smaller than that of the adult, brain water content is increased, and brain myelination is incomplete until age 2 years. As a result, the brain is soft and prone to injury. Due to the anatomy and biomechanical factors observed in young children, acceleration and deceleration injury yields a greater amount of force applied to the brain and greater frequency of shear injury. Children appear to experience age-dependent pathology following pediatric TBI. In infants and young children, subdural hematomas and diffuse injury are more common than focal injuries, particularly in those suffering abusive head trauma.[119]

TBI refers to the primary brain injury that occurs at the time of the inciting event and the subsequent secondary brain injury that arises from derangements in cerebral blood flow, ischemia, and the inflammatory response to injury. Primary brain injury results from the immediate force of trauma. These forces can produce focal injury to the brain. Shearing of blood vessels can produce epidural hematoma, subdural hematoma, and/or subarachnoid hemorrhage. Parenchymal injury is worsened by compression from the mass effect of blood. The result is parenchymal injury exacerbated by increased swelling of the injured brain that is trapped in a confined space. The intracranial vault is incompressible and holds a fixed volume of brain, cerebrospinal fluid (CSF),

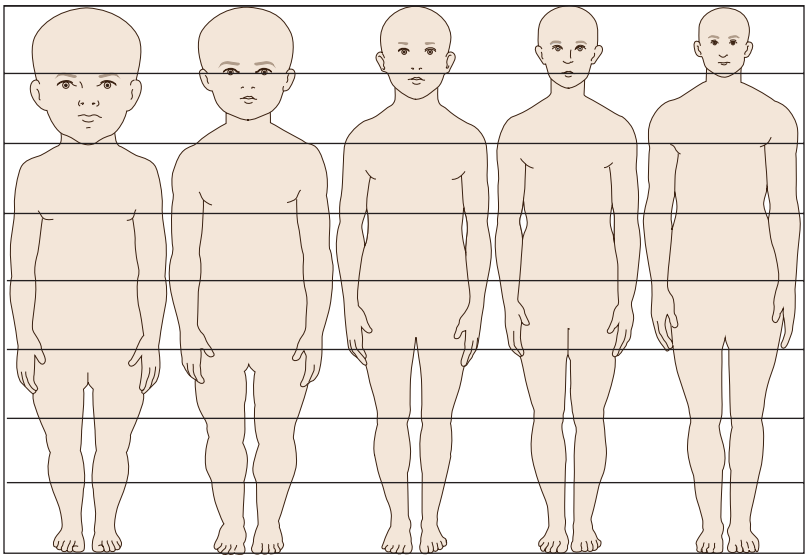

FIGURE 48-7 Graphic representation of head size relative to body size in infants through adulthood. In infants and children, the head is disproportionately larger and the limbs relative smaller, resulting in a higher center of gravity.

and blood. Any increase in volume of one of the cranial constituents must be compensated by a decrease in volume of another. This concept, the Monro-Kellie doctrine, serves as the basis for the management of brain injury.[120]

Initial compensation for the increase in intracranial volume is displacement of CSF to the spinal canal and displacement of venous blood to the jugular veins to reduce intracranial pressure (ICP). Once these compensatory mechanisms are exhausted, even small increases in cerebral edema and intracranial volume lead to significant increases in ICP, further compromising cerebral perfusion. Cerebral ischemia and edema follow and, if uninterrupted, result in brain herniation and death. Care of the primary brain injury may require neurosurgical intervention, but reduction in secondary brain injury can be initiated as early as the prehospital phase of care by nonneurosurgeons. It must be remembered that secondary brain injury develops in the initial minutes following primary brain injury. A myriad of physiologic and metabolic alterations ensue. Hypotension, hypoxia, and hypo- or hypercarbia have been demonstrated to exacerbate secondary brain injury and increase the risk of death.[32] All can be addressed by the nonneurosurgeon by the restoration of respiration and circulation. The acute management of TBI is directed to prevent or ameliorate events that promote secondary brain injury. To date, prevention of delayed secondary brain injury as a result of neuronal cell degeneration and traumatic axonal injury with neuronal cell death remains investigational.[121] Contemporary therapies focus on cerebrovascular dysregulation, swelling, metabolism, and ischemia.

The GCS is a scoring tool that permits assessment and stratification of the severity of brain injury. GCS correlates with the risk of disability or death.[122] Calculation of the GCS and physical examination permit stratification of injured children with mild, moderate, or severe TBI. Validated decision instruments direct the need to obtain brain imaging.[109] In general, any child with an abnormal GCS should undergo brain imaging. Additional history (loss of consciousness >5 seconds, amnesia), symptoms (vomiting, persistent headache), or physical findings (raccoon eyes, battle sign) may prompt brain imaging. The purpose of brain imaging is to exclude or confirm a brain injury, identify extra-axial blood collections, and determine the degree of brain compression. Prompt neurosurgical intervention may be needed for evacuation of extra-axial blood with significant mass effect, decompressive craniectomy for impending herniation or control of ICP, and placement of an intraventricular drain or ICP monitor. Delays in craniotomy or placement of ICP monitoring are associated with worse outcome.[123] Goals of ICP monitoring are to adjust therapies to maintain the ICP less than 20 mm Hg and maintain a minimum cerebral perfusion pressure (CPP) of greater than 40 mm Hg.[124]

Not all children with minor TBI require imaging. For children with minor TBI, a period of observation with scheduled neurologic assessment is recommended. Children with intracranial injuries may initially present with only headache and vomiting due to increased ICP, and thus it is recommended to consider imaging or a period of observation. It must be remembered that even in the setting of minor TBI, there is significant risk of ongoing cognitive and behavioral issues. Decision instruments for selective imaging of children can be used to reserve imaging only for those with abnormal GCS, symptoms of increased ICP (vomiting, headache), or other signs of head injury (skull fracture, battle sign, raccoon eyes).[109] Plain x-rays may demonstrate a skull fracture but provide no information regarding the underlying brain injury and cannot substitute for CT. The CT is reviewed for mass lesions, early signs of brain swelling, or evidence of diffuse brain injury. Conversely, a normal CT scan and brief period of observation may permit discharge with continued observation at home obviating the need for hospitalization.[125]

For moderate to severe TBI, the treatment is based on the Brain Foundation guidelines first published in 2003 and updated in 2012.[124] The current guidelines are derived from Level II/III evidence. Level II evidence supports the use of hypertonic saline and therapeutic hypothermia, but the evidence does not support the use of corticosteroids or immunomodulatory diets. The remaining guidelines provide Level III evidence for a CPP greater than 40 mm Hg; ICP monitor for GCS less than 8; adequate analgesia, sedation, and paralytics; seizure prophylaxis with phenytoin; and avoidance of severe hyperventilation (Pco_2 <30 mm Hg). Initial measures to address secondary brain injury are elevation of the head of the bed 30° to maximize venous drainage, definitive airway management for GCS less than 8 or rapidly declining GCS, administration of oxygen, and restoration of circulation. Even brief episodes of hypoxemia and/or hypotension have detrimental effects and increase mortality.[126,127] All may be initiated prior to neurosurgical intervention. Decreases in cerebral blood flow in the initial 24 hours following severe TBI in infants and young children have been associated with poor outcome.[56,127]

In patients who require mechanical ventilation, a Pco_2 of 35 to 40 mm Hg is optimal. Lower values risk unacceptable reductions of cerebral blood flow and potential increased secondary brain injury due to ischemia. Like mechanical ventilation, early hyperosmolar therapy may be initiated prior to neurosurgical evaluation either with hypertonic saline or mannitol. The advantage of hypertonic saline is that it also serves as a volume expander and can be administered in the hypotensive patient, unlike mannitol. Pediatric patients with severe TBI appear to tolerate a high osmolar load. Serum osmolality should be maintained at less than 360 mOsm/L. Once the mass effect of bleeding or increased ICP has been addressed, care of the brain-injured child becomes largely supportive. Additional adjuncts have been proposed, largely based on adult evidence of neuroprotection and neurorecovery with administration of excitatory amino acids, antagonists to the *N*-methyl-D-aspartate receptor, dopamine agonists, benzodiazepines, β-blockers, anticonvulsants, and antidepressants, but remain unproven.[128] In the event of refractory intracranial hypertension or impending herniation, decompressive craniectomy may be considered. Level III evidence suggests that it may be effective in reversing early signs of neurologic deterioration or herniation and in treating intracranial hypertension refractory to medical management; however, there is insufficient evidence to define patients who may or may not benefit.[124]

TBI impacts the life of individuals and their families. For individuals hospitalized after a TBI, almost half (43%) have a related disability 1 year after the injury. Approximately 5.3 million Americans are living with a TBI-related disability, and the consequences of severe TBI can affect all aspects of an individual's life.[129]

Spine and Spinal Cord Injury (See Chapter 26)

Spinal column and spinal cord injury are uncommon in children. Fractures of the spine constitute less than 1% of all pediatric fractures. In a study of the NTDB, Polk-Williams et al[130] reported that 1.59% of patients suffered an injury to the cervical spine; 0.38% had associated spinal cord injury associated with their spinal column injury, and 0.19% had an isolated spinal cord injury without a radiologic abnormality (SCIWORA). Despite the low incidence of cervical spine injury, immobilization is indicated in all children with significant head injury or multisystem injury. The cervical spine is susceptible to bony and ligamentous injury in the child. The neck is poorly muscularized, the ligaments lax, and the vertebral bodies wedged anteriorly with a tendency to slide forward with flexion. SCIWORA is particularly hazardous since children may only present with transient neurologic findings but then go on to develop neurologic deficits hours to days after the initial injury[131] (Fig. 48-8). The most common mechanisms of injury are road traffic accidents, sports, and falls. A homogenous distribution of spinal cord injuries is observed. Nearly all children who present with intact motor or sensory function recover, but only 37% to 54% with an incomplete injury (American Spinal Injury

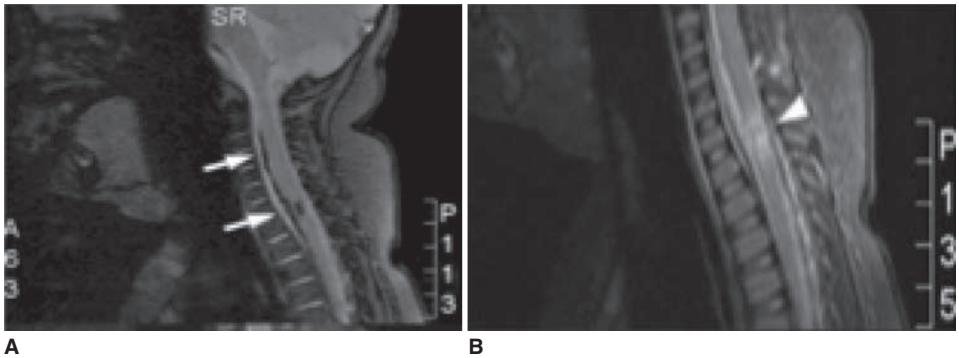

FIGURE 48-8 Spinal cord injury without a radiologic abnormality in a child. The magnetic resonance image demonstrates (**A**) significant spinal cord contusion and hemorrhage from C7 to T1, as well as ventral subdural hemorrhage from C2 through C7 and (**B**) evidence of interspinous ligament rupture between C5 and C6. FIGURE 48-9 Atlantoaxial dislocation. This injury may be associated with a high spinal cord injury causing apnea at the scene.

Association Impairment [ASIA] Scale B or C) or 13% with a complete injury (ASIA Scale A) achieve a full neurologic recovery. Magnetic resonance imaging (MRI) is particularly useful in the diagnosis and prognosis of SCIWORA, given its accuracy for ligamentous injury, soft tissue injury, and spinal cord injury.[131] Young children most often suffer upper cervical spine injury, whereas older children and adolescents injure the lower cervical spine like adults[132] (Fig. 48-9).

When evaluating the pediatric spine, anterior displacement of C2 vertebra on C3 may be observed. Pseudosubluxation is a benign variant that may be observed in up to 20% of children suffering polytrauma.[133] In the absence of head injury or distracting injury, the cervical spine can be cleared by clinical examination.[110] All other children require imaging. CT scan has supplanted plain radiographs due to its superiority in detection of injury but at the cost of increased ionizing radiation exposure. Thus, the cervical spine should be cleared by clinical exam whenever possible. Hannon et al[134] have proposed an innovative algorithm specific to children using clinical examination and screening radiographs with focused CT reserved for abnormal radiographs. Such an approach will require validation in a larger cohort of children prior to widespread application.

Thoracic and lumbar spine injury is even less common in children; however, in the child with a lap belt sign, there is a significant risk of a fracture in the lumbar spine. The Chance fracture results from flexion and distraction of the upper lumbar vertebrae around the lap belt during rapid deceleration. Modern restraint design has not mitigated the risk of injury, likely due to submarining of the hips beneath the lap belt and hyperflexion secondary to forward excursion of the pelvis and legs during the collision.[135] There is a high incidence of an associated neurologic deficit that is most often transient but may be permanent in up to 10% of children.[136] Mahan[136a] found that spinal column injury is most common in children over the age of 8 years. Nearly one-third have multilevel injuries, 6% of which are noncontiguous, emphasizing the importance of complete imaging of the spine.

Management of an injury to the spinal cord parallels that of TBI with an emphasis on avoidance of secondary injury. Spine immobilization is essential to avoid further injury. Resuscitation ensures perfusion of the injured spinal cord. High cervical cord injury may produce a distributive form of shock (neurogenic) because of autonomic disruption, loss of sympathetic vascular tone, relative hypovolemia, and decreased peripheral vascular resistance. Fluid administration is usually adequate to restore blood pressure, but in some cases, a vasopressor (eg, phenylephrine) will be added to maintain adequate blood pressure. In rare cases, autonomic dysregulation produces bradycardia that may require administration of a drug with chronotropic effects such as dopamine. As in adults, the use of high-dose corticosteroids has been abandoned and is no longer recommended.[137]

Spinal cord decompression and spinal column stabilization are the most common indications for operative treatment. However, many spinal column injuries in children are managed nonoperatively until adolescence when treatment generally patterns what is recommended in adults. The outcome for children suffering an injury to the spinal cord is related to the level and severity of injury. In a series of children with injury to the cervical spine who were assessed using functional independence measures, most communicated independently, fed themselves independently, and had independent locomotive function following rehabilitation.[132] Review of the literature demonstrates that pediatric patients with traumatic SCI have a better neurologic recovery potential when compared to adults. If the injury is sustained prior to their adolescent growth spurt, unlike adults, they have a higher likelihood of developing scoliosis.[138]

Thoracic Injuries

Thoracic injuries account for 4% to 15% of pediatric trauma admissions. About 80% of thoracic injuries in children are from a blunt mechanism. Penetrating injuries are more likely to be lethal than blunt injuries. Isolated thoracic trauma has a mortality rate of approximately 5%. Children with combined head, thoracic, and abdominal trauma have a mortality rate that approaches 40%. Thoracic trauma is likely to be present in children who present with a low SBP, an elevated respiratory rate, and abnormalities on physical examination of the thorax.

Injuries to the lung and chest wall are the most common type of thoracic problem. Lung injuries, mainly contusions, account for almost half of all chest injuries. Chest wall injuries

(ribs and sternum) and pneumothorax/hemothorax account for about one-quarter each. Most of these can be managed with supportive care (oxygen, pain control, and physiotherapy) and, in some cases, a pleural drain. Injuries to the major airways, heart, and great vessels are much less common and compose less than 1% of all thoracic injuries.[139] They are much more likely to be lethal and often require an operation.

The child's thorax has unique anatomic and physiologic properties that are important to the diagnosis and treatment of thoracic trauma. The chest wall is more compliant in children because the ribs are more easily deformed and there is less muscle. This allows a greater transmission of energy to the intrathoracic organs when a blunt force is applied. The mediastinum is more mobile than in older patients, especially in young children. Unilateral changes in thoracic pressure, such as with a tension pneumothorax, can lead to a shift of the mediastinum that impairs venous blood return to the heart. Because the ribs of young children are more compliant, they tend to bend, not fracture. Consequently, rib fractures are relatively uncommon in young children. For the same reason, injuries to the lung, liver, and spleen lying underneath the ribs are more common.[34]

The assessment of a child with a suspected chest injury is based on the history, physical examination, and plain chest x-ray. A standard anteroposterior (AP) chest x-ray alone will reveal almost all significant chest injuries.[106,140] Although CT scanning will identify more injuries than conventional chest radiograph,[106] the results rarely lead to a change in management. CT scanning can be avoided in most cases of chest trauma to minimize radiation exposure, except for those with abnormal plain films, high-risk mechanisms, or abnormal physical findings.[141] Children who do not meet these criteria are very unlikely to have a significant chest injury.[77]

The history should document the circumstances of the injury, the subsequent course, and any interventions such as IV fluid administration or blood transfusion. The physical examination should include inspection for bruises and other external signs of injury; palpation for rib tenderness, crepitus, and tracheal deviation; and auscultation for diminished or asymmetric breath sounds. All victims of chest trauma should have a chest x-ray and a hemoglobin/hematocrit. If the clinical assessment supplemented by the chest x-ray and hematocrit is normal, no further diagnostic or therapeutic intervention is required. If the clinical assessment and/or the chest x-ray are abnormal, treatment can be initiated as appropriate, or further diagnostic tests can be ordered. Ultrasound examination of the chest (extended FAST [E-FAST]) has been reported for diagnosing a pneumothorax or hemothorax.[142] E-FAST may be more sensitive than a conventional AP chest x-ray in detecting a small pneumothorax or hemothorax. When a specific injury is suspected based on clinical assessment and plain chest x-ray, a CT scan, ultrasound, or transthoracic or transesophageal echocardiography can be used to confirm the diagnosis. Bronchoscopy is indicated in selected patients thought to have a major airway injury that is usually manifested by a massive or continuing air leak. Conventional angiography is seldom needed for diagnostic purposes.

RIB FRACTURES

Rib fractures are less common in children compared to adults.[143] This is believed to be because their ribs are flexible, so they tend to bend but not break. This is also why flail chest is much less common in children. Rib fractures following trauma indicate significant blunt force with an increased likelihood of serious injury. In a study of the NTDB, Rosenberg et al[144] showed that mortality doubled from 1.8% without rib fracture to 5.8% for one rib fracture and then nearly linearly increased to 8.2% for seven fractures. Children with two or more rib fractures were more likely to require a thoracostomy tube, thoracotomy, thoracoscopy, and/or laparotomy.[144] Rib fractures in children less than 2 years of age and posterior rib fractures are highly predictive of nonaccidental trauma.[145] The treatment of rib fractures in children is supportive. Pain management may include systemic analgesics, intercostal nerve blocks, and epidural analgesia.

PULMONARY CONTUSION

One of the most common thoracic injuries in children is a pulmonary contusion, which can occur with blunt or penetrating trauma. Pulmonary contusions decrease lung compliance and cause ventilation/perfusion mismatch. Both can lead to hypoxia. A chest x-ray taken during the initial assessment is the most common means of diagnosing a pulmonary contusion. CT is more sensitive and may show areas of pulmonary contusion not appreciated on a plain x-ray. However, contusions seen on CT but not visible on plain x-rays are of little clinical significance. Conversely, significant pulmonary contusion visible on plain x-ray correlates with impairment of oxygenation, carbon dioxide exchange, and duration of ventilator support.[146] Treatment of a pulmonary contusion includes appropriate fluid resuscitation, supplemental oxygen, pain management, and strategies to prevent atelectasis and pneumonia. Most children recover quickly from this injury, but some patients develop pneumonia or respiratory distress syndrome. In an occasional patient, a large pulmonary contusion may cause life-threatening hypoxia that cannot be supported with conventional or advanced techniques of ventilation including high-frequency oscillation. Extracorporeal life support has been used in extreme circumstances to support patients with severe pulmonary contusions and secondary respiratory distress syndrome.

PNEUMOTHORAX AND HEMOTHORAX

Most pneumothoraces can be definitively treated with a thoracostomy tube appropriately sized for the patient. A small pneumothorax without mediastinal shift that can be seen on CT, but not plain x-ray, does not require treatment.[107] A tension pneumothorax should be treated emergently as in an adult with a needle thoracostomy in the second intercostal space in the mid-clavicular line, followed by a chest tube in the anterior axillary line at the nipple level (Fig. 48-10). A hemothorax should be drained. Historically, a large chest tube was placed, but contemporary evidence suggests that a

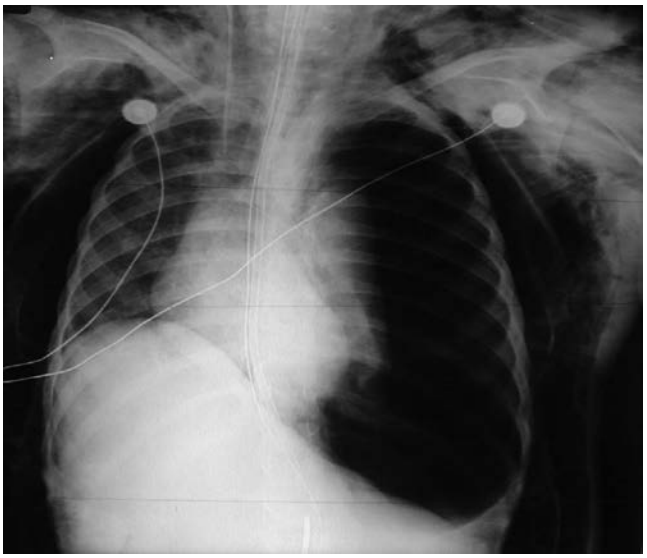

FIGURE 48-10 Left tension pneumothorax. Note flattening of the left diaphragm and deviation of the mediastinum to the right.

small-bore chest tube is equally effective as a large-bore tube and may reduce the risk of empyema[147] (Fig. 48-11).

Duration of tube thoracostomy and retained hemothorax appear to be the greatest risk factors for posttraumatic empyema.[148] Therefore, it is imperative that if a small-bore catheter is used, the chest is effectively drained and the chest tube removed as early as possible. Thoracotomy is indicated to control the bleeding if more than 15 mL/kg of blood drains immediately or if bleeding continues at a rate of greater than 2 to 3 mL/kg/h for 3 or more hours; this is rarely necessary in children.

MEDIASTINUM

Although extremely rare, tracheobronchial, cardiac, major blood vessel, and esophageal injuries do occur and should be ruled out. Major tracheobronchial injuries typically occur in the membranous part of the trachea or mainstem bronchus. They may cause a major air leak that leads to a tension pneumothorax and a massive ongoing air leak after placement of one or more chest tubes. When a lobe or lung fails to expand after placement of a chest tube, a major airway injury should be ruled out (Fig. 48-12).

These patients should be taken to the operating room for bronchoscopy and possible thoracotomy. Temporary control may be achieved by advancing an ETT beyond the leak, but open repair is often needed. Primary repair of a major airway injury is ideal, but when a lobar bronchus is completely avulsed, a lobectomy may be a better option.

Blunt cardiac injuries are rare. The most common type is a myocardial contusion for which there is no specific therapy.[149] Free wall rupture and valve disruption have also been reported, but survivors are rare. Free wall injuries may cause pericardial tamponade, which is manifest by pulsus paradoxus. FAST exam or echocardiography can confirm the diagnosis of pericardial effusion. Contusions may cause dysrhythmias and hypotension. The diagnosis of blunt cardiac contusion is largely based on clinical suspicion supplemented by electrocardiogram and serum cardiac enzyme levels. An echocardiogram is unnecessary except in the rare cases of cardiac failure or valve disruption.

Injuries to the great vessels do occur in children injured in high-speed highway crashes and other mechanisms characterized by great force and rapid deceleration, but they are rare. In a review of the NTDB, Heckman et al[139] found that only

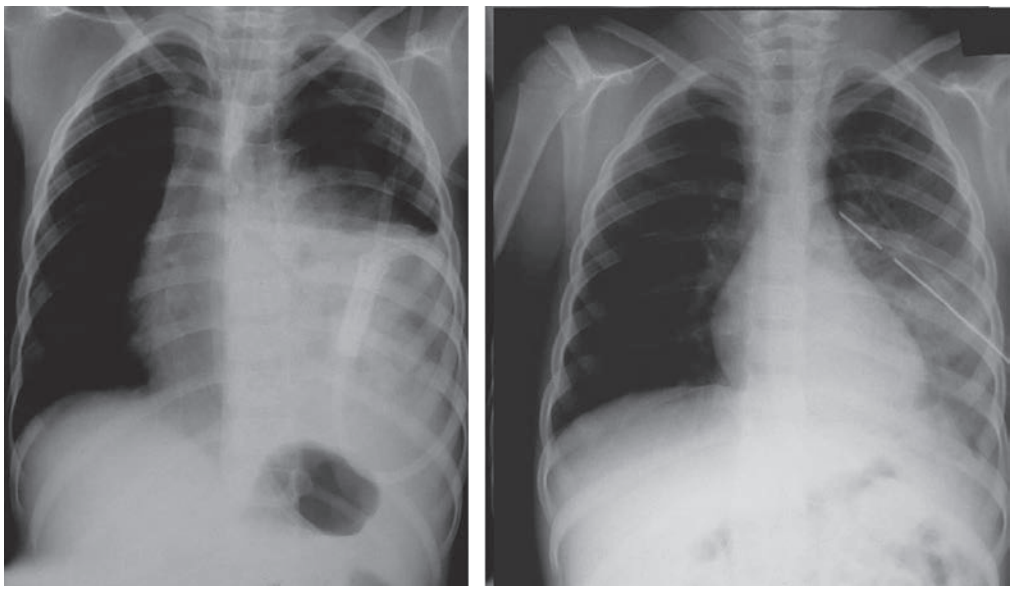

FIGURE 48-11 (**A**) Hemopneumothorax. (**B**) Complete resolution with no further intervention after evacuation of the air and blood by a chest tube.

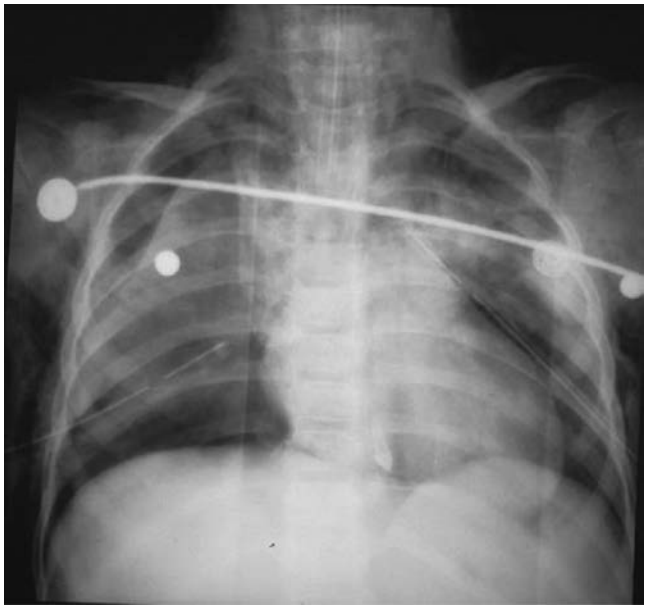

FIGURE 48-12 Major bronchial injury with large air leak and persistent pneumothorax despite intercostal drain.

34 (0.1%) of 26,940 patients suffered injury to the thoracic aorta, but the observed mortality was high (41%). The true incidence may be underestimated due to prehospital death.

Clinical predictors of thoracic aorta injuries include a low SBP on admission; increased respiratory rate; abnormal thoracic exam, especially on chest auscultation; an associated fracture of the femur; and a GCS of less than 15. If there is a high index of suspicion based on history, physical examination, or an x-ray of the chest, further testing is required. Helical chest CT and transesophageal ultrasound (echocardiography) have been found to be equally sensitive when compared with aortography in the detection of an aortic injury. Once the injury is found, the treatment of thoracic aortic injuries is like that in adults. β-Blockers should be started early. Treatment options include nonoperative management for minor intimal tears and operative management for more extensive injuries. Operative repair can be accomplished by thoracotomy and direct repair, usually with an interposition graft. Endovascular stent graft repairs have definite advantages, if a correctly sized graft is available.[150] The long-term outcome of endovascular stenting in children is unknown.

TRAUMATIC ASPHYXIA

This injury is caused by compression of the chest and upper abdomen that produces a marked elevation of pressure in the superior vena cava and its feeding branches. The clinical manifestations are swelling of the face and petechial hemorrhages in the skin above the nipple line and in the conjunctivae.[151] Occasionally, respiratory arrest due to hypoxia ensues, but most children recover uneventfully with supportive measures including elevation of the upper body and oxygen by mask or nasal cannula.

COMMOTIO CORDIS

A direct blow to the anterior chest, typically in the mid-sternal area, may cause sudden cardiac collapse from ventricular fibrillation. Mortality is high.[152] Young children appear most at risk due to their thin, pliable anterior chest that affords decreased protection to the heart. Age and participation in sports that risk a blow to the anterior chest appear to be the most important risk factors. In a review of the US commotio cordis registry, Maron et al[153] reported an overall mortality of 72%. From 1970 to 2012 survival has steadily increased from 10% to 58%, perhaps due to more rapid response times, access to defibrillation in the field, and improved public awareness of the condition.[153]

Abdominal Injuries

Blunt or penetrating forces can cause abdominal injuries, but blunt injuries are much more common in children. The most common causes are falls, motor vehicle crashes, and direct blows to the abdomen. Physical abuse or nonaccidental trauma is another important cause of abdominal injury in children.[154,155] Solid organ and hollow organ injuries are equally common in child abuse, but solid organ injuries are much more frequent in unintentional trauma. The most common abdominal injuries are to the solid abdominal organs—the spleen, liver, and kidneys. Injuries to the hollow structures—the stomach, duodenum, small bowel, colon, biliary and pancreatic ducts, renal pelvis, ureters and bladder, and major blood vessels—are relatively rare. Significant intra-abdominal injury may result from a relatively minor force, especially in young children, because of the lack of effective protection by the muscle layers of the body wall and the ribs primarily for the liver and spleen. The seat belt syndrome is a rare but important type of blunt abdominal trauma caused by compression of the bowel and/or the pancreas by a seat belt positioned above the pelvis against the spine in deceleration crashes. It may be associated with an unstable fracture-dislocation of the lumbar spine (Chance fracture) and occasionally with spinal cord injury. The hallmark is a transverse bruise across the lower abdomen.[156]

In general, there are two important types of intra-abdominal injury: solid organ injury (liver, spleen, kidney) that can cause bleeding and hollow organ injury (intestine, bile or pancreatic duct, renal pelvis, ureter, bladder) that can cause peritonitis and sepsis. Thus, it is useful to think about the assessment of abdominal trauma using this framework. Is there evidence for bleeding or peritonitis, the two key threats to life from abdominal trauma and the two key indications for an operation?

Clinical assessment is the most important step in the diagnosis of abdominal injuries because it is the best way to detect signs of bleeding or peritonitis. Abdominal CT with IV contrast is the best way to determine the exact nature of an intra-abdominal injury, but CT should be limited to patients in whom there is reason to suspect such an injury.[104] Not every "trauma" patient needs an abdominal CT scan.

The indications for CT scanning should ideally be defined by hospital-specific decision rules to avoid unnecessary radiation exposure.[77,111,141]

Clinical assessment is also the most useful guide to the treatment of abdominal trauma. CT will typically reveal the anatomy of an intra-abdominal injury, but it is not very helpful in deciding how to manage the injury. A CT scan is very useful in documenting the exact nature of an intra-abdominal injury, but the decision to treat nonoperatively or by laparotomy is almost always made on clinical grounds, not by the CT scan. We have found that children who present to the ED after blunt abdominal trauma by a nonmotorized force with a normal GCS and SIPA are unlikely to have a solid organ injury that will require intervention. For injured children who meet these criteria, it is safe to forgo a CT scan.[157]

The history should document the circumstances of the injury, especially the mechanism, the subsequent course, and any interventions, such as IV fluid administration or blood transfusion. The mechanism may point to a specific injury. For example, a blow from a bicycle handlebar may cause an injury to the gastrointestinal tract or pancreas. Blunt abdominal trauma without a clear mechanism in an infant should prompt consideration of child abuse.

The physical examination should include inspection for bruises, especially lap belt bruises and other external signs of injury, distension, presence or absence of bowel sounds, and focal or diffuse tenderness with or without rigidity. The seat belt sign, a well-defined transverse bruise, band of erythema, or skin abrasion across the lower abdomen, is associated with an increased risk of intra-abdominal organ injury, especially to the bowel and pancreas.[111,158,159] All victims of abdominal trauma should have a urinalysis and a hemoglobin/hematocrit. If the clinical assessment supplemented by the urinalysis and hematocrit is normal, no further diagnostic or therapeutic intervention is required. If there is hemodynamic instability with frank evidence of intra-abdominal bleeding or clear evidence of peritonitis, a laparotomy is indicated. For the majority of patients who fall between these extremes in whom the diagnosis is in doubt, further observation with repeat clinical evaluation and further diagnostic tests are indicated. This is especially true for patients with an abnormal GCS score. Nasogastric or orogastric drainage is indicated in all children requiring a laparotomy and in selected children undergoing observation and further workup, especially if they are obtunded, distended, or vomit frequently.

Liver function tests, serum amylase, and lipase may be helpful in patients with mild to moderate abdominal pain and tenderness who are suspected of having an intra-abdominal injury or injuries; however, an abnormal result is not a clear indication for a laparotomy or imaging. A CT with IV contrast may also help in these circumstances, especially if consciousness is reduced, as noted earlier. Conventional FAST examinations lack sensitivity in detecting abdominal organ injuries, and up to one-third of solid organ injuries will be missed by FAST.[57] Contrast-enhanced ultrasound (CEUS) may be an exception because there is evidence that CEUS may be more accurate than conventional ultrasound in detecting injuries to the liver, spleen, kidneys, and pancreas.[160] CEUS may be especially useful in the assessment of abdominal trauma due to low-energy mechanisms.[161] A conventional FAST examination may help to establish the presence of abnormal amounts of fluid in the abdomen; however, FAST has not been shown to be accurate enough for definitive diagnosis of abdominal injuries. FAST can be helpful in physiologically unstable patients who have other injuries that could be the cause of their instability but are too unstable for CT scanning.[57] Injuries to the liver and spleen are graded based on CT findings according to the organ injury scaling system developed by the American Association for the Surgery of Trauma.[162] This is the same system used for adults.

Minimally invasive surgery has been successfully applied to both blunt and penetrating abdominal injuries in adults and children both for diagnosis and definitive therapy. It should only be considered as an option in children who are hemodynamically stable. Laparoscopy can reduce the rate of nontherapeutic laparotomy, especially in penetrating trauma where the indication for surgical intervention depends more on the mechanism than the physiologic impact as in blunt trauma. Even in cases where conversion to an open procedure proves necessary, laparoscopy may allow better placement of a smaller incision instead of the conventional long midline laparotomy. On the down side, the risk of missing an injury to the bowel may be higher with laparoscopy than with an open laparotomy.

In cases of abdominal trauma in which the patient has lost physiologic and metabolic reserve evidenced by continuing shock with metabolic acidosis, hypothermia, and coagulopathy from massive blood loss, damage control surgery may be lifesaving. Damage control is most often needed in penetrating trauma cases with major vascular and/or intestinal injury or blunt liver injury with major damage to the hilum or retrohepatic venous structure. Damage control surgery aims to save the patient's life by doing only what is necessary to reverse the acidosis, hypothermia, and coagulopathy cycle. This is accomplished in three stages:

1. Focused operation to stop bleeding and further contamination
2. Resuscitation in the ICU including rewarming, transfusion, and hemodynamic support
3. Reoperation for definitive repair and wound closure

Switching to damage control should be considered when the patient's core temperature falls below 34°C, arterial pH falls below 7.2, international normalized ratio/prothrombin time are greater than 1.5 times normal, abnormal bleeding is observed, and cumulative blood loss exceeds 40 mL/kg or 50% of the baseline blood volume.[163]

DIAPHRAGM

Rupture of the diaphragm is rare in children, and most occur on the left side.[164] The usual mechanism is a high-energy abdominal injury such as can occur in a motor vehicle crash or fall from a great height. Children with a diaphragmatic

injury often suffer multiple injuries with high severity.[164] When the diaphragm is ruptured, the liver and spleen are often also injured. The diagnosis is most often made on plain abdominal or chest radiographs, but an apparently normal plain x-ray cannot exclude it. Diaphragm injuries are obvious when gas-filled bowel loops are seen in the chest, but they may be subtle. When suspected, repeat plain radiographs, ultrasound, or CT scan should confirm the diagnosis. Diaphragm injuries should be repaired urgently by a transabdominal approach.

GASTROINTESTINAL TRACT

Injuries to the bowel are relatively uncommon compared to injuries to the liver and spleen. Most are caused by a direct blow to a focused area of the abdominal wall from a seat belt, fist, handlebar, or butt end of a hockey stick or similar mechanism. The lap belt complex is a constellation of injuries due to a deceleration injury in a restrained child (Fig. 48-13). These children are often improperly restrained with the seat belt across the mid abdomen rather than the bony pelvis. A lap belt ecchymosis identifies a child at risk of pancreas injury, hollow viscus injury, major vascular injury, and spinal cord/column injury.[82,111,165] Holmes et al[111] reported that 5% of children suffering blunt injury required an intra-abdominal intervention when a lap belt ecchymosis was present. Contrast-enhanced CT is highly sensitive in the diagnosis of solid organ injury, but it is less sensitive in diagnosing injuries to the small and large bowel. Pneumoperitoneum and extravasation of enteral contrast indicate intestinal perforation, but they occur in less than half of cases. Suspicious CT findings include bowel enhancement/thickening, mesenteric stranding, and free fluid in the absence of a solid organ injury, but none of these is considered diagnostic. Occult intestinal perforation will cause peritonitis.[165] Diagnostic delay is not uncommon but does not appear to adversely affect outcome in children,[156,166] unlike in adults.[167] Repeated clinical assessment is performed with attention to unexplained tachycardia, fever, and/or peritoneal irritation.[168] Diagnostic peritoneal lavage or laparoscopy can be used to identify hollow viscus injury in the child with CNS injury, multiple injury, or equivocal findings of intestinal perforation.

(**A**) Characteristic abdominal wall ecchymosis demonstrating malposition of the restraint across the mid abdomen. (**B**) Abdominal computed tomography scan with free fluid without solid organ injury. (**C**) L2 compression fracture (Chance fracture). (**D**) Transection of jejunum visualized by laparoscopy.

Blunt force trauma can cause a contusion to the bowel that results in a mechanical obstruction, avulsion of the mesentery, or frank perforation. Delayed mechanical obstruction from a stricture or delayed free perforation may occur in an area of devascularization. Duodenal hematomas cause feeding intolerance and vomiting that is usually temporary. Ultrasound, upper gastrointestinal series, or CT can confirm the diagnosis of duodenal hematoma. The hematoma will usually resolve after a period of bowel rest. Surgical intervention is seldom needed. Contusions to the intestine may occur, and cases have been reported of delayed presentation of intestinal obstruction due to stricture or adhesions.[168] In the case of intestinal perforation, the injury is generally amenable to resection of the perforation and primary anastomosis.

LIVER

Liver injuries are very common but fortunately seldom require operative treatment. Almost all are caused by blunt trauma. The main risk is bleeding, but this is rarely life threatening since most liver injuries involve the parenchyma only, not the named perihepatic or intrahepatic vessels or biliary system. Most injuries to the liver heal spontaneously. Liver injuries are most commonly found on an abdominal CT scan. In rare cases, a major hilar, intrahepatic or retrohepatic blood vessel injury will present with massive blood loss that requires immediate laparotomy. A useful criterion for operative intervention is the estimated loss of greater than 50% of the circulating blood volume. Operations for massive liver bleeding can be very difficult, even lethal. It is very important to avoid intraoperative hypothermia, acidosis, and coagulopathy. An MTP should be invoked, and red blood cells, fresh frozen plasma, and platelets should be transfused in a 1:1:1 ratio. Direct repair of major hepatic and perihepatic vascular injuries should be attempted if it can be accomplished promptly with appropriate vascular control before the lethal triad of hypothermia, acidosis, and coagulopathy develops. Damage control surgery should be considered as an option, as in adult liver trauma. Liver packing and adjunctive therapeutic embolization have been reported in children.[169]

SPLEEN

Injuries to the spleen are also very common (Fig. 48-14). Almost all are caused by blunt forces. Patients with splenic injuries tend to fall into one of two groups: those with isolated splenic trauma often from a direct blow and those with splenic trauma in the context of multiple other significant injuries. The former almost always heal spontaneously and almost never need an intervention. The latter are more likely to require a blood transfusion and, in some cases, operative intervention. Some authorities have suggested that splenectomy rates be used as a quality measure of care given that splenectomy rates are higher in nontrauma centers compared to designated trauma centers.[170] Nonoperative management is recommended for all patients with blunt splenic injury who are hemodynamically stable. The main indication for operative intervention is failure to restore hemodynamic

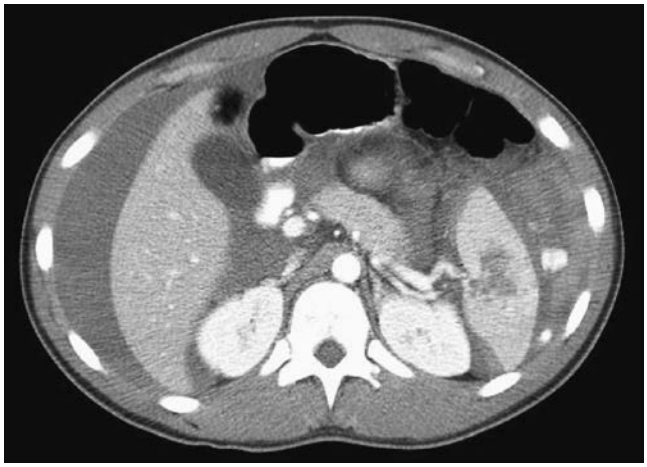

FIGURE 48-14 Splenic injury with a vascular "blush" sustained in a football game. The bleeding stopped after one transfusion.

physiology (pulse rate and blood pressure) in the normal range for the patient's age. As in liver trauma, a useful criterion for operative intervention is the estimated loss of greater than 50% of the circulating blood volume. If an operation is indicated, an attempt should be made to salvage the spleen by splenorraphy or partial splenectomy. Transarterial angioembolization (AE) has been used successfully in adults as an alternative to operative intervention. AE has been reported in children for various indications including active bleeding with an arterial blush on CT, hemodynamic instability, high-grade injury on the organ injury scale, and pseudoaneurysm formation, but experience in children is minimal and the indications for AE in children are not established.[171] If a laparotomy is undertaken, an attempt should be made to stop the bleeding and salvage the spleen by direct repair or partial splenectomy, leaving at least one-third of the splenic parenchyma with an intact blood supply. Prompt splenectomy should be carried out if the bleeding is massive or if there are other significant intra-abdominal injuries that need attention. Patients who require a splenectomy should receive appropriate immunization against the encapsulated organisms *Haemophilus influenzae* type B, pneumococcus, and meningococcus. For children with solid organ injury (liver, spleen, kidney), the success of nonoperative management approaches 95%.[172] Children who fail nonoperative management typically fail early, within the first 24 hours of injury. Children who are hemodynamically stable are admitted for a period of observation based on injury grade and discharged home with activity restrictions for 2 to 6 weeks (organ injury grade + 2 weeks). Follow-up imaging is not performed routinely.

PANCREAS

Blunt injuries to the pancreas are the fourth most common abdominal organ injury after the spleen, liver, and kidneys. They usually result from a direct blow from an object, such as a bike handlebar, or other similar mechanism that compresses the pancreas against the spine. Pancreatic injuries are difficult

to diagnose and may be missed at initial presentation. They are classified according to the organ injury scaling system developed by the American Association for the Surgery of Trauma.[162]

The most common symptoms suggesting pancreatic injury are fever, epigastric pain that radiates to the flank or back, anorexia, nausea, and vomiting. There is usually tenderness in the epigastrium. However, the symptoms and signs may be minimal in the initial 12 to 24 hours after injury even when the main duct has been disrupted. In the first few hours after injury, serum amylase levels have low sensitivity and specificity for major pancreatic trauma; persistent and rising elevations are more predictive.[173] CT scanning detects most major pancreatic injuries, although they may be missed on the initial study. Endoscopic retrograde cholangiopancreatography (ERCP) can be used to confirm and define the nature of a ductal injury[174] (Fig. 48-15). Magnetic resonance cholangiopancreatography (MRCP) is reported to be accurate in the identification of pancreatic ductal injury and may help to clarify the need for ERCP.[175] Stent placement by ERCP may be beneficial in cases of proximal duct injury.

Most pancreatic injuries, especially grade I and II injuries, will resolve spontaneously with the important exception of injuries to a major intrapancreatic duct. The management of pancreatic injury with ductal transection in children is controversial.[174,176] Pancreatic ductal injury can be successfully managed conservatively but usually only after a long period of pain, feeding intolerance, and parenteral nutrition. A pseudocyst may develop, requiring drainage. To avoid a prolonged recovery and complications, many experts advocate early distal pancreatectomy based on CT evidence of a transection of the main duct in the mid body of the pancreas. A multicenter study of the management of pancreatic injury in children found that children managed with distal pancreatectomy had earlier return to enteral feeding, shorter hospital stay, fewer procedures, and fewer pancreatic-related complications.[176] This multicenter experience suggests that pancreatic resection is superior to nonoperative management when the pancreatic duct is transected.

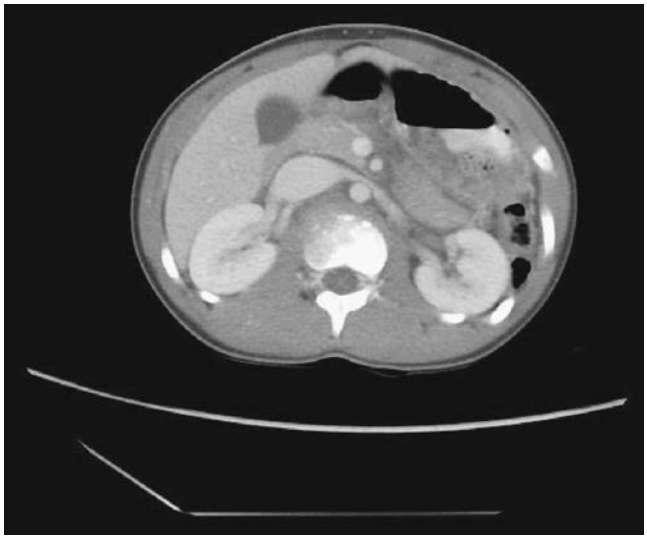

FIGURE 48-15 Transection of the mid body of the pancreas after a direct fall onto a bicycle handlebar. Major duct disruption was confirmed by endoscopic retrograde cholangiopancreatography. The child recovered promptly and uneventfully after a laparoscopic distal pancreatectomy.

KIDNEY

Blunt injuries to the kidneys are common. Some, but not all, result in gross or microscopic hematuria.[177] Contusions are the most type of blunt kidney injury. Almost all heal spontaneously, but in rare cases, massive damage to the kidney results in major bleeding that produces hemodynamic instability and requires surgical intervention, usually a nephrectomy. Four-phase abdominal CT IV contrast is the recommended diagnostic test to define kidney injuries.[178] There are limited reports of therapeutic angiographic embolization to control renal hemorrhage.[169] In some cases, a urine leak from the collecting system is noted on the CT scan. Most of these will also heal spontaneously. Ureteral stenting may facilitate healing of urine leaks. Injuries involving the renal arteries, either frank disruption or an intimal tear that impairs blood flow, are another type of rare kidney injury. These are seldom recognized promptly enough to salvage the kidney.

BLADDER

Bladder injuries are uncommon in children.[179] They typically occur in the setting of pelvic fracture or direct blows to the lower abdomen in the presence of a full bladder.[180] Injury is suggested by gross hematuria.[181] Extraperitoneal injuries generally resolve with urethral drainage. Intraperitoneal injuries require surgical repair.[179]

VASCULAR INJURY

Vascular injuries are uncommon in children. In a review of the NTDB, Barmparas et al[182] found that the incidence of vascular injury was 0.6% in children less than 16 years of age. Over the age of 16 years, the incidence increased to 1.6%. The most common site of vascular injury occurred in vessels of the upper extremity. The incidence of thoracic aortic injury was extremely low (0.03%).[182] Iatrogenic injury is most common in young children usually from diagnostic catheterization, cannulation for extracorporeal membrane oxygenation, vascular access, or arterial/venipuncture.[183] Collateralization is more rapid in infants and the very young. Therefore, a nonoperative approach with anticoagulation and observation is generally pursued in iatrogenic injury if the limb is not threatened.[184] If successful, periodic reevaluation becomes necessary to ensure that limb length discrepancy or claudication does not develop over time due to inadequate blood supply in the growing extremity.

Noniatrogenic injury increases with age. Most are penetrating. In a large civilian experience, Corneille et al[185] reported that 1.4% of injured children suffered vascular injury with a mean age of 12.7 ± 4.1 years. Nearly two-thirds sustained

vascular injuries following penetrating trauma. One-third of patients with torso vascular injury died. Primary repair was the most common technique used in arterial repair, and limb salvage was possible in 97.4%.[185] Outcome of extremity vascular injury is determined by early diagnosis and treatment. Delayed diagnosis is associated with poorer outcome. Assessment proceeds as in the adult with examination directed to hard or soft signs of vascular injury. An arterial pressure index (API) should be measured in children without absolute indications for exploration. An API less than 0.9 suggests that a vascular injury may be present, and a CT arteriogram (CTA) should be considered. CTA can be used in children with comparable results to adults.[186]

Blunt pediatric vascular injury is less common than iatrogenic or penetrating vascular injury. Supracondylar fractures are the most common cause of limb ischemia in children, with neurovascular complications reported in up to 24%. Due to collateral circulation at the elbow, obvious limb ischemia and injury to the brachial artery may not be evident. Louahem et al[187] reported a 14% incidence of ischemia in supracondylar fractures prior to reduction; 1% demonstrated delayed return of pulse after reduction, but none required revascularization. The authors suggest that anatomic reduction of the fracture, early fixation, and a conservative approach will result in good outcome.[187] In a review of the NTDB of children sustaining blunt brachial artery injury managed either with observation or arterial reconstruction, Tan et al[188] found that both approaches resulted in similar outcomes, suggesting that arterial reconstruction does not confer significantly better outcome than nonoperative management, particularly in those age 0 to 6 years. Mommsen et al[189] reported that lower vascular injury following blunt injury was associated with severe limb trauma and a lower limb salvage rate of 69%. Arterial injuries were managed with primary repair, patch, or graft for revascularization, with the most common site being the femoral artery. The impact of mangled extremity and blunt force mechanism on limb salvage is demonstrated by 100% limb salvage when mangled extremity severity score is less than 7 that falls to 33% with a score of greater than 7.[189]

Blunt cerebrovascular injury (BCVI) occurs in approximately 0.1% of adults following blunt trauma. If asymptomatic patients are screened, the incidence increases to 1%.[190] The incidence appears lower in children. In a review of the NTDB, Lew et al[191] reported that 0.03% of blunt-injured children suffered BCVI. Injuries associated with an increased risk included chest trauma (fourfold), combined head and chest trauma (sixfold), basilar skull fractures (fourfold), intracranial hemorrhage (sixfold), and clavicle fractures (eightfold), but these differ from most screening criteria used in adults. A third suffered neurologic complications. Since most asymptomatic children do not undergo screening, the true incidence is unknown. In a study of six Level I pediatric trauma centers, Azarakhsh et al[192] found that only 17% of children with one or more adult screening criteria underwent diagnostic imaging (CTA or magnetic resonance angiography), likely due to concerns for radiation exposure from imaging. Jones et al[193] reported in a series of children with BCVI that 22% developed a stroke 17 ± 6 hours after injury (range, 1–72 hours) and adult screening indications were absent in two-thirds. In asymptomatic children who underwent screening CTA and treatment with antithrombotic agents, 31 of 32 remained asymptomatic.[193] In contrast, Kopelman et al[194] found in that in children with BCVI, Eastern Association for the Surgery of Trauma screening criteria were present in 91% of the patients, and of those studied, the incidence of BCVI was 21%. As in the study by Jones et al,[193] no patient treated suffered a stroke.[194] The failure to detect the injury prior to the onset of symptoms leads to a marked increased risk of stroke, arguing that children at risk of BCVI should undergo screening. Using computer modeling, Malhotra et al[195] concluded that selective CTA in high-risk patients and selective anticoagulation are the optimal strategy in children.

For arterial reconstruction in young children, primary repair or autologous vein graft is generally preferred. For extremity vessels in the young, microsurgical repair may be necessary. Vein grafts in children are prone to aneurysmal dilatation. Prosthetic grafts may be used for larger vessel (>6 mm) reconstruction, but with growth, the graft may become a fixed point of stenosis requiring later revision. One of the largest experiences of pediatric vascular injury was accrued by the military in the management of wartime injuries in the Iraq and Afghanistan conflicts from 2002 to 2011; 155 children sustained penetrating vascular injury involving the extremity (65.9%), torso (25.4%), and neck (8.6%). Survivors with extremity vascular injury underwent vessel ligation or arterial reconstruction using greater saphenous vein or synthetic grafts. Limb salvage was achieved in 95%. The authors attributed the high limb salvage rates to damage control resuscitation, use of vascular shunts, regional or systemic anticoagulation, and liberal use of fasciotomy. A mortality rate of 18% was observed for both upper or lower extremity vascular injury, but mortality was increased fourfold in children with penetrating torso vascular injury. Good short-term results were achieved, but as the authors recognize, the long-term outcome of these children undergoing vascular reconstruction remains unknown.[196]

Successful endovascular repair of a pediatric aortic injury or other great vessel injury has been reported[150] (Fig. 48-16). Current access systems, small access or target vessels, and available stent or endograft size in conjunction with growing blood vessels that can lead to graft migration limit widespread application in children. Current limitations suggest that it is unlikely that the endovascular approach will supplant open repair except in adolescents with aortic injury, in those with access vessels and target vessels of adequate size, and in children in whom further growth is unlikely, reducing the risk of graft migration. Since the natural history of endografts or stents in children is unknown, treatment with endograft placement will necessitate lifelong surveillance.

Venous Thromboembolism

Injured children have a low incidence of venous thromboembolism (VTE) relative to adults. A decreased capacity to

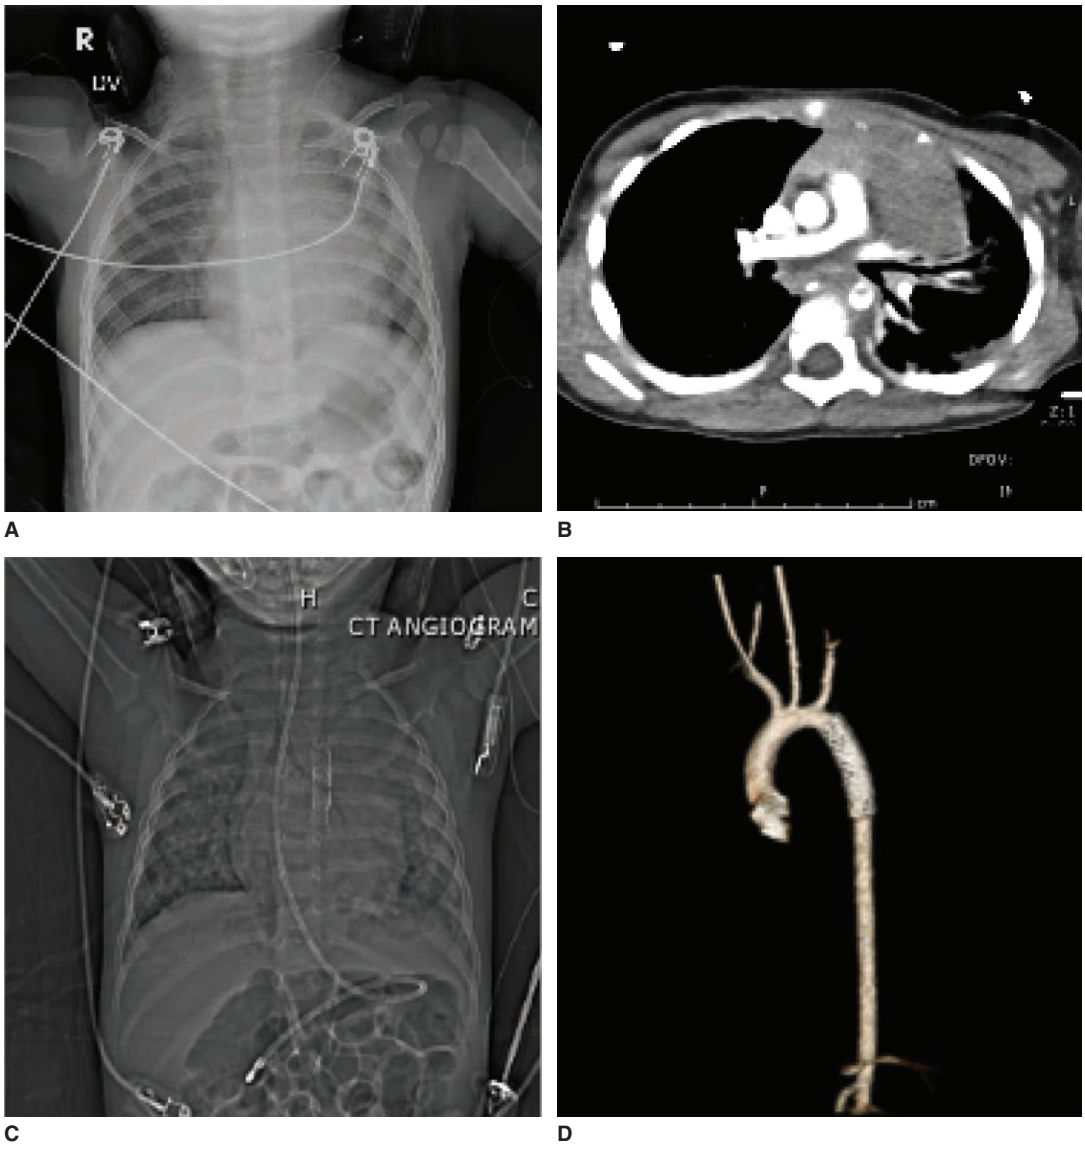

FIGURE 48-16 Two-year-old crushed by a trailer at low speed. (**A**) Chest radiograph demonstrating right rib 1 to 3 fractures and loss of the aortic knob. (**B**) Computed tomography (CT) angiogram demonstrating periaortic hematoma with dissection. (**C**) Radiograph following successful percutaneous placement of aortic stent. (**D**) CT angiogram three-dimensional reconstruction demonstrating aortic stent without extravasation.

generate thrombin, increased capacity of α_2-macroglobulin to inhibit thrombin, and enhanced antithrombotic potential by the vessel wall have been implicated as possible reasons for the low incidence of VTE during childhood.[197] The annual incidence is 5 per 10,000 hospital admissions of children.[198] Two peaks are observed, the first in the neonatal period and the second in adolescence. Teenage girls demonstrate double the rate of VTE compared to teenage boys, which is in part attributed to the effects of pregnancy or contraceptives. Central venous catheter is the most important risk factor for VTE in children, including trauma patients. Hanson et al[199] found that 67% of VTEs occurred at the site of a previous or existing central venous line. The rate of VTE in injured children is 3.3 per 1000 admissions. Children with VTE tend to be older and have higher Injury Severity Scores. Additional risk factors include thoracic injury and spinal injuries.[200] In a study of pediatric trauma patients, Van Arendonk et al[201] found that the risk of VTE was low in children less than 12 years old, but increased to 0.3% in those age 13 to 15 years and to 0.8% in those age 16 years or older. In support of this observation, Liras et al[202] measured hypercoagulability using thromboelastography maximal amplitude in trauma patients. They found that hypercoagulability and the risk of VTE increased with age in children up to age 15 years (1–12 years, 1.5%; 13–14 years, 2.3%, 15 years, 5.1%) but fell to 3.6% in those age 16 to 30 years.[202] In one study, children at high risk of bleeding were defined as those older than age 13 years with four or more of the following: projected immobility greater than 5 days, GCS less than 9, presence of a central venous line, spinal cord injury, complex lower extremity

Summary of EAST and PTS recommendations for VTE prophylaxis in children hospitalized following trauma

Question	Recommendation
1. Pharmacologic Prophylaxis in Children Hospitalized after Trauma	1. In children hospitalized after trauma who are at low risk of bleeding, we conditionally recommend pharmacologic prophylaxis be considered for those >15 y old and in younger postpubertal children with ISS >25. We conditionally recommend against the use of routine pharmacologic prophylaxis in prepubertal children, even with ISS >25.
2. Mechanical VTE Prophylaxis in Children Hospitalized after Trauma	2. In children hospitalized after trauma, we conditionally recommend mechanical prophylaxis be considered for those >15 y old and in younger postpubertal children with ISS >25 versus no prophylaxis or in addition to pharmacologic prophylaxis.
3. Active Ultrasound Surveillance for VTE in Children Hospitalized after Trauma	3. In children hospitalized after trauma, we conditionally recommend against active surveillance for VTE with ultrasound compared with daily physical examination alone for earlier detection of VTE.

FIGURE 48-17 The Pediatric Trauma Society (PTS) and the Eastern Association for the Surgery of Trauma (EAST) evidence-based recommendations for venous thromboembolism (VTE) prophylaxis for children hospitalized after trauma in 2017. ISS, Injury Severity Score. (Adapted with permission from Mahajerin A, Petty JK, Hanson SJ, et al. Prophylaxis against venous thromboembolism in pediatric trauma: a practice management guideline from the Eastern Association for the Surgery of Trauma and the Pediatric Trauma Society. *J Trauma Acute Care Surg*. 2017;82(3):627-636.)

fracture, operative pelvic fracture, use of inotropes, CPR during resuscitation, exogenous estrogen, chronic inflammatory state, history of previous clot, known thrombophilia, and current malignancy. Patients with a low risk of bleeding were administered chemoprophylaxis with low-molecular-weight heparin subcutaneously twice daily. High-risk patients in danger of bleeding underwent screening ultrasound on pediatric ICU (PICU) day 7. A decrease in total VTE and clinical VTE was observed after guideline implementation without an increase in bleeding complications.[199] Unlike adults, there are a limited number of studies in children regarding the risks and benefits of VTE prophylaxis. Applying the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) methodology, the Pediatric Trauma Society and the Eastern Association for the Surgery of Trauma proposed evidence-based recommendations for VTE prophylaxis for children hospitalized after trauma in 2017 (Fig. 48-17).[203] More definitive guidelines will likely emerge only after the conduct of clinical trials examining the benefit of VTE prophylaxis in critically ill or injured children.

Musculoskeletal Injuries

Musculoskeletal trauma is common in children and accounts for up to 25% of all traumatic injury in children. Contusions, open wounds, sprains/strains, and fractures are the leading reasons for musculoskeletal evaluations in children and adolescents, and approximately 15% will be admitted to the hospital. Of children hospitalized, Galano et al[204] found in review of the Kids' Inpatient Database that the most common injuries were femur fracture (21.7%), tibia and/or fibula fracture (21.5%), humerus fracture (17.0%), radius and/or ulna fracture (14.8%), and vertebral fracture (5.2%). Most significant injuries result from falls, motor vehicle crashes, and auto–pedestrian accidents, but in young children or infants, fractures from child abuse must be considered.[205] In children less than 18 months of age treated for lower extremity fracture in a Level I pediatric trauma center, 41 of 55 lower extremity fractures were attributed to abuse, and the most common fracture was of the femur.[206]

Pediatric bone is less dense and more porous than adult bone. The increased porosity of pediatric bone allows for greater energy absorption and decreases propagation of fracture lines, which in part explains the infrequency of comminuted fractures in children. The increased porosity, however, leads to increased susceptibility to compression force. The periosteum is thick relative to adults and minimizes fracture displacement. The periosteum may tear on the side of the fracture but remains intact on the opposite side, resulting in a unique fracture pattern not observed in adults. In a greenstick fracture, the bone is fractured with only partial disruption of the periosteum, resulting in angulation without displacement. In the torus fracture or buckle fracture, there is compression of the bone. Finally, injury can occur without visible evidence of a cortical fracture, and the periosteum remains intact but a bend in the bone is observed.

The physis or growth plate of developing bones provides longitudinal growth. It is the weakest part of the bone. Compression, avulsion fractures, or fractures involving the articular surface may occur. Up to a third of fractures in children involve the growth plate.[207] The Salter-Harris (SH) classification stratifies injury to the physis and guides management. Type I injuries are separations of the growth plate without bony fracture. Type II fractures include a variable amount of metaphseal bone with the epiphyseal fragment, and the fracture line is the same as in Type I fractures, except where it extends into the metaphysis. Type III injuries include a physeal component as in type I, with an extension of the fracture line through the epiphysis into the joint. Type IV injuries are characterized by the fracture line extending through the epiphysis, physis, and metaphysis. These injuries will result in premature arrest if not anatomically reduced. Type V injuries are crush injuries to the plate (Fig. 48-18).

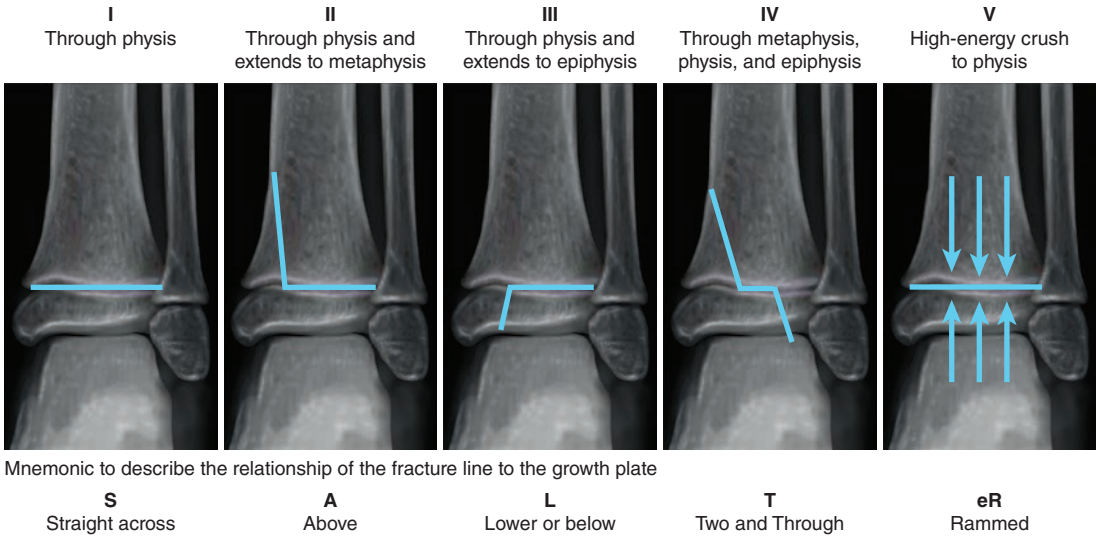

FIGURE 48-18 Salter-Harris classification of physeal fractures. (Reproduced with permission from Jones C, Wolf M, Herman M. Acute and chronic growth plate injuries. *Pediatr Rev.* 2017;38(3):129-138. Copyright © 2017 by the AAP.)

Complete injury to the physis may result in arrest of longitudinal growth. Incomplete injury may result in angular deformity. Other complications include malunion, nonunion, or avascular necrosis. SH types III and IV fractures that involve the resting layer of the physis are most at risk of growth disturbance. The most frequent sites of physeal fracture associated with abnormal growth are the distal femur, proximal and distal tibia, and distal radius. In a review of the literature, Basener et al[208] found that 52% of distal femoral growth plate fractures had some form of growth disturbance and 22% developed a leg length discrepancy of greater than 1.5 cm. SH I fractures had the lowest incidence of growth disturbance, whereas SH IV fractures had the highest rate of growth disturbance.

Examination is directed to sites of deformity, swelling, tenderness, ecchymosis, and/or soft tissue injury. Minimal findings may be present in children, and a high index of suspicion is necessary for diagnosis. In the fractured extremity, a neurovascular examination distal to the area of suspected fracture should be performed. The fracture should be splinted to reduce pain and avoid further injury. Plain radiographs are used to confirm fractures and should include the joint proximal and distal to the fracture. If there is overlying soft tissue and proximity to a joint, then involvement of the joint should be excluded. Management of the fracture may include open or closed reduction and, less commonly, skeletal traction or external fixation. The choice in treatment is influenced by age, location of the fracture, and the extent of soft tissue injury. Healing of fractures in children is more rapid than in adults. A stable union can be achieved in a neonate within 1 week. This is attributed to the thick periosteum that reduces the extent of bone injury, stabilizes the fracture, and is the major contributor to new bone formation. Children demonstrate the ability to remodel, and young children demonstrate the greatest remodeling potential. However, children are also at increased risk of overgrowth, deformity, or growth arrest, with the latter associated with injury to the growth plate.

In children with significant crush injury, ischemia, or closed fracture with significant bleeding, the extremity should be assessed for signs of compartment syndrome. Significant pain, especially with flexion, suggests the diagnosis. Paresthesia, pallor, paralysis, and pulselessness are later findings. Ferlic et al[209] reported a 3% incidence of acute compartment syndrome in children with lower extremity fracture that resulted from high-energy transfer. The time to diagnosis averaged 17 hours but was observed as late as 65 hours after injury.

Pediatric pelvic fractures are infrequent in children and account for only 1% to 2% of fractures. Pelvic fracture generally follows motor vehicle crash or auto–pedestrian accident. Children with pelvic fracture and concomitant multisystem injury demonstrate the same risk of death as adults (5%).[210] Chia et al[211] found that 78% of children with pelvic fracture had an associated injury, with a third requiring surgery. Similarly, Spiguel et al[212] reported a high incidence of associated organ injury involving two or more organ systems: neurologic, 54%; vascular, 39%; pulmonary, 31%; and genitourinary, 15%. AP radiographs and CT are used to identify the fracture and associated injuries. Hemorrhage or death from exsanguination from pelvic fracture is rare in children.[83] The use of therapeutic AE[213] and preperitoneal pelvic packing[214] to control bleeding in children with pelvic fracture has been reported. Similarly, the risk of genitourinary injury appears low. In a series of 212 children with pelvic fracture, Tarman et al[180] found that 14% had hematuria but only 2 (0.9%) of 212 sustained significant injury to the bladder or urethra. Treatment is individualized based on patient age, fracture classification, and stability of the pelvic ring. Pelvic ring injuries tend to be more stable, as the relatively thick periosteum restricts bony displacement. Most pelvic injuries in children are treated nonoperatively with weight bearing and gradual return to activity. Operative fixation is recommended for acetabular fractures with displacement, intra-articular fracture, and pelvic ring fracture with significant displacement.

CHILD ABUSE

In 1962, Kempe et al[215] published a landmark article titled "The Battered-Child Syndrome," which described a collection of injuries from repeated beatings. This article led to the mandate that all physicians should be required to report confirmed or suspected instances of child abuse.[215] Since then, the incidence of child abuse, often referred to as nonaccidental trauma or sometimes as nonaccidental injury, has increased exponentially. Annually, 3 million cases of child abuse and neglect are reported to child welfare systems in the United States each year. One-third are substantiated (around 12 per 1000 children).[216] Pediatric hospitals, especially trauma centers, receive and care for many abused children. Pediatricians with specialized training in this field are commonly asked to provide their expertise in the workup and identification of the perpetrator, potential mechanisms and outcomes of physical abuse, and long-term care. There is often a strongly associated social component. Rubin et al[217] reported that, in a cohort of abused children, 72% came from single-parent households, 37% had mothers whose age was less than 21 years, and 26% had a history of prior child welfare involvement in their families. Regardless, it is important to emphasize that the potential for child abuse is present in all socioeconomic classes. An organized approach with participation of abuse specialists, social workers, and child protective services is essential in assessing the circumstances that contributed to the child abuse and facilitate placement of the victim and siblings into a safe environment after hospital discharge. Some medical disorders may mimic child abuse, including accidental bruising, bleeding disorders, and skeletal diseases such as osteogenesis imperfecta and rickets, but these are rare.[218]

Abusive injuries have been reported for virtually every organ in the body. Infants are at the greatest risk for abusive head trauma (AHT) or shaken baby syndrome, the leading cause of fatal head injuries in children less than 2 years of age. A recent consensus report by experts in the field put to rest a number of alternative theories that have been proposed to explain some cases of suspected AHT.[219] As children age, soft tissue injury, fractures, and thoracic and abdominal visceral injuries become more prevalent. In a systematic review of children suffering abusive visceral injury, Maguire et al[154] found that abused children with visceral injury were younger (2.5–3.7 years) and more likely to die (53%) in comparison to children suffering unintentional injury (age 7.6–10.3 years; mortality 21%). Child abuse represents 3% to 4% of all cases seen in pediatric trauma centers but accounts for a disproportionate share of mortality in the very young. In one recent report from two Level I pediatric trauma centers, physical child abuse caused more than 50% of all infant trauma deaths.[220]

Clinicians must be familiar with the signs of child abuse to protect and care for those who cannot protect themselves. A thorough history and physical examination are the key to the diagnosis of physical child abuse (Table 48-3). Suspicion should be raised if there is a discrepancy between the history and the extent of injury, if there are explanations that do not fit, or if there are long periods between the time of the incident and the time to medical attention. Often the reported mechanism of injury is a fall from a crib, couch, or bed while the child was unattended. The risk of death for infants and children up to age 5 years from falls less than 1.5 m is less than one in a million.[221] Tarantino et al[222] showed that few children falling from heights of less than 4 ft suffer serious or life-threatening injury, so if a life-threatening injury is present with a history of a fall from less than 4 ft, the likely cause is abuse. Any significant injury occurring after a relatively minor mechanism should prompt further investigation. Unexplained events such as loss of consciousness should be questioned. A history of repeated trauma treated at different EDs with "doctor shopping" is suspicious. Fractures from different time periods as well as long bone fractures in children under 3 years of age should alert the clinician to the possibility of child abuse. A history that changes over time or between caregivers and inappropriate responses by the parents or other caregivers to the medical opinions given should raise concern for abuse. Finally, it is important to observe the relationship between the child and the parents to judge whether the relationship appears strained or inappropriate.

On examination, it is very important to look for and document bruising. Multicolored bruises suggest repeated injury over time. Bruising patterns can distinguish abusive from accidental injury. Pierce et al[223] found that bruising was common in both groups; however, bruises of the torso, ear, or neck in

TABLE 48-3: Components of the History and Physicial Examination Suspicious for Child Abuse

History components for physical abuse

- No explanation or vague explanation given for significant injury
- Explicit denial of trauma in a child with obvious injury
- Details of the history change
- Explanation provided is inconsistent with pattern, age, or severity of injury
- Explanation is inconsistent with child's physical or developmental capabilities
- Unexplained delay in seeking medical care
- Different witnesses provide different explanation for injuries
- Patient, caregiver, or witness gives history of inflicted injury

Physical examination components for physical abuse

- Any injury to a preambulatory infant, including bruises, mouth injury, fracture, and intracranial or abdominal injury
- Injuries to multiple organ systems
- Multiple injuries in different stages of healing
- Patterned injuries
- Injuries to nonbony locations, such as the torso, ears, face, neck, or upper arms
- Significant injuries that are unexplained
- Additional evidence of child neglect or failure to thrive
- Different forms of injury present (eg, burns, fractures)

a child 4 years of age or younger and bruises in any region for an infant less than 4 months of age are predictive of abusive injury. Peculiar injuries such as bites, cigarette burns, or rope marks as well as sharply demarcated second- and third-degree burns in patterns that suggest forceful immersion in hot water indicate abusive injury. Other concerning injuries are those in odd places such as the perioral, genital, or perianal areas. Old scars or healed fractures on x-ray are suspicious for repetitive abuse. Long bone fractures in children younger than 3 years old, multiple subdural hematomas, especially without a new skull fracture, and retinal hemorrhages are all highly predictive of abuse. Head injury is more severe and mortality increased in AHT when compared to accidental head injury[224] (Fig. 48-19). Roach et al[119] found that children with AHT had higher rates of diffuse axonal injury, subdural hemorrhage, skull fractures, and epidural hemorrhages when compared to unintentionally brain-injured children. Moreover, mortality was threefold greater in the AHT cohort.[119] Similarly, an acute abdomen in a young child following minor trauma should arouse suspicion. Approximately 10% of abused children will suffer visceral injury, and nearly half of those will require a laparotomy due to the frequency of intestinal perforation.[155]

FIGURE 48-19 Axial image of a computed tomography scan of the brain performed without intravenous contrast shows large, bilateral, low-density, extra-axial fluid collections that are subdural hematomas. In the frontal aspect of the left chronic subdural hematoma, a linear focus of high density is seen, and this represents an area of acute subdural hematoma within the chronic subdural hematoma. (Reproduced with permission from D'Alessandro DM, D'Alessandro MP. How old are those subdural hematomas? December 3, 2007. Pediatric Education.org. https://pediatriceducation.org/2007/12/03/how-old-are-those-subdural-hematomas/. Accessed January 22, 2020.)

Any child suspected of suffering nonaccidental injury should undergo comprehensive evaluation that includes a skeletal survey to identify new and old fractures, careful examination of the skin, and, in the setting of TBI, a fundoscopic examination for retinal hemorrhages. CT scans and MRIs should be obtained according to clinical indications. It is important to consider that up to a third of confirmed cases of abuse will not be recognized by physicians during the initial evaluation.[225] The presence of acute respiratory compromise before admission; bruising of the torso, ears, or neck; bilateral or interhemispheric subdural hemorrhages or collections; and any skull fractures other than an isolated, unilateral, nondiastatic, linear, parietal fracture in acutely head-injured children age less than 3 years old admitted to the PICU is predictive of child abuse.[226] Examining physicians in all 50 states are required to report any case of suspected abuse to Child Protective Services (CPS). Once reported, it is up to CPS to investigate and proceed with the appropriate measures. In a series of children who survived AHT, a third were discharged to foster care (39%) or relatives (16%), but nearly a fourth of abused children were returned to their home and parents. Even more alarming, successful prosecution of the assailant occurred in less than a third of all cases despite the fact that the perpetrator was known in 42% of cases.[224]

CONCLUSION

Pediatric trauma is a major public health issue. Injury rates and deaths have declined significantly over the past 30 to 40 years, but trauma is still the leading cause of death for children in most parts of the world. Efforts should continue to expand pediatric prehospital resources and pediatric trauma centers within the United States and around the world. The spectrum of injuries and the systematic approach to the diagnosis and treatment of injured children are modeled after the care of the adult trauma victim. As in adults, most pediatric trauma patients are otherwise healthy, and a good recovery is achievable except for those with severe CNS trauma. There are many unique aspects to pediatric trauma. Most injuries are blunt. Child abuse is common in infants and toddlers. The child's airway is easily compromised. Massive blood loss may be masked by a normal or near-normal SBP. A tool such as SIPA can facilitate shock recognition. CT scans account for most of the radiation exposure of trauma patients, with the greatest risk from exposure in children.

Geriatric Trauma

Deborah M. Stein • Angela M. Crawford • Jay A. Yelon

KEY POINTS

- For the year 2016, the National Trauma Data Bank noted that 43% of all patients in the registry were 55 years or older and the mortality for this group was 58% of all deaths reported.
- There is evidence that immune function is significantly attenuated during the aging process and that cytokine response is impaired as well.
- In the event of hypovolemia secondary to trauma, the "stiffer" heart with atherosclerotic changes in elderly patients may be unable to compensate with tachycardia and an increase in cardiac output.
- The Trauma-Specific Frailty Index includes reviews of comorbidities, daily activities, health attitude, sexual function, and albumin level.
- In the National Trauma Triage Protocol, a systolic blood pressure of 110 mm Hg in an injured patient 65 years of age or older is a criterion for transport to a trauma center.
- When performing rapid sequence intubation in an elderly patient, the doses of induction agents may need to be reduced between 20% and 40% to minimize the risk of cardiovascular depression.
- Elderly patients on anticoagulants who have had a negative computed tomography (CT) scan of the brain after injury should have a follow-up CT of the brain before discharge from the emergency department, although the time frame for observation is controversial.
- Many of the falls in older trauma patients are from a standing height but still lead to significant injuries requiring hospitalization.
- Preexisting conditions such as cirrhosis, congenital coagulopathy, chronic obstructive pulmonary disease, ischemic heart disease, and diabetes mellitus have a significant negative impact on mortality in older trauma patients.
- Mortality in elderly trauma patients is significantly reduced in an intensivist-model intensive care unit (ICU) as compared to an open-model ICU.

INTRODUCTION

According to census projections, the elderly population in the United States, defined as age more than 65 years, is experiencing the largest growth in history. Members of the post–World War II "baby boom" (75 million people born from 1946 to 1964) were 46 to 64 years old in 2010.[1] In 2014, there were more than 40 million elderly Americans (age ≥65 years) representing 14.5% of the US population. By the year 2060, it is projected that the elderly sector of the population will more than double to about 98 million.[2]

The ever-increasing mobility and active lifestyles of today's elderly place them at increased risk for serious injury. In fact, data from the National Trauma Data Bank (NTDB) for the year 2016 revealed that 43% of all patients in the registry were 55 years old or older and the mortality for this group was 58% of all deaths reported to the NTDB.[3] Injury is now the seventh leading cause of death in the elderly population.[4]

The elderly have a higher morbidity and mortality, have more preexisting medical problems, and demonstrate a senescent physiologic response to injury when compared to younger individuals. The reasons for the differing response are unknown; the literature is contradictory in places, and there are a limited number of prospective randomized trials that focus specifically on the elderly. This is best demonstrated by a lack of consensus on the definition of what age constitutes elderly. Historically, geriatric patients were considered to be patients over the age of 65 years, as noted earlier; however, there are a variety of organ-specific injuries that demonstrate rising morbidity and mortality at chronologic ages less than 65 years. As such, elderly patients should be assessed by the

degree of frailty and viewed from the vantage of the physiologic response to an injury or injury complex rather than a specific age. Despite these limitations, this chapter focuses on an overview of care for the injured geriatric patient.

AGING

Declining cellular function is part of the aging process. Eventually, this will lead to organ failure. The aging process is characterized by impaired adaptive and homeostatic mechanisms, resulting in an increased susceptibility to the stress of injury. This is commonly perceived as decreased physiologic reserve. Insults commonly tolerated by younger patients can lead to devastating results in the elderly patient. Differences in the metabolic response to injury were studied by Frankenfield et al.[5] In their study, they compared injured patients by dividing them into those older than 60 years and those who were younger. These investigators concluded that the metabolic response to injury is significantly attenuated in the elderly population. This was demonstrated by the older group having less fever, less oxygen consumption, more hyperglycemia, and more azotemia.[5] This may be driven by the fact that there is evidence that immune function is significantly attenuated during the aging process and that cytokine response is impaired as well. This immune senescence is, in part, characterized by reduced neutrophil function. Butcher et al[6] investigated a group of patients who sustained mild trauma (hip fracture) and were older than 65 years of age. Neutrophil phagocytic function was assessed immediately after injury, and patients were then followed for 5 weeks for clinical infection. When compared to a younger cohort, the older patients had a significant reduction in neutrophil phagocytic function as measured by significantly depressed superoxide production.[6] Additionally, nearly half of the elderly population suffered bacterial or fungal infection within the study period, compared to no infection in the younger patients. These authors suggested that the defect in the aging immune system may be a result of decreasing dehydroepiandrosterone (DHEA); that is, in the presence of the physiologic stress of injury, patients have an obligatory rise in corticosterone levels, which is immune suppressive.

ORGAN FUNCTION AND AGING

Cardiac

Cardiovascular comorbidities are most frequently seen in the elderly patient. Cardiac function declines by 50% between the ages of 20 and 80 years. The declining function is combined with a decreased sensitivity to catecholamines, so the expected cardiovascular response to hypovolemia may not be apparent.[7] This may be further complicated by a variety of medications, including β-blockers.[8] The cellular elements of the conductive system and the myocytes themselves are gradually replaced by fat and fibrous tissue. The resultant less resilient stiffer heart is more prone to dysfunction and dysrhythmias. Atherosclerotic changes in the arteries are common, and valvular anatomy is changed by tissue thickening. In addition, the increased afterload causes an increase in systolic blood pressure (SBP) and enlargement of the heart. The system is generally well compensated while at rest; however, in the event of hypovolemia, elderly patients generally are unable to compensate with tachycardia and an increase in cardiac output. There is a blunted response to adrenergic stimulation as well, because there are decreased baroreceptor reflexes in response to hypovolemia. As such, the response by the aged heart is generally characterized by an increase in systemic vascular resistance. Despite "normal" blood pressure, many of these patients have evidence of tissue hypoperfusion.[9] The end result of these age-related changes is a decreased ability to respond to the stress of injury or critical illness.

Pulmonary

There are significant anatomic and physiologic changes associated with aging that occur in the respiratory system. With age-related loss in bone density, there is development of thoracic kyphosis, and rib calcification is associated with a decrease in transverse thoracic diameter. In addition, muscle mass is reduced and the elastic recoil of the lung decreases with age. These anatomic changes result in decreased compliance of the chest. This results in a reduction in functional residual capacity and gas exchange.[10] The elderly also have a decreased cough reflex, decreased function of the mucociliary epithelium, decreased response to foreign antigens, and an increase in oropharyngeal colonization with microorganisms. These changes place the elderly patient at risk for hospital-acquired pneumonia.[11]

Although the number of alveoli remains constant with aging, alveolar surface area decreases after the age of 30 years. This results in decreased alveolar surface tension, which ultimately interferes with alveolar gas exchange. The alveoli are also noted to flatten and become shallow, thereby decreasing the effective surface area for gas exchange. Diffusion capacity is decreased because of the decrease in effective surface area and an increase in alveolar-capillary membrane thickness.[12]

Renal

Above the age of 50 years, renal mass is lost as progressive sclerosis of the glomeruli occurs with a corresponding fall in glomerular filtration rate. Between the ages of 50 and 80 years, there is a decrease in glomerular filtration rate by about 45%.[7] Generally, this is not detected by routine renal function testing, as it is accompanied by a decrease in total muscle mass and production of creatinine. Measurement of creatinine clearance by serum creatinine may be lowered as a result of decreased muscle mass and can give a false indication of renal function. The Cockroft-Gault formula should be used with caution to estimate the degree of dysfunction in the basal state and should not be used in the acutely stressed patient. Furthermore, the endocrine response of the kidney to antidiuretic hormone and aldosterone is abnormal. This

results in a decrease in the ability of the kidney to concentrate urine. Elderly patients may be able to maintain a deceptively adequate urine flow despite hypovolemia. As such, urine output should be used cautiously as a surrogate for renal perfusion.[13,14]

Many elderly patients are azotemic at baseline. The normal thirst response to dehydration may be impaired, and this is especially true in patients with underlying neurologic disease. These age-related changes in renal function put the older patient at significant risk for acute kidney injury following trauma and the confounding nephrotoxic insults following injury. Likewise, the elderly are at risk for developing untoward effects of aggressive volume resuscitation such as hyperchloremic metabolic acidosis and volume overload. Care must be maintained when dosing renally excreted drugs to these patients.

Skin/Soft Tissue and Musculoskeletal System

Older people undergo an obligatory loss of lean body mass. This loss is estimated to be about 4% every 10 years after the age of 25. This loss then increases to approximately 10% after the age of 50. The loss of muscle is accompanied by a proportional increase in adipose tissue. From a skeletal aspect, osteoporosis is a common feature of aging that results in a loss of 60% of trabecular bone and 35% of cortical bone.[15] This makes the elderly individual at risk for fractures, especially those involving the vertebrae, hip, and distal forearm. There are age-associated changes of the joints and cartilages resulting in osteoarthritis and other degenerative features affecting nearly all joints, as well. Degenerative changes in the cervical spine are particularly worrisome in the older population, and mobility is greatly affected, putting this area at risk for injury, particularly during oral intubation.[16]

Skin changes with aging are well documented. As the epidermis become thinner, changes in the blunted epidermal-dermal rete pegs place patients at risk for a shear injury. There is a decrease in the skin adnexa, resulting in increased skin dryness and slower healing as well. Overall, there is decreased sensation, decreased vascularity, and impaired lymph flow, all impacting normal wound healing. Skin changes and depressed wound healing may complicate underlying fractures, specifically pelvic fractures and open fractures.[17]

Endocrine

Normal adrenal function is critical in the response to the stress of injury. Basal, circadian, and stimulated cortisol secretion remain intact with aging. There is a decrease in DHEA production, which may predispose the physiologically stressed elderly patient to a hypercortisone state (Table 49-1). Additional age-related changes that affect endocrine function include decreased production of thyroxin and tissue responsiveness as a result of senescence.[7]

Additionally, there is some evidence for age-related decrease in testosterone contributing to increased fragility in men older than age 50. Testosterone levels are significantly decreased in men older than age 70, suggesting that this testosterone change could result in lack of energy and decreased strength, which may increase an elderly male's risk for injury.[16]

Functional Reserve

Maintaining homeostasis in the face of physiologic stress is a demonstration of good functional reserve. Declining functional reserve in the elderly may precipitate a decline in performance when the patient is exposed to chronic or acute illness. When faced with a physical insult, homeostasis may be poorly maintained (Fig. 49-1). The decline in functional reserve is heterogeneous, and a variety of factors will impact the magnitude of the loss of functional reserve. These include age-related disease and their treatments, genetics, lifestyle choices, and environmental factors. It is clear that older patients do not tolerate injury as well as younger patients, and they have substantial complication rates. What is not clear is the reason for this discrepancy, as previously noted. The impact of preexisting medical problems,[18-20] in combination with a declining functional reserve, often results in a poor outcome after trauma. This impact on outcome may be reduced by early intensive care unit (ICU) admission and an aggressive management approach to the patient.

Frailty

Surgeons have intuitively recognized the impact of aging on the patient's ability to tolerate operations and trauma. Recently, there has been a growing body of literature to objectively evaluate the aged patient for risk stratification purposes.[20-22] Although we would like to be able to use functional reserve clinically, there is no standardized method for measuring and quantifying this heterogeneous parameter. There is wide variability in the age at which individuals have physiologic deterioration. Conceptually, the closer a patient is able to approach maximal organ function in the face of stress, the better the likelihood for recovery and a favorable outcome. Because functional reserve cannot be quantified, frailty is now recognized as a surrogate that can be used clinically. Frailty is recognized as a unique aspect of health status that can be a marker of decreased reserves and increased vulnerability in elderly patients. In other words, frailty is a phenotypic expression of physiologic reserve and resistance to stressors. Recently, the American College of Surgeons National Surgical Quality Improvement Project developed guidelines on preoperative assessment of the geriatric patient.[21] Included among a variety of evaluations and assessments is frailty scoring. Fried et al[22] proposed a widely accepted operational definition that is composed of five parts (Fig. 49-2).

Understanding the impact of frailty on an older trauma patient is important. It can predict discharge disposition and may have a role in goals-of-care discussions with patients and families. Investigators from the University of Arizona have developed and validated a Trauma-Specific Frailty Index (TSFI). Over a 2-year period, 200 patients were evaluated

TABLE 49-1: Organ System Changes with Aging

Organ system	Functional changes	Implications for care
Cardiac	Declining function	Lack of "classic" response to hypovolemia
	Decreased sensitivity to catecholamines	Risk for cardiac ischemia
	Decreased myocyte mass	Dysrhythmias
	Atherosclerosis of coronary vessels	Elevated baseline blood pressure
	Increased afterload	
	Fixed cardiac output	
	Fixed heart rate (β-blockers)	
Pulmonary	Thoracic kyphoscoliosis	Increased risk for respiratory failure
	Decreased transverse thoracic diameter	Increased risk for pneumonia
	Decreased elastic recoil	Poor tolerance to rib fractures
	Reduced FRC	
	Decreased gas exchange	
	Decreased cough reflex	
	Decreased mucociliary function	
	Increased oropharyngeal colonization	
Renal	Loss of renal mass	Routine renal labs will be normal (not reflective of dysfunction)
	Decreased GFR	Drug dosing for renal insufficiency
	Decreased sensitivity to ADH and aldosterone	Decreased ability to concentrate urine
		Urine flow may be normal with hypovolemia
		Increased risk for acute kidney injury
Skin/soft tissue/ musculoskeletal	Loss of lean body mass	Increase in body fat
	Osteoporosis	Increased risk for fractures
	Changes in joints and cartilages	Decreased mobility
	Degenerative changes (including c-spine)	Difficulty for oral intubation
	Loss of skin elastin and subcutaneous fat	Risk of skin injury due to immobility
		Increased risk for hypothermia
		Challenges in rehabilitation
Endocrine	Decreased production and response to thyroxine	Occult hypothyroidism
	Decreased DHEA	Relative hypercortisone state
		Increased risk of infection

ADH, antidiuretic hormone; DHEA, dehydroepiandrosterone; FRC, functional residual capacity; GFR, glomerular filtration rate.

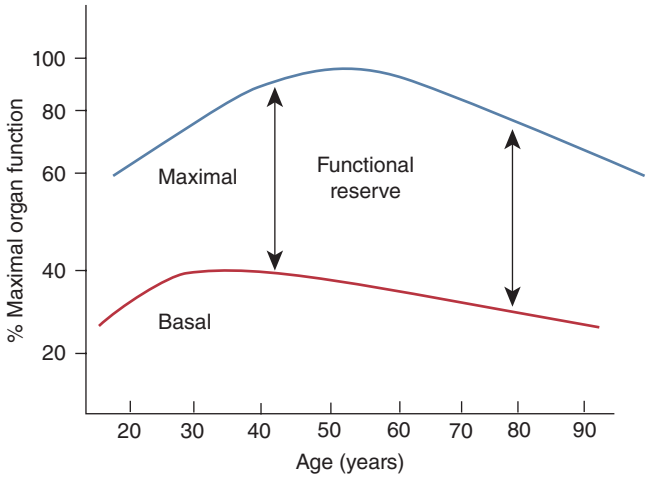

FIGURE 49-1 The functional reserve is the difference between basal function (red line) and maximal function (blue line). Even in healthy individuals, this functional reserve is reduced. (From Muravchick S. *Geroanesthesia: Principles for Management of the Elderly Patient*. St. Louis, MO: Mosby; 1997, with permission. Copyright © Elsevier.)

using their 15-variable TSFI (Table 49-2), and patients were assessed for favorable or unfavorable discharge dispositions. The investigators were able to demonstrate that the TSFI reliably predicted a patient's discharge disposition, whereas age itself was not predictive.[23] This same group enrolled 350 patients, again used the TSFI, and found that frail patients were more likely to have had a trauma-related readmission (odds ratio [OR], 1.4; 95% confidence interval [CI], 1.2–3.6) and/or repeated falls (OR, 1.6; 95% CI, 1.1–2.5) over the 6-month period. Overall 6-month mortality was 2.8% (n = 10), and frail elderly patients were more likely to have died (OR, 1.1; 95% CI, 1.04–4.7) compared with nonfrail patients.[24] Maxwell et al[25] evaluated the influence of physical frailty and cognitive decline by sampling patients age 65 years or older admitted to a Level I trauma center with a primary injury diagnosis. Surrogates of 188 patients were interviewed within 48 hours of hospital admission to determine preinjury cognitive and physical frailty impairments. Follow-up completed on 172 patients at 6 months and 176 patients at 1 year to determine posthospitalization status and outcomes revealed

Frailty score: Operational definition	
Criteria	**Definition**
Shrinkage	Unintentional weight loss ≥10 pounds in past year
Weakness	Decreased grip strength
Exhaustion	Self-reported poor energy and endurance
Low physical activity	Low weekly energy expenditure
Slowness	Slow walking

Interpretation of the frailty score

The patient receives 1 point for each criterion met.

0–1 = Not frail
2–3 = Intermediate frail (pre-frail)
4–5 = Frail

Frail patients are at much higher risk of adverse health outcomes.

Intermediate frail patients are at elevated risk (less than frail ones) but are also at more than double the risk of becoming frail over three years.

FIGURE 49-2 Frailty score: operational definition.[24] (Reproduced with permission from Chow WB, Rosenthal RA, Merkow RP, et al. Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg.* 2012;215:453-466. that overall median physical frailty scores did not return to baseline in the majority of survivors at 1 year. Further study analysis revealed that preinjury cognitive impairment and preinjury physical frailty are independently associated with physical function (frailty).[25] This study adds additional support to the idea that the assessment of frailty in the elderly trauma patient will have an increasing role for patient care, resource utilization, and outcomes-based research.

GENERAL MANAGEMENT OF THE ELDERLY PATIENT WITH INJURIES

Triage

Improper triage seems to contribute to the poor outcomes experienced by some elderly trauma patients. The effectiveness of triage can be evaluated by looking at the interaction between injury severity and complication rate, mortality, or requirement for intervention.[26] According to the American College of Surgeons Trauma Quality Improvement Program (ACS TQIP), elderly patients have an increased risk of undertriage by both emergency medical services and emergency department personnel. Undertriage is associated with a twofold

TABLE 49-2: Trauma-Specific Frailty Index (TSFI)

Fifteen Variable Trauma-Specific Frailty Index

Comorbidities			
Cancer history	Yes (1)	No (0)	
Coronary heart disease	MI (1)	CABG (0.75)	PCI (0.5)

increase in the risk of death. To mitigate late recognition of significant injuries, a lower threshold for trauma team activation should be used for the elderly trauma patients. In many cases, this approach would require elevating the level of activation based on age.[27] Elderly patients with severe injuries who are not treated with full trauma team activation are considered undertriaged. Multiple studies have shown a larger incidence of undertriage in older patients as compared to younger patients, so undertriage can be viewed as a modifiable risk factor for poor outcome in the older patient.[26-32] Lehmann et al[29] demonstrated that the classic physiologic criteria for trauma team activation, that is, blood pressure and heart rate, both failed to independently predict hospital mortality or the need for urgent interventions. These authors attributed the older patient's "pseudostability" to declining functional reserve and the interaction of premorbid medications. Use of initial vital signs in the elderly population can be misleading. In a study from Los Angeles, patients 70 years of age and older who were admitted to the trauma center were reviewed. The hypotension or tachycardia criteria for trauma team activation were not met in 63% of patients with an Injury Severity Score (ISS) of greater than 15% and 25% of patients with an ISS greater than 30. In this study, the overall mortality rate in "stable" patients not meeting any of the standard trauma team activation criteria was 16%.[26] The National Trauma Triage Protocol now suggests that an SBP of 110 mm Hg be used as a criterion for transport to a trauma center ("110 SBP is the new 90") for patients above the age of 65 years old. Brown et al[33] from Pittsburgh recently evaluated data from the NTDB and were able to show that the new criterion of an SBP of 110 mm Hg in patients older than 65 increased the sensitivity in predicting mortality in geriatric trauma patients. In a similar approach, the group at the University of Arizona has suggested that the Shock Index (SI = heart rate/SBP) can be used as a field triage tool for elderly patients. Using data from the NTDB, these investigators were able to demonstrate that an SI greater than 1 reliably predicted mortality with statistically better fidelity than the individual components of the index.[34]

Interestingly, "minor" injury can have major impact on the older patient. Rib fractures and pulmonary contusions can lead to an abrupt decompensation, and injuries such as intracranial hemorrhage are commonly underappreciated. It has been suggested that a patient age 70 or older be used as a criterion for trauma team activation.[26] The age at which triage and management issues become problematic is controversial also. The current recommendation of the Advanced Trauma Life Support (ATLS) program is 55 years of age.[35] This is based on data from the Major Trauma Outcome Study (MTOS), which noted a significant increase in mortality between the ages of 45 and 54 years.[36] The Trauma Injury Severity Score (TRISS) uses a similar age cutoff, although a recent work examining TRISS methodology seems to indicate that an older age is more accurate. Using the Ohio Trauma Registry, Caterino et al[30] examined mortality trends. Regression analysis identified 70 years of age to be the most promising cutoff for predicting increased odds of mortality.[30]

Initial Assessment

AIRWAY

The airway of the elderly patient poses specific challenges for providers because these individuals have a significant loss of protective airway reflexes. Patients may have dentures or be edentulous, with the former making bag-mask ventilation easier, whereas arthritic changes may make mouth opening difficult. Finally, when performing rapid sequence intubation, the doses of induction agents may need to be reduced between 20% and 40% to minimize the risk of cardiovascular depression.[37]

BREATHING

After airway control, oxygenation and ventilation are the next priority in the elderly trauma patient. The anatomic and physiologic changes in the respiratory system associated with aging are reviewed earlier. Changes in the compliance of both the lungs and the chest wall result in an increased work of breathing with aging. These changes associated with the possibility of nutritional deficits and the supine position place the elderly trauma patient at high risk for respiratory failure. Given a suppressed heart rate response to aging, respiratory failure may present in a more insidious fashion. Diagnosis can sometimes be difficult when interpreting clinical and laboratory information in the face of preexisting respiratory disease or nonpathologic changes in ventilation associated with age. Frequently, decisions to secure a patient's airway and provide mechanical ventilation may be made prior to fully appreciating underlying premorbid respiratory conditions. As noted earlier, the risk of ventilator-associated pneumonia and the possibility of prolonged ventilation are significant.[37]

CIRCULATION

Age-related changes in the cardiovascular system place the elderly trauma patient at significant risk for being mislabeled as being "hemodynamically normal." Scalea et al[38] found significant measurable hemodynamic compromise in elderly patients who were clinically stable after initial evaluation. Since the elderly patient may have a fixed heart rate and cardiac output, the response to hypovolemia will occur by increasing systemic vascular resistance. To further demonstrate the lack of classic symptoms as they relate to cardiovascular pathology, Chong et al[39] evaluated troponin I levels following emergency orthopaedic surgery in 102 patients over the age of 60, and 52.9% had elevated levels. The majority of patients with elevated troponin levels had no cardiac symptoms but had an increased mortality within 1 year of the event. Furthermore, because many elderly patients have preexisting hypertension, the seemingly "acceptable" blood pressure may truly reflect a relative hypotensive state. As such, identifying the patient who has significant tissue hypoperfusion is mandatory. Several measurements continue to be used to make this diagnosis. These include base deficit, serum lactate, age-adjusted SI, and tissue-specific end points.[10,40-42] Resuscitation of the geriatric hypoperfused patient is the same as all other patients

and based on appropriate fluid and blood administration. Fluid overload in the elderly population once adequate perfusion is established should be considered because there may be a fine line between hypovolemia and cardiac failure. The elderly trauma patient with evidence of circulatory failure should be assumed to be bleeding. Given the incidence of elderly people with preexisting disease states, however, one should keep in mind that some physiologic event may have triggered the incident leading to injury. Ultimately, an aggressive approach to resuscitation of the elderly patient with overt shock or tissue hypoperfusion should result in acceptable outcomes. Less aggressive measures based on the patient's age are not acceptable.

DISABILITY

Traumatic brain injury (TBI) is a problem of epidemic proportion in the elderly population, and older age is a known variable for a poor outcome following brain injury.[43] Age-related atrophy will cause the dura to become more adherent to the skull, causing an increased risk for subdural hematomas. Additionally, older patients are more commonly prescribed anticoagulant and antiplatelet medications for preexisting medical conditions. These two factors place the elderly individual at high risk for intracranial hemorrhage. Atherosclerotic disease is common with aging and may contribute to a primary or secondary brain injury. Moderate cerebral atrophy may permit intracranial pathology to initially present with a normal neurologic examination. This increase in potential space due to atrophy may mask the early signs of mass effect from intracranial hematoma. Additionally, age-related pupillary abnormalities may make initial evaluation of brain stem reflexes inaccurate. Early identification and timely appropriate support including correction of therapeutic anticoagulation can improve outcomes.[44]

SPINAL CORD INJURY

Traumatic injuries to the spinal column and/or spinal cord account for a significant number of traumatic injuries in the elderly population. Typically, older patients sustain an incomplete spinal cord injury (SCI), as opposed to complete injuries, likely due to the less severe mechanism of injury. Upper cervical injuries are the most common location of fractures and SCIs in the elderly population.[45] Three types of injury that appear to be relatively specific to the elderly population include (1) central cord syndrome; (2) cervical extension/distraction injuries; and (3) odontoid fractures. Management of elderly patients with spinal injuries must take into account their preexisting conditions, pathophysiologic characteristics, and age-related disorders that affect the population.[45]

EXPOSURE

Musculoskeletal changes associated with the aging process pose special concerns during the initial assessment of the elderly trauma patient. Loss of subcutaneous fat, nutritional deficiencies, chronic medical conditions, and associated medical therapies will place the elderly patient at risk for hypothermia and the risks associated with immobility (pressure ulcers, delirium). Rapid evaluation and early mobilization will minimize morbidity.

MANAGEMENT OF SPECIFIC INJURIES

Traumatic Brain Injury

In the elderly age group, TBI accounts for more than 140,000 emergency department visits each year, of which a majority result in hospitalization.[46] Falls are the leading cause of TBI for people over the age of 65 years (59.4%), followed by motor vehicle collisions (11.6%), based on the National Health Statistics Reports for 2016.[47]

Although the guidelines for the treatment of TBI have been established, they do not address the challenges of managing TBI in older patients, and research is limited. An investigation using the New York State Trauma Registry compared mortality and functional outcome in elderly versus younger patients.[48] In this study, Susman et al[48] demonstrated increased mortality in patients older than 65 years but also showed that mortality increased as patients aged. These investigators also showed that a majority of elderly patients sustain TBI from falls and appear to have only a mild TBI at admission but still have a much higher mortality compared to younger patients. This same group then looked at the total effect of age on mortality after TBI.[49] They concluded that mortality from TBI increases after 30 years of age but has a sharp rise after the age of 70. Given the anatomic changes associated with aging on the brain and the fact that a majority of elderly patients present with a Glasgow Coma Scale (GCS) score consistent with a mild brain injury, a high index of suspicion must be maintained with the elderly patient presenting with any mechanism of head trauma. Antipsychotic dopamine antagonist drugs and medications for glaucoma may affect neurologic examination, including evaluation of pupil size and responsiveness. To further address this, Mack et al[50] investigated the use of computed tomography (CT) of the brain in elderly patients. This study specifically looked at mild brain injury (GCS 13–15). In their study of 133 elderly patients, 14.3% had radiographic evidence of acute intracranial pathology. The authors noted that there were no useful clinical predictors of intracranial injury. The American College of Emergency Physicians recommends a noncontrast CT scan of the head for all patients age 65 years or older who present with a mild head injury. The use of anticoagulation in many geriatric trauma patients complicates the recommended indications for imaging. In this group, the incidence of intracranial hemorrhage is higher; therefore, a more liberal use of early CT scanning is warranted. Additionally, patients on preinjury anticoagulants should have repeat CT scanning even in the absence of intracranial hemorrhage on initial imaging if they are going to be discharged from the emergency department, although the time frame for observation and repeat imaging is controversial.[51] Outcome following TBI, most often measured as mortality, has historically been

considered to be worse in the geriatric population. Age, admission GCS, Charlson comorbidity index, Head Abbreviated Injury Scale (AIS) score, and ISS have all been found to be reliable for predicting mortality.[51] The Extended Glasgow Outcome Scale score has been reported to gradually improve for at least 1 year in most age groups after TBI, except in the geriatric population. Functional outcome and independence, cognitive function, mental health, and quality of life are important outcome measures in TBI. In a multi-institutional trial, a group of elderly patients surviving their initial moderate to severe brain injury (Head AIS = 3) were evaluated following discharge from acute care. In this cohort, there were few patients with a low GCS score who survived, and this left patients with a GCS of 13 to 15 to be evaluated. Functional outcome for these patients, as measured by the Glasgow Outcome Scale and modified Functional Independence Measure, was good to excellent. Older patients, however, required more inpatient rehabilitation and took longer to recover when compared to younger patients.[52] Aggressive initial management including inpatient and long-term rehabilitation in the elderly patient with TBI can dramatically influence outcomes.

Rib Fractures

Fractures of the bony thorax are common injuries seen in older patients. Rib fractures in the elderly pose a significant risk for morbidity and mortality when compared to younger patients who, in general, suffer little morbidity. The morbidities in the elderly include inadequate pain management, need for intubation, prolonged ventilatory support, and the development of pneumonia. Bulger et al[53] investigated the impact of rib fractures after blunt chest trauma in the elderly. This study showed a linear relationship between age, number of rib fractures, complications, and mortality. In a similar study, Holcomb et al[54] retrospectively evaluated 171 patients. These authors demonstrated an increase in negative outcomes based on increasing age and number of rib fractures. By grouping ages and number of rib fractures, their data revealed that patients with more than four rib fractures who are older than age 45 years had increased morbidity (ICU length of stay [LOS], total LOS, ventilator days, and pulmonary complications). The University of Washington Harborview Medical Center evaluated different interventions for reduction of morbidity and found the literature supported a bundled rib fracture management protocol that they developed and instituted at their facility. This rib fracture management protocol incorporates many of the tenets proposed by Todd et al,[55] but with broader inclusion criteria, early initiation of multimodal pain therapy, and frequent function-based scoring driven by nursing staff and the patient. Multivariate analysis by Todd et al[55] demonstrated that post-pathway implementation patients had significantly decreased ICU LOS, hospital LOS, pneumonia, and mortality. The recommendations for pain management from the Eastern Association for the Surgery of Trauma and Trauma Anesthesiology Society include the use of epidural analgesia and multimodal analgesia (ie, use of different classes of analgesics, including combinations of opioids with other agents such as nonsteroidal anti-inflammatory drugs, pregabalin/gabapentin, and acetaminophen) versus opioids alone to treat pain.[56] Further work is required in this area, and readers are encouraged to refer to Galvagno et al[57] on evidence-based guidelines for analgesia. In an evaluation of data from the NTDB of the American College of Surgeons Committee on Trauma, Flagel et al[58] reviewed a large patient population. These investigators showed that the overall mortality rate for patients with rib fractures was 10%. This rate increased for each additional rib fracture independent of age. A similar trend noted increasing pulmonary complications with additional rib fractures. The incidence of pneumonia in patients with up to five rib fractures ranged from 3% to 5.2%. This increased to 6.8% to 8.4% for patients with six or more rib fractures. These authors were unable to demonstrate that age is a risk factor for mortality in patients with rib fractures. Most recently, data from a multicenter study of 1621 patients were published by the Research Consortium of the New England Centers for Trauma.[37] The investigators evaluated patients over the age of 50 years with nearly isolated rib fractures. Of interest, 35% of the patients were admitted to the ICU with an average ICU LOS of 16.5 days and a total hospital LOS of 27.5 days. Intubation was required in 12% of patients, and 4.3% went on to require tracheostomy. Univariate analysis of the data revealed that risk factors for mortality were preexisting coronary artery disease or congestive heart failure (CHF), increasing age, ISS, number of ribs fractured, and increasing AIS for associated body regions. On multivariate analysis, the strongest predictors of mortality were admission to a high-volume trauma center, preexisting CHF, intubation, and increasing age. Carver et al[59] evaluated 683 patients with rib fractures and vital capacity performed within 48 hours; average patient age was 58 years old, and the median ISS was 13. The investigators found that every 10% increase in vital capacity was associated with a 36% decrease in likelihood of pulmonary complications. Additionally, the presence of fractured ribs and vital capacity of less than 30% were significantly associated with pulmonary complications.[59] Taken together, this body of literature supports the identification of elderly patients with rib fractures and early recognition of respiratory failure with aggressive supportive maneuvers to potentially reduce morbidity and mortality.

Abdominal Injury

Nonoperative management of solid organ injuries in the elderly should follow the same basic tenets of management for all hemodynamically stable patients; however, this approach must be used with caution in the elderly trauma patient. The classical physiologic response to hemorrhage, which may be used as a criterion to attempt nonoperative care or as a marker for "failure" of nonoperative management, may not be present. In a 6-year retrospective analysis of patients sustaining blunt splenic injuries, Albrecht et al[60]

evaluated the utility of nonoperative management of these injuries in patients older than 55 years. In this small study of 37 patients meeting inclusion criteria, 13 patients went directly to the operating room. Of the remaining 23 patients, nonoperative management was successful in 15 (62.5%) and failed in 8 (33.3%). Characteristics of the group that failed nonoperative management included higher American Association for the Surgery of Trauma splenic organ injury scale grade and large hemoperitoneum. In a larger retrospective study of 1482 patients, 15% (n = 224) of whom were age 55 years or older, the mortality of the older population was significantly higher than the younger group (43% vs 23%). In this study, 80% of patients over the age of 55 years were successfully managed nonoperatively, with 24 patients of the original 132 patients subsequently requiring exploration. Although not statistically significant, there was a trend toward an increased failure rate with increasing grade of injury. When evaluated by grade of injury, grade I injuries had a success rate for nonoperative management, which was similar for younger and older patients. Success rates for older patients were lower for grade II (73% vs 54%) and grade III (52% vs 28%) injuries. All elderly patients with grade IV and V injuries required operation, either immediately or for failed nonoperative management.[61] The data suggest that nonoperative management of splenic injury in the elderly patient should be undertaken with caution. An appreciation of the grade of injury and assuring hemodynamic stability are absolute requirements. Overall mortality is higher in the injured elderly than for younger patients for both operative and nonoperative management.[62]

Pelvic Fractures

Osteoporosis, falls, and fractures are major public health issues among the elderly population. Fractured bones are extremely common after trauma, and women are at particular risk because of lower bone density. Pelvic fractures pose a significant special risk for elderly patients, with challenges involving the acute phase of fracture management, timing of operation, and functional outcome. The group from the R Adams Cowley Shock Trauma Center compared outcomes of patients (<55 vs >55 years old) sustaining pelvic fractures over a 2-year period.[63] A blood transfusion was required in 62% of older patients compared to 36% of the younger population (P <.0035). This study showed that lateral compression fractures, which are generally considered less serious injuries in younger patients, occurred 4.6 times more frequently than anteroposterior (AP) fractures, and 8.2 times more frequently in older patients undergoing transfusion as compared with AP compression. Further analysis revealed that patients who received transfusion were 2.8 times more likely to be over the age of 55. Mortality for the younger group was 6.2%, compared to 20.5% for the older group (P = .0034). Even after adjusting for ISS, death was four times more likely in the elderly patients. The authors concluded that elderly patients with pelvic fractures are more likely to have substantial bleeding and transfusion requirements and require angioembolization and ICU admission. The authors suggested that every elderly patient with a pelvic fracture should be considered hemodynamically unstable until proven otherwise.

Extremity Injury

Attention to extremity injuries is a high priority in the elderly because ambulation and activities of daily living may be profoundly affected. Distal radius and proximal humerus fractures are common among the elderly population; they are the second and third most common fractures in adults over the age of 66,[64] with hip and pelvic fractures ranking number 1.[65] Hip fracture prognosis is quite poor, with 1-year mortality rates estimated to range from 20% to 30%. Among patients who were independent prior to fracture, 1 year after hip fracture, 25% remained in nursing homes and 60% required assistance in one or more activities of daily living.[65]

Consideration in the management of the elderly patient with orthopedic trauma is the timing of operation. The decision to proceed with an orthopedic operation is made based on extraorthopedic injuries, physiologic status, and the magnitude of the operation planned. Early fracture fixation should be accomplished as soon as life-threatening injuries are addressed. In a series of 367 elderly patients with hip fractures, a delay in operation for more than 2 days was associated with more than double the risk of death within the first postoperative year.[66] Current standard of care is that operative fracture fixation should occur as soon as possible when physiologic conditions have been optimized to allow earliest possible mobilization.

Burns

The elderly burn patient has a higher mortality for a given size burn than younger patients. In fact, predictors of survival from burn injury continue to rely on age as a significantly weighted variable alongside sex, percentage total body surface area (TBSA), and concomitant inhalation injury influencing elder burn victim morbidity and mortality. Despite significant advances in the science and management of burn injury, the LD_{50} (burn size with a lethality of 50% of patients) for burns in the 65 years or older population remains approximately 35% TBSA. Older individuals are at significant risk for burn injury due to impaired mobility, diminished senses, and slower reaction time, all of which make it difficult to reach safety, ultimately leading to deeper and more extensive burns.

Predicting survival in older burn patients is important. It provides a framework for discussing realistic clinical expectations with patients and their families and may allow for appropriate utilization of resources associated with the intensive care of burn patients. Wibbenmeyer et al[67] attempted to address this predictive model in relation to modern burn care. They reviewed 308 burn patients over the age of 60 years. A majority of these patients sustained flame burns, including 41.4% in household incidents. At least one preexisting medical problem was present in 64% of the patients, and the

median TBSA size was 13%. The mortality for the cohort was 30.2%, with an LD_{50} of 30%. When this was further evaluated, the LD_{50} was age dependent. Specifically, it was 43.1% for patients age 60 to 69.9, 25.9% for age 70 to 79.9, and 13.1% for age 80 and older. As expected, the presence of an inhalation injury had a significant negative impact on survival. These authors concluded that death was significantly related to age, TBSA burn, and presence of inhalation injury, whereas comorbidities did not impact mortality. The Baux score, calculated as the sum of the age of the patient and the TBSA burn, is an estimate of the percent mortality and is supported by data from this study. The Abbreviated Burn Severity Injury (ABSI) score, calculated as the weighted sum of age, gender, TBSA, percentage of full-thickness injury, and presence of inhalation injury, was also predictive of survival, but less so than the Baux score. The authors were unable to demonstrate an improvement in survival over the 20-year period of data collection.

Controversies remain regarding aggressive, early excision (24–72 hours after burn) of deeply burned tissues and the benefits of early skin grafting in terms of decrease in infections, shorter hospital stay, and early functional recovery. Ho et al[68] reported outcome data on 94 patients over the age of 60 years from their regional burn center. When compared to a younger population of burn patients, the older patients had a longer LOS, a mortality of 7.4%, and no differences in outcome based on early versus late excision. Deitch[69] had shown earlier that early wound closure decreased LOS and number of septic complications and improved mortality. The studies from Ho et al[68] and Wibbenmeyer et al[67] did not show the benefits of early excision. Finally, gender seems to impact outcomes in elderly burn patients. Chang et al[70] from the University of Utah demonstrated a higher mortality, longer LOS, and less likelihood of being discharged home for older female patients when compared to older men.

Maintaining an aggressive approach to the older burn patient is warranted in the context of survivable injuries. Advanced age, larger burns, and the presence of inhalation injury are all negative predictors of survival in this population. Realistic therapeutic expectations are important for patients, their families, and the burn team when taking care of these very challenging patients.

Falls

In 2013, 2.5 million nonfatal falls among older adults were treated in emergency departments, and more than 734,000 patients were hospitalized. In addition, approximately 25,500 older adults died from unintentional fall-related injuries in the same year.[71] For older trauma patients, many of these falls are from a standing height but still lead to significant injuries requiring hospitalization.[72] Preexisting medical conditions, medications, and other variables play a significant role in ground-level falls. Unfavorable discharge dispositions and mortality are significant in this group of patients. The group from Harborview Medical Center examined 1352 elderly patients admitted to their trauma center after a ground-level fall. Deaths occurred in 12% of the patients during the index admission. Of the survivors, 50% were discharged to a skilled nursing facility (SNF), and only 6% were discharged to home. Nearly 45% of patients were readmitted within 1 year following discharge, with patients requiring an admission to the ICU during the index admission to be at highest risk for readmission. The overall 1-year mortality for the entire group, including those who died during the index admission, was 33%. Patients discharged to an SNF were three times more likely to die than patients discharged home.[73]

Because the societal and financial impact for older adults sustaining falls is significant, developing effective prevention measures is mandatory. Optimizing medications to prevent hypotension and hypoglycemia; encouraging physical exercise to prevent osteoporosis and prevent skeletal muscle loss; instituting environmental modifications, such as grab bars and clutter removal; and reducing environmental hazards all play a significant role in preventing falls. Fall prevention programs aim to detect individuals at high risk for falls and to remove those risk factors that can lead to falls in the elderly.

Penetrating Trauma

With the growth in the proportion of elderly people, there will be an obligatory rise in the number of elderly trauma patients. By far, blunt trauma is the predominant mechanism for injury; however, there are still a significant number of people over the age of 65 years who are victims of penetrating injury. Most of these patients are victims of self-inflicted injuries mediated by chronic illness and depression. When examining patients over the age of 55 between the years 1982 and 1987 in the original MTOS, elderly patients had a higher mortality when compared to a younger cohort.[74] In addition, Finelli et al[75] reported a significantly higher mortality in the elderly (52%) compared to younger patients (20%) sustaining gunshot wounds. In contrast, Roth et al[76] from Los Angeles County Hospital and the University of Southern California retrospectively reviewed 79 patients over the age of 55 years who suffered penetrating injuries. Their data showed no difference in mortality between elderly and younger patients (23% vs 18%). Interestingly, 50% of the elderly patients who died presented with "normal" vital signs.[76]

Elder Abuse

The discussion of geriatric trauma would not be thorough without considering elder abuse. Elder abuse includes not only physical violence, but also acts of neglect. This may include withholding food, medications, hygiene, or monetary or emotional support. A high index of suspicion is important because signs and symptoms of elder abuse may be attributed to chronic diseases. On the secondary survey of the elder trauma patient, a complete history and physical examination noting unusual features should be documented. Findings that should arouse suspicion for abuse may include delays in seeking treatment, coming to medical attention without the caregiver, a caregiver who dominates the conversation, unkempt

appearances, unusual wounds such as multiple bruises, "glove and stocking" injuries, and genital injuries.[77]

CRITICAL CARE

In a large retrospective statewide trauma registry review of 22,571 patients with blunt trauma, of whom 7117 were elderly, ICU utilization was evaluated.[78] The entire population had an ICU admission rate of 42.7% with a mean ICU LOS of 5.77 ± 8.86 days. In contrast, the elderly patients had a lower ICU admission rate of 36.7% when compared to the younger population (45.5%). Interestingly, elderly patients admitted to the ICU had a significantly longer ICU LOS. The lower utilization of ICU resources in the elderly may be explained by a higher early mortality and/or end-of-life decisions that may have precluded admission to an ICU setting.

Preventable complications in the elderly trauma patient significantly impact outcome. DeMaria et al[79] demonstrated an association of complications with death (32%) and an association of deaths from multisystem organ failure (62%). The relationship between senescence and infection deserves mention. Bochicchio et al[80] showed an increase risk of infection in elderly patients (39%) when compared to a younger population (17%) (P <.05). Once infected, the elderly patient is at much higher risk for death (28%) than his or her younger counterparts (5%) (P <.005). An aggressive approach to the older patient with infection is essential for improved outcomes.

Scalea et al[81] suggested that early invasive monitoring of the geriatric trauma patient can improve outcome. Noninvasive monitoring of elderly patients has been investigated in the critical care setting, but little has been concluded regarding the critically ill trauma patient.[82] There is a movement in emergency medicine and critical care as well as surgery toward use of point-of-care ultrasound. Murthi et al[82] looked at the utility of cardiac ultrasound to evaluate hemodynamics and resuscitation. In this study, these investigators compared focused rapid echocardiographic evaluation, a hybrid of the point-of-care examination and transthoracic echocardiography, versus assessment using a vascular catheter. They were able to show that the echocardiographic assessment correlated well with data from a pulmonary artery catheter, with the benefit of noninvasiveness and real-time evaluation after therapeutic interventions. Although not specifically studied in elderly patients, this noninvasive method will likely become a mandatory diagnostic technique for intensivists.

Because the elderly will fail to demonstrate the classic physiologic responses to shock, it is important to maintain an aggressive approach toward monitoring and resuscitation. The utility of invasive monitoring and aggressive critical care is demonstrated in a study on outcomes of elderly patients with the acute respiratory distress syndrome (ARDS). In this study, Eachempati et al[83] evaluated a protocol approach to ARDS using lung protective ventilator strategy and invasive hemodynamic monitoring. In a group of 210 elderly patients with ARDS, the investigators were able to demonstrate a lower mortality when compared to historical controls despite a higher severity of illness.[83]

Delirium in the elderly trauma population is now recognized as a significant risk factor for morbidity and mortality in the ICU. Delirium is characterized as a disturbance of consciousness associated with a fluctuating mental status and disorganized thought, occurring in at least 20% of hospitalized patients over the age of 65 years. In addition, it increases hospital costs by $2500 per patient, resulting in $6.9 billion of Medicare hospital expenditures.[84] There is also a threefold higher mortality over 6 months following a single episode of delirium in the ICU.[85] Understanding the impact of delirium in the trauma patient has only recently been investigated. Pandharipande et al[86] undertook a prevalence study of delirium in their trauma and surgical ICUs. Using the Confusion Assessment Method for the ICU (CAM-ICU), a validated screening tool, these investigators found an overall prevalence of delirium of 70% (73% in surgical patients and 67% in trauma patients).[86] The Intensive Care Delirium Screening Checklist is another validated tool for use in ICU patients. This scale assesses delirium symptoms over an 8- to 24-hour period because delirium typically fluctuates throughout time, and the "spot" nature of the CAM-ICU assessment may miss an episode of delirium if the symptoms are not present at the time of assessment. The group from the trauma center at Denver Health Medical Center performed a 4-month study of 69 patients admitted to their trauma ICU following injury. They found a 59% incidence of delirium overall and a higher incidence if the patient was mechanically ventilated. Upon univariate analysis, age proved to be a predictor for the development of delirium; however, on multivariate analysis, the strongest predictors for transitioning into delirium were lower arrival GCS, higher packed red blood cell transfusion amount, and higher multiple organ failure score.[87] Most recently, a two-center study examining the impact of delirium on outcomes was performed. A total of 134 patients were evaluated, and 63% progressed to delirium during their ICU stay. The patients with delirium had more ventilator days and longer ICU and hospital LOS. These investigators were unable to show a relationship between increasing age and the development of delirium.[88] The association of advanced age with delirium is strong in most studies, and delirium and dementia are highly interrelated; however, the nature of this interrelationship remains poorly examined.[84] The association of delirium with opioid narcotics and benzodiazepines is well established, and care must be taken in prescribing these medications to all patients but especially the elderly. In addition, the issue of appropriate and goal-directed analgesia and sedation is commonly faced by the ICU staff. Finally, delirium represents one of the most common preventable adverse events among older persons during hospitalization,[89] implying that the development of delirium in a patient may reflect processes of care in the hospital, and, therefore, may be a reflection of the quality of care of that individual. Those caring for elderly injured patients must be aware of the development, diagnosis, prevention, and, if needed, appropriate treatment of delirium in order to provide the highest quality of care to this population.[90]

OUTCOMES

Injured elderly patients admitted to the hospital consume significant health care resources. Average hospital LOSs are generally around 10 days, and usually the LOS in the ICU is longer than for younger patients (except for early deaths). In addition, hospital-acquired complications are independent predictors of mortality in this age group. In 2002, Richmond et al[91] reported their 10-year retrospective review of geriatric trauma from a statewide trauma registry. They evaluated all patients age 65 years or older who were included in the registry. Nearly 62% of the patients were injured as a result of a fall, whereas 22.6% were injured in a vehicle collision. Operation was required in 28% of patients, and 37% of the cohort had a preexisting medical condition. The average LOS was 11.5 days, one-third of the group required admission to the ICU, and 10% of all patients died. These investigators found that as age increased, the patients had higher mortality and more complications and more required discharge to a facility other than home. The patients who died had a greater number of injuries with more body regions involved and a resultant higher ISS.

Admission physiologic markers may predict those at risk for mortality. In a statewide trauma registry review from Pennsylvania, elderly patients who were hypotensive, had a GCS of 3, or had a respiratory rate of less than 10 all had a significantly increased risk of death.[78] The nine-center Prognostic Assessment of Life and Limitations After Trauma in the Elderly (PALLIATE) consortium has validated the Geriatric Trauma Outcome Score (GTOS) as a prognosis calculator for injured elders. A total of 10,984 subjects were included, with the identified subjects age 65 to 102 years admitted from 2000 to 2013. GTOS was specified using the following formula: [GTOS = age + ISS × 2.5) + 22 (if transfused packed red blood cells at 24 hours)]. Subjects in the GTOS validation study showed that increasing age and injury severity both contributed to mortality. The penetrating trauma subgroup (n = 150) had a higher mortality rate, at 20.0%.[25]

Although the literature is not unanimous concerning factors that correlate with mortality or poor functional outcomes, several items that have generally been shown to be predictive have been described. These include advanced age, increasing severity of injury, shock, prolonged mechanical ventilation, male gender, significant head injury, and sepsis. Trauma also appears to have not only short-term but also long-term effects on elderly survival. A study by Xu et al[92] found that survival time for seriously injured older adults was significantly shorter when compared with survival times for the minor and no injury groups in the elderly. The study used an integrated version of the public use National Health Interview Survey (NHIS) produced by the Integrated Health Interview Series (Minnesota Population Center and State Health Access Data Assistance Center, 2016) consisting of participants age 65 years and older. A total of 79,504 older adults were used to estimate mortality risk. There was a clear difference in mortality risk by injury status. More than 38% of seriously injured older adults died within 11 years, 27.9% of those with minor injuries died, and 24.9% of those with no injury at baseline died. The survival time for the minor injury group was also significantly shorter than for the non-injury group. The probability of death reached 25% by 14 quarters (or 3.5 years) after baseline for seriously injured older adults, by 21 quarters (or 5.25 years) for patients with minor injuries, and by 26 quarters (or 6.5 years) for the non-injured group. At 44 quarters, or 11 years, the probability of survival dropped to 40.3% for seriously injured older adults, 52.6% for older adults with minor injury, and 55.9% for non-injured older adults.[92] In summary, elderly trauma patients are at greater risk for mortality, prolonged institutional care, lack of return to preinjury status, and reduced midterm survival.

PREEXISTING CONDITIONS

The interaction between injury and patient factors has been studied extensively, but data are conflicting regarding the impact of these factors on mortality. Despite this, there is a large body of evidence documenting that preexisting conditions (PECs) will impact morbidity and, likely, mortality. Morris et al[20] identified five PECs that appeared to influence outcomes. In that study of over 3000 patients, one-fourth of patients over the age of 65 years had one of the five PECs. These investigators identified cirrhosis, congenital coagulopathy, chronic obstructive pulmonary disease, ischemic heart disease, and diabetes mellitus as PECs that influenced outcomes in trauma patients. Patients with one or more of these PECs were nearly two times more likely to die than those without PECs. The same authors then reported the interaction between injury and host factors, which included age, gender, and PECs.[19] Although injury severity was the primary determinant of mortality, host factors also played a significant role. These studies were later corroborated in a study by Grossman et al,[18] in which an ISS greater than 30 was considered the LD_{50}. Each additional year of age greater than 65 years carried a mortality increase of 6.8%, and PECs with the greatest impact on mortality were hepatic disease, renal disease, cancer, and CHF.[18] The impact of PECs was demonstrated in a study from the group at Vanderbilt University in which they studied a predictive mortality model incorporating PECs (University Health System Expected Mortality [UHC-EM]) and compared it to TRISS methodology. The UHC-EM is derived from data on diagnosis-related groups and includes both anatomic injury and PECs, whereas TRISS uses only unadjusted vital signs and pattern of injury. The study was a 7-year retrospective review of all patients admitted to the Vanderbilt Trauma Center, and elderly patients were compared to a younger cohort. The UHC-EM was able to predict mortality better than TRISS in elderly patients, demonstrating the impact of PECs.[93]

COMPLICATIONS

There seems to be a relationship between PECs and the development of postinjury complications that increase mortality. In a study reviewing a large statewide trauma registry

by Taylor et al,[78] 6.2% of elderly patients developed pneumonia, with preexisting pulmonary disease and increased ISS as risk factors. Pneumonia predicted both an increased ICU and hospital LOS. In this study, 5.9% of patients developed an acute kidney injury, which resulted in a greater than 10-fold increase in mortality. Finally, the development of sepsis, which occurred in only 1.2% of patients, significantly increased mortality, ICU LOS, and hospital LOS. The only risk factor identified for the development of sepsis was an increased ISS.[78] The impact of failure to rescue in the elderly has been investigated in a large database of emergency surgical patients. The failure to rescue rate was twofold higher in the elderly compared to younger patients, correlating with a similar disproportionate increase in mortality.[94] For elderly trauma patients who survive their initial injury, cardiovascular, pulmonary, and infectious complications are common and contribute significantly to mortality. Complications are a significant sequela in this group of high-risk patients.

RESOURCE UTILIZATION

The association between age as an independent predictor and outcome as documented by increased mortality and hospital LOS is well supported in the literature. Although hospital LOS is increased, ICU utilization is less than in a younger population.[78,95] As previously noted, this is due to an increased early mortality seen in the elderly as well as decreased ICU admission resulting from advanced directives. Data from the Healthcare Financing Administration demonstrated that ICU use decreased with age and was least likely for patients over 85 years old.[96] Young et al[97] looked at outcome in a cohort of elderly trauma patients. Although the older group had a higher mortality rate, there were no differences in hospital or ICU LOS or in ICU admission rate. In the study by Taylor et al,[78] the elderly group had a lower ICU admission rate (36.7%) compared to younger trauma patients (45.5%); however, elderly patients, once admitted to the ICU, had a longer ICU LOS. The impact of withholding or withdrawing care may influence ICU LOS.

STRATEGIES FOR IMPROVING OUTCOMES

Triage

There are numerous studies suggesting that elderly trauma patients are "undertriaged" (underestimation of injury severity) to trauma centers despite the proven mortality benefit of trauma center care. Statewide data from Maryland demonstrated that fewer elderly trauma patients were transported to trauma centers despite meeting physiologic criteria for trauma triage.[98] The group of undertriaged elderly patients had a significantly higher mortality, discharge disability rate, and complication rate when compared to a group of younger patients. Meldon et al[99] demonstrated a significant survival benefit for severely injured elderly patients when treated in a trauma center (56%) versus a nontrauma center (8%).[99] Undertriage of older patients could be due to inadequate training, unfamiliarity with protocol, and possible age bias; however, assessment of this group is less likely to demonstrate hypotension or tachycardia than are younger patients, as previously noted.

Medications

The increased awareness in medication reconciliation and its impact on patient safety is prominent in current health care literature. The acuteness of the hospital admission and, at times, the initial underappreciation of significant anatomic injury result in a potentially modifiable situation highlighting the importance of knowledge of a patient's premorbid medications and the potential interaction of any newly prescribed medications. The Beers criteria are used by consensus for safe medication use in elderly patients.[100] Using this system along with expert input from geriatricians and pharmacists may reduce adverse drug reactions in older patients.

There are a number of medications specifically related to the injured patient that deserve mention. β-Blockers are used in approximately 20% of elderly patients with coronary artery disease and 10% of patients with hypertension. The inherent physiologic blockade of the expectant response to hypovolemia may provide obstacles to triage and treatment. Additionally, the impact of prolonged β-blockade on the progression and outcome of trauma and burn injury is not fully understood.

Anticoagulant medications include warfarin, heparin, low-molecular-weight heparin, the antiplatelet agent clopidogrel, and anti-Xa inhibitor oral anticoagulants. Aspirin and nonsteroidal anti-inflammatory medications may also cause coagulopathy. Anticoagulation with warfarin and/or antiplatelet therapy poses significant problems for the bleeding patient. Warfarin therapy carries a 1% per year risk of spontaneous intracranial hemorrhage even in the absence of trauma.[101] Assessment of the therapeutic level is important because many patients will be sub- or supratherapeutic. Many studies assessing the impact of warfarin on trauma and, specifically, trauma to the brain are limited in that they do not address the clinical level of anticoagulation. To address this limitation, a study of 3242 trauma patients over the age of 50 years was performed. In this retrospective analysis, data on the international normalized ratio (INR) were used as a surrogate for warfarin anticoagulation. These investigators demonstrated a mortality rate of 22.6% in the group with an INR greater than 1.5 compared to 8.2% for those with an INR less than 1.5. After adjusting for age and ISS, the odds of death for each one-unit increase in INR was 30%.[101] Patients with supratherapeutic anticoagulation fare even worse. For reversal of warfarin, prothrombin complex concentrate (PCC) is now recommended over fresh frozen plasma (FFP). The use of PCC leads to shorter time for normalization of the INR, reduction of clinical progression of intracerebral hemorrhage, and reduced mortality rates as compared with treatment with FFP.[102]

Antiplatelet therapy is less well studied. This class of drugs includes aspirin and clopidogrel and is increasingly used

for a wide variety of cardiovascular problems. In a registry review of patients over the age of 50 years who sustained a TBI, patients taking aspirin or clopidogrel were compared to those not receiving antiplatelet therapy. The group receiving antiplatelet therapy had a mortality of 23% compared to 8.9% (P = .016) in the control group. Risk factors for death in this study included age greater than 76 years and GCS less than 12.[103] Peck et al[104] from San Diego retrospectively looked at a group of elderly patients with blunt TBI. They compared patients taking anticoagulants and/or antiplatelet medications at the time of injury with patients not taking such medications. The anticoagulation/antiplatelet group had a higher mortality, and the authors attributed this to the use of antiplatelet agents, with the most frequently used medication being clopidogrel.[104] Patients sustaining a TBI while taking clopidogrel have been shown to have progression of intracranial hematomas (ICHs). Joseph et al[105] retrospectively reviewed 71 patients with an ICH who were taking clopidogrel at the time of injury. There was a fivefold increase in progression of ICH and a twofold increase in progression of ICH based on clinical deterioration. These authors suggested routine repeat head CTs in patients with an ICH who had taken clopidogrel.[105] Management of TBI patients on preinjury antiplatelet agents remains controversial. One randomized trial of platelet transfusion in patients with intracranial hemorrhage demonstrated improved outcomes, whereas other studies have failed to show an impact of platelet transfusion on clinically relevant outcome measures.[51]

Rapid reversal of anticoagulation with transfusion of FFP is beneficial. Reversal of an elevated INR to normal within 2 hours reduced mortality from 48% to 10% in one study.[106] Fortunately, and contrary to initially expected results, large recently published series showed that trauma patients receiving new oral anticoagulants had a better outcome than those anticoagulated with vitamin K antagonists.[107] Reversal of newer oral anticoagulant agents, which include factor Xa inhibitors and direct thrombin inhibitors, is not well established because there are limited data. This highlights the need for specific screening protocols for coagulopathy in this setting. The Neurocritical Care Society and the Society of Critical Care Medicine have assembled guidelines intended for use by clinicians providing care to intracranial hemorrhage patients exposed to antithrombotic agents. This 13-person group analyzed the quality of literature evidence and provided treatment recommendations based on the Grading of Recommendations Assessment, Development and Evaluation (GRADE) system. This guideline addresses commonly encountered antithrombotic-associated intracranial hemorrhage scenarios for which data and experience have been reported. Refer to the summary of recommendations for further information.[108]

Specialists

The role of the geriatrician in the management of the elderly trauma patient is logical. There are age-specific nuances in the care of the elderly that make the geriatric specialist an invaluable member of the extended trauma team. There have been publications noting improvement in outcomes of geriatric trauma patients when a geriatrician became involved in their care.[106] Fallon et al[109] described the idea of a "geriatric trauma team." This involved mandatory consultation from a group of interested and dedicated geriatricians. The consultants were able to address a variety of medical conditions in elderly trauma patients at study sites. These included pain management, rehabilitation, delirium, and advanced care planning, to name a few. Most notably, the group of patients seen in consultation had a lower mortality than a group of elderly trauma patients not seen by a geriatrician. To study this concept prospectively, Lenartowicz et al[110] from Toronto established a Geriatric Trauma Consultative Service (GTCS) that was composed, at a minimum, of an advanced practice nurse in geriatrics and a geriatrician who performed a comprehensive geriatric assessment. All patients age 60 years and older were evaluated by the GTCS. The authors looked at geriatric-specific complications (falls, delirium, and restraint use) and trauma-specific complications (pressure ulcers, venous thromboembolism, myocardial infarct, pneumonia, cardiac arrest, and missed injury). There were less consult requests to internal medicine and psychiatry, and ultimately, there was less delirium and a decreased incidence of patients being discharged to long-term care facilities.[110]

There are age-specific interventions that may improve outcome in the elderly injured population. As previously noted, one of the first attempts to address this was work from the trauma service at Kings County Hospital Center in Brooklyn, New York. In this study, the authors were able to demonstrate an outcome benefit from early invasive monitoring and intervention.[81] A study from Nathens et al[111] investigated the impact of an intensivist-model ICU on trauma-related mortality. In this large multicenter study, the authors concluded that an intensivist-model ICU when compared to an open-model ICU significantly reduced mortality. Furthermore, the greatest risk reduction was seen in the elderly population (relative risk, 0.55; 95% CI, 0.39–0.77).

End of Life

The ICU is an environment in which end-of-life decisions are made on a regular basis. In fact, 38% of all hospitalized patients who die in the United States spent at least 10 days in the ICU in one review.[112] Older patients, having an understanding of their own wishes regarding health care, frequently use advance directives and health care proxies. Often, patients know these legal entities through interaction with an astute family physician or by way of a previous elective hospital admission. Understanding the logistics of these documents is mandatory when caring for trauma patients. Given the acute onset of trauma and a patient's inability to predict future injury, trauma practitioners must rely on a written document that may have been written years prior or by interactions with a health care proxy. The health

care proxy is an individual who is appointed by a competent adult. In the event that the individual is no longer able to make health care decisions, the proxy would "speak" on behalf of the patient. There is evidence that physicians frequently have differing opinions regarding a clinical outcome compared to the health care proxy, as well as personal beliefs that can influence end-of-life decisions.[112] Withholding and withdrawing life support is commonly practiced in ICUs. Common reasons for this are futility, patient suffering, and the anticipation of a poor quality of life.

Futility is a concept with a distinct ethical definition. Unfortunately, the term is applied frequently in situations that are strongly influenced by the local environment and culture. What may be viewed as futile by one physician may not be seen the same way by another. As such, utilization of an ethics consultation will be important. The perception of suffering of elderly trauma patients is a cause of emotional distress for the ICU staff.[113] The ubiquitous use of analgesics and sedatives in the ICU is necessary, but the science is imprecise. Most surgical ICU patients who survive indicate that they would repeat the experience again if necessary.[114] End-of-life decisions based on this argument are not indicated. Using the argument of a poor quality of life is commonly based on the perceptions, beliefs, and personal interpretation of quality of life of the health care providers. Care must be taken to not interject one's own beliefs when counseling families. Most ICU survivors indicate that they have an acceptable quality of life and would undergo treatment again.[115] Data on the quality of life following ICU treatment after injury are not widely available. Limiting care in the elderly trauma patient in whom survival is unlikely is necessary. Importantly, this care at the end of life may not be consistent with patient preferences and values and may place unnecessary emotional, physical, and financial burden on dying patients and their family members. Using standard ethical concepts and precise diagnoses will help facilitate discussions with families. Palliative care consultations have been used successfully with trauma patients, which can improve family and staff satisfaction with end-of-life care.[116] There is emerging evidence that advance care planning early during an acute care hospitalization can reduce ICU admissions and that time-limited trials and proactive early palliative care consultation in the ICU can reduce the LOS and intensity of treatment for patients who die in the ICU.[117]

ORGAN DONATION

Donation of organs from the elderly requires "expanded criteria" that are specific to the Organ Procurement Organization. From San Diego and Imperial Counties, patients older than 60 years without hypertension or a serum creatinine greater than 1.5 mg/dL can be considered for donation. In the interval between 2009 and 2013, 11% to 14% of annual donors from the San Diego and Imperial County Organ Procurement Organization were older than 60 years.[118] Thus, it seems reasonable to consider otherwise healthy seniors as suitable candidates for organ donation.

CONCLUSION

As the elderly population continues to grow and lead an active lifestyle, the trauma surgeon will be increasingly called upon to treat injured geriatric patients. An understanding of the unique anatomic, physiologic, and psychiatric aspects of the aging adult is mandatory. This, coupled with an appreciation of a variety of PECs, the impact of medications, and respect for advanced medical decisions, should form the basis of our approach to care.

Early identification of the critically injured elderly patient, physiologically based resuscitation, and timely intervention for correctable injuries will optimize utilization of resources, decrease complications, and improve outcomes in this unique and special population.

Wounds, Bites, and Stings

Alisa Cross • Amanda Celii • Roxie M. Albrecht

KEY POINTS

- The four phases of wound healing are hemostasis, inflammation, proliferation, and maturation/remodeling.
- Significant influences on wound healing include age, nutrition, body habitus, and social history.
- The decision to use antibiotics for a wound will depend on host factors (eg, age, comorbidities, immunocompromised state), wound characteristics, and location.
- Wounds with significant contamination, ischemia, or tissue loss are left open to heal by secondary intention.
- Transmission of HIV or hepatitis C through saliva from a bite is rare, and HIV testing after human bites is not necessary.
- Jaws of larger dogs are capable of generating 200 to 450 pounds per square inch of pressure, and fractures under the injury to soft tissue should be ruled out.
- Rabies is a vaccine-preventable viral disease primarily caused by the bite of a rabid animal and has a worldwide distribution.
- In up to 40% of patients, the bite of a brown recluse spider will lead to necrosis of soft tissue due to local ischemia.
- Pit vipers including rattlesnake, water moccasin, and copperhead snakes have a heat-sensing pit located behind their nostrils.
- Although the mouth of a snake is colonized with bacteria like all animals, local infection following a snakebite is rare.

INTRODUCTION

Millions of patients are treated for traumatic wounds annually. These wounds are managed by a variety of practitioners, including surgeons, specialty surgeons and physicians, and advanced practice providers. The majority of wounds are straightforward and heal satisfactorily regardless of the technique used; however, there are wounds that require special care or attention, which will be discussed in this chapter. Wound management priorities include healing without infection, maintenance of normal function, and acceptable cosmesis. The simplest technique that will meet these requirements should be employed in treating a wound and will vary with the nature of the wound, its anatomic location, and the clinical situation.

WOUNDS

Wound Healing

Wounds, whether created electively or as a result of traumatic injury, are an integral component of the surgical patient; thus, understanding the pathways and mechanisms of wound healing is critical for the optimal care of surgical patients. This fund of knowledge is applicable to the care of patients with acute wounds and facilitates the development of therapeutic options for patients with chronic or nonhealing wounds. Wound healing is often divided into phases in order to aid understanding of the complex process. These phases are hemostasis, inflammation, proliferation, and maturation and remodeling (Table 50-1). Although these phases are often described as discrete events, it is important to realize that characteristics and elements of these phases overlap. Wound repair is a dynamic and complex process of inflammation characterized by a well-coordinated pattern of cell migration, proliferation, and differentiation, along with angiogenesis and matrix remodeling. The essential characteristics of the early phase include hemostasis and inflammation. The intermediate phase is characterized by cell proliferation, migration, angiogenesis, and epithelialization, whereas the late phase involves collagen production with contraction of the wound. Ultimately, all wounds undergo continuous remodeling for the rest of the patient's life.

TABLE 50-1: Phases of Wound Healing and Activity

Stage	Predominant cells	Activity	Time course
Hemostasis	Platelets	Vascular congestion Platelet plug formation	Immediate
Inflammation	Neutrophils	Clearance of necrotic tissue/microbes	Hours 6–48
	Macrophages	Wound debridement Angiogenesis	Hour 48–day 4
	Lymphocytes	Matrix synthesis Cell immunity/antibody production Lymphokines regulate collagenase	Day 5
Proliferation			Days 4–12
Angiogenesis	Endothelial cells	Vascular growth	Hour 48–day 4
Fibroplasia	Fibroblasts	Matrix/collagen synthesis	Day 3–3 months
Epithelialization	Epithelial cells	Wound coverage	Variable
Maturation/remodeling	Fibroblasts/myofibroblasts	Matrix deposition Collagen remodeling Vascular maturation/regression	Day 21–1 year

A chapter on wounds would not be complete without expansion on the four phases of healing briefly described earlier. The first phase, or hemostasis (coagulation) and inflammation phase, occurs to minimize hemorrhage from disrupted blood vessels. Hemostasis precedes inflammation. Vasoconstriction occurs from the effects of vasoactive mediators (epinephrine, norepinephrine, prostaglandins, serotonin, and thromboxane). Adherence and aggregation of platelets and the activation of the coagulation cascade result in the generation of fibrin, leading to clot formation. Activated platelets degranulate and release chemotactic and growth factors from α granules, such as platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), platelet-activating factor (PAF), serotonin, and fibronectin.

The inflammatory phase is characterized by increased vascular permeability, chemotaxis of cells from the circulation into the wound, release of cytokines and growth factors, and the activation of migrating cells. Inflammatory cells are attracted by chemokines released by platelet activation. Vasoconstriction dissipates and a period of vasodilation commences mediated by histamine, prostaglandins, kinins, and leukotrienes. Blood flow is increased, and inflammatory cells (neutrophils, macrophages, lymphocytes) and factors to mitigate infection are abundant in the wound. The predominate cell in the first 24 to 48 hours, the neutrophil, releases the inflammatory mediators and bactericidal oxygen free radicals, decreasing bacterial counts in the wound. Macrophages, derived from circulation monocytes, migrate into the wound and peak at 3 days, and persist until wound healing is complete. Macrophages phagocytize debris and bacteria and secrete collagenases, elastases, and cytokines. These cytokines further stimulate chemotaxis and proliferation of fibroblasts and smooth muscle cells. Endothelial cells are attracted to the wound by further macrophage substance release for promotion of angiogenesis. Additionally, cytokines mediate nitric oxide synthesis, which has antimicrobial properties and stimulates collagen synthesis.[1,2]

T-lymphocytes are attracted to the wound around day 5 by the cellular release of interleukin (IL)-1 from neutrophils, playing a role in cellular immunity and antibody production, in addition to secretion of lymphokines (heparin-binding epidermal growth factor and fibroblast growth factor). IL-1 also contributes to the regulation of collagenase activity.

The proliferative phase occurs from about day 4 to day 12, overlaps with the inflammatory phase, and includes epithelialization, fibroplasia, angiogenesis, and contraction. Revascularization occurs in parallel with fibroplasia. Healthy tissue adjacent to the wound sprouts capillary buds that extend into the wound. Endothelial cells from the side of the venule closest to the wound begin to migrate in response to angiogenic stimuli. The newly formed venules diverge along one of two pathways; they either differentiate into arterioles or undergo apoptosis and ingestion by macrophages. Mediators of angiogenesis, endothelial cell growth, and chemotaxis include cytokines produced by platelets, macrophages, and lymphocytes; low oxygen tension; wound acidemia; and high lactate levels.[3,4] Fibrin proliferation and collagen deposition replace the provisional fibrin matrix and provide a stable extracellular matrix at the wound site consisting of collagen, proteoglycans, and fibronectins. This activity is regulated by PDGF and TGF-β, with the latter having a central role in wound healing.[5] Granulation tissue formation deep in the wound provides a transitional replacement for normal dermis. It consists of a dense network of blood vessels and capillaries, elevated cellular density of fibroblast and macrophages, and randomly organized collagen fibers. Epithelialization is occurring at the wound surface and begins within a few hours of injury. Epithelial cells arising from the wound margins and dermal epithelial appendages become activated and migrate over the viable connective tissue. Basal keratinocytes lose their tight

attachments and begin to migrate across the wound. The migration of these edge basal cells during wound closure has been described as being akin to cells "leapfrogging" over one another, rather than crawling across the wound to cover the defect.[6,7] As the migrating epithelial cells advance and begin to cover the wound, proliferation begins to ensure that sufficient cells are available to cover the wound. This is one of the areas of wound healing that is impeded by steroids. It has been shown that glucocorticoids impede epithelial growth factor (EGF)–mediated cellular migration.[8] Once the wound has been bridged, the migrating epithelial cells change shape to become more columnar, followed by surface keratinization.[9] Epithelialization is complete in approximately 48 hours in approximated wounds, but completion of epithelialization can depend on the size and depth of the wound, tissue defect, and contamination or infection. Investigations remain ongoing regarding the signals or stimuli that bring the proliferative phase of wound healing to an end.

Collagen formation and deposition are critical to the reconstructive phase of wound healing, and transition to the remodeling phase of wound healing is delineated by a state of collagen equilibrium. Fibroblasts are also responsible for the production of other matrix constituents, including fibronectin and the glycosaminoglycans.[10] Wound collagen synthesis is increased for at least 4 to 5 weeks.[11,12] Initially, there is an increase in type III collagen followed by a decline and increased deposition of type I collagen, the dominant fibrillar collagen in skin.[13] Wound breaking strength, as compared to uninjured or normal tissue, is 3% at 1 week, approximately 20% at 3 weeks, 50% at 4 to 6 weeks, and if healing occurs without complications, 80% at 10 to 12 weeks, and has no further increase thereafter. The tensile strength of a wound will never reach that of uninjured tissue.[14-17] Increased collagen turnover continues for at least several years.[18]

The final phase a wound undergoes is the remodeling or contraction from the edges of the wound to the center in a centripetal fashion, resulting from a complex interplay between fibroblast and the extracellular matrix material. During reepithelialization, the wound edges progress toward each other at a rate of 0.6 to 0.75 mm/d, and the rate of contraction is dependent on a wide variety of factors. The correct balance between too little contraction, which leads to nonhealing wounds, and too much contraction, which leads to contractures, is important for optimal healing. New research is questioning longstanding theories on the mechanism of wound contraction. Modified fibroblasts with smooth muscle (SM)–like features, including the expression of α-SM actin (ACTA2), were first observed by Gabbiani and colleagues in granulation tissue of healing wounds. This led to the theory that myofibroblasts promote wound contraction and collagen production.[19,20] Subsequent in vitro studies demonstrated that myofibroblasts generate increased contractile force as compared to fibroblasts, and that the mechanism is related to ACTA2 incorporation into stress fibers and increased focal adhesion size.[21] ACTA2 levels were found to associate with a fibroblast's ability to wrinkle a deformable substrate and enhance collagen gel contraction.[22] The compelling hypothesis that myofibroblasts are essential for wound contraction is balanced by a counterhypothesis that myofibroblasts are not essential for wound contraction. This counterhypothesis is supported by studies in human sacrococcygeal pilonidal sinus wounds noting contraction without a high density of myofibroblasts being present; studies showing that full-thickness excisional wounds in rats capable of unwounded wound contraction in the absence of myofibroblasts, fibroblasts, and myofibroblasts produce similar contractile forces; studies demonstrating ACTA2 absence in free-floating collagen lattice contraction; studies showing that suppression of ACTA2 expression in rodents treated with vanadate did not alter wound contraction; and most recently, two studies demonstrating that ACTA2 expression is not necessary for wound closure.[23,24] Thus wound contraction mechanisms remain an active area of research for approaches to promotion of healing in chronic wounds or reducing scar contractures and fibrosis.

Patient Factors That Affect Wound Healing (Table 50-2)

The speed of wound healing and tensile tissue strength are affected by the patient's overall health status and the specific structure or organ that is wounded or injured. Skin and fascia are the strongest tissues in the body but regain tensile strength more slowly than other tissues. The viscera, stomach, and small intestine have weaker tensile strength but progress faster through the healing cycle, and in the colon, the speed is similar but the tensile strength varies from the cecum to the sigmoid. Patient factors are important in the discussion of risks of wound closure and complications.

The overall health or the disease state of the patient has a significant influence on wound healing, including age, nutrition, body habitus, and social history.[25]

AGE

The thinning of the skin and tissues in the elderly predisposes them to injury. Age and coexisting chronic disease

TABLE 50-2: Patient Factors That Affect Wound Healing

Age
Gender
Weight
Nutritional status
Hydration status
Alcohol use (acute and chronic)
Smoking tobacco (nicotine, carbon monoxide, hydrogen cyanide)
Immune responses (cancer, AIDS, chemotherapy, catabolic steroids)
Chronic disease (diabetes mellitus, cirrhosis, chronic kidney disease)
Radiation exposure
Ischemia/hypoxemia
Specific structure or organ injured

slow the phases of wound healing. Every phase of healing undergoes age-related changes, which includes enhanced platelet aggregation, increased secretion of inflammatory mediators, delayed infiltration of macrophages and lymphocytes, impaired macrophage function, decreased secretion of growth factors, delayed reepithelization, delayed angiogenesis and collagen deposition, reduced collagen turnover and remodeling, and decreased wound strength.[26] Additionally, sex hormones play a role in age-related wound healing, with studies showing that aged males have further delays when compared to aged females. Estrogen has been found to improve age-related impaired wound healing in both men and women, whereas androgens negatively regulate cutaneous wound healing.[27]

OBESITY

Many of the wound issues surrounding obesity result from increased wound tension and pressure combined with perfusion deficits and hypoxemia resulting in ischemia in the subcutaneous tissues. Obesity is also associated with altered immune and inflammatory responses with discoveries of induced changes in adipose tissue that may initiate and perpetuate a chronic low-grade inflammatory state. Phenotypic switching of protective M2 macrophages to proinflammatory M1 macrophages exacerbates the inflammatory process. Adipose tissue itself excretes angiogenic inhibitors and fibrotic mediators, thus creating extracellular matrix that prevents angiogenesis and further adding to hypoxia. There are supportive findings that obesity-related changes in cellular and immune function are improved by weight loss.[25,28]

NUTRITION

The primary sources of energy for wound healing include fats and carbohydrates. The major fuel for adenosine triphosphate (ATP) synthesis is glucose. Protein is a source of energy for capillary formation, fibroblast proliferation, proteoglycan synthesis, collagen synthesis, and wound remodeling. The semi-essential amino acid arginine is required during periods of maximal growth, severe stress, and injury, and the most abundant amino acid is a major source of metabolic energy for rapidly proliferating cells. Glutamine is critical in the inflammatory stage of wound healing. β-Hydroxy-β-methylbutyrate (HMB), a metabolite of the essential amino acid leucine, is responsible for inhibiting muscle proteolysis, modulating protein turnover, and enhancing collagen deposition.

Vitamins C, A, and E have antioxidant and anti-inflammatory effects important to wound healing, and deficiencies result in impaired wound healing. Micronutrients such as magnesium, zinc, and iron are also important in acute and chronic wound healing.

The nutrients needed for wound healing are complex, suggesting that nutritional support including supplementation of these critical components may benefit wound healing. A summary of studies has reported that high-dose supplementation of zinc and vitamin C, in addition to a regular diet, may support the healing of surgical wounds in healthy subjects, and formulations enriched with glutamine and antioxidant micronutrients may support the healing of traumatic wounds and can improve the healing of burns.[29] Glutamine supplementation has been shown to improve wound breaking strength, increase levels of mature collagen, and decrease complications in colorectal and colon cancer treatment.[30] The combination of arginine, glutamine, and HMB has been shown to increase hydroxyproline levels and improve bursting pressure in a colon anastomosis model, improve muscle strength following surgery, reduce acute inflammation from radiation, and impact secondary wound healing in ischemic and diabetic wounds. There are few studies, however, evaluating the use of this combination in acute wound healing models, and recent studies question the benefit of these supplements in the critically ill population.[31]

ALCOHOL AND SMOKING

The exposure to ethanol is most apparent in the proliferative phase of wound healing with most effects on angiogenesis, collagen production, alterations in protease balance at the wound site, and impairment of the early inflammatory response increasing the incidence of infection.[32] Smoking affects wound healing in the proliferative and inflammatory phases. The inflammatory healing response is attenuated by a reduced inflammatory cell chemotactic responsiveness, migratory function, and oxidative bactericidal mechanisms. In addition, the release of proteolytic enzymes and inhibitors is imbalanced. The proliferative response is impaired by reduced fibroblast migration and proliferation in addition to downregulated collagen synthesis and deposition.[33]

Priorities in Wound Management

The management of acute traumatic wounds should be thought of in a three-phase decision algorithm, and while progressing through the algorithm the wound should be protected from further injury and contamination (Fig. 50-1).

The first phase of wound management includes an assessment of the injured patient directed toward identifying and rapidly treating life-threatening injuries. The most readily apparent wound is not always the most important injury that will need to be addressed. Even the most dramatic of wounds should not distract the physician from first addressing fundamental life-threatening injuries. Advanced Trauma Life Support principles should be applied with purposeful attention to the primary ABCDEs (airway, breathing, circulation, disability, exposure) followed by a directed secondary survey to establish appropriate priorities. If there is ongoing hemorrhage contributing to the patient's current or potential hemodynamic stability, techniques may include direct pressure, packing with plain gauze or hemostatic agents, pressure dressings, and temporary or partial wound closure of scalp, face, junctional, truncal, and extremity wounds, as well as reduction and splinting of fractures. Finally, potential junctional or extremity tourniquet placement may need to be considered for extremity wounds with hemorrhage that is uncontrolled

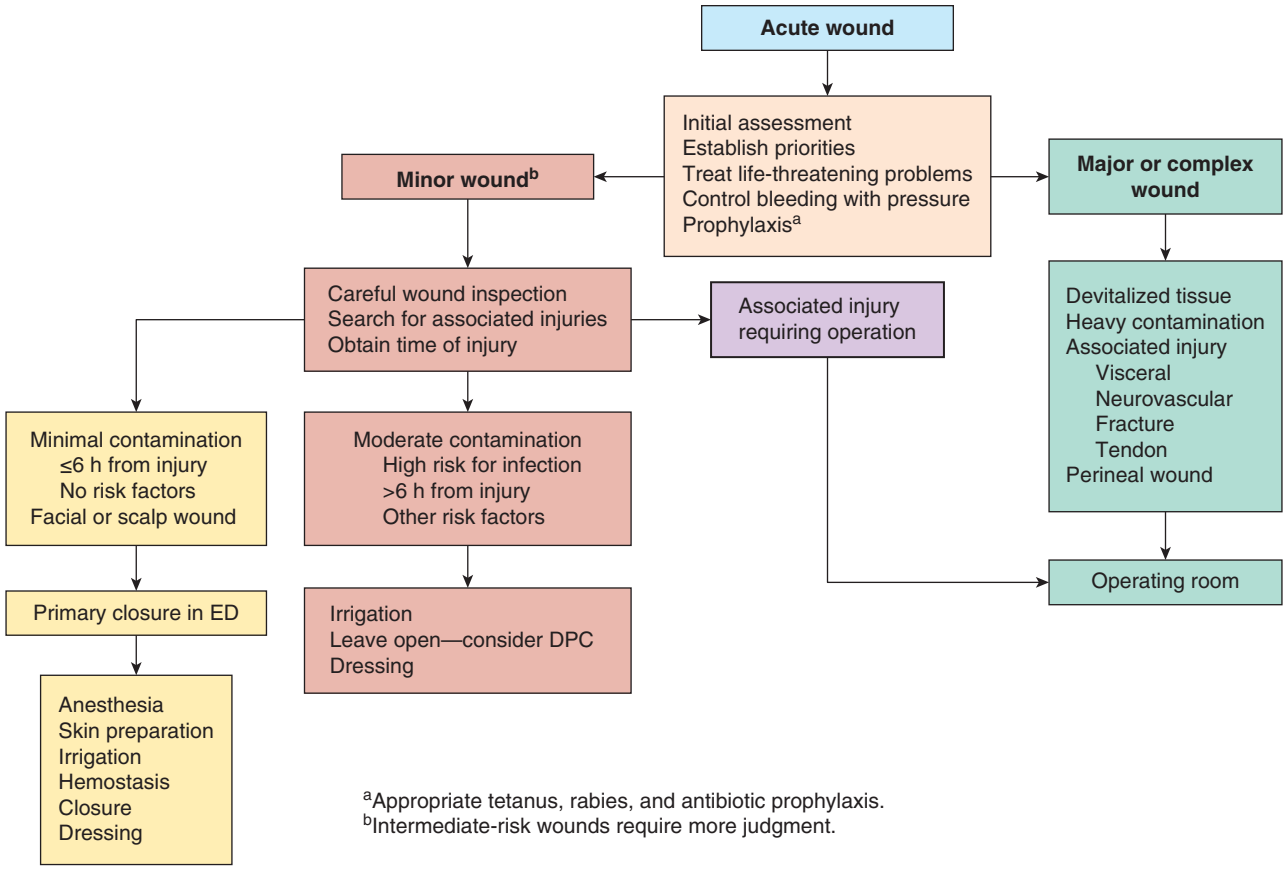

FIGURE 50-1 Algorithm for the treatment of an acute wound. DPC, delayed primary closure; ED, emergency department.

with these prior methods. Hemorrhage from scalp lacerations may lead to significant anemia and shock, especially in the elderly and children. This may be prevented with pressure dressing application, hemostatic temporary closure, or application of disposable or reusable Raney clips. Junctional tourniquets for axilla and inguinal hemorrhage control are in trials in the military and prehospital settings,[34] and current widespread training is ongoing regarding the indications and application of tourniquets for extremity trauma.[35]

Once life-threatening injuries are treated or are being treated, the second phase of the wound management algorithm concerns how to deal with the wound itself. Key questions to be considered in this phase are as follows: (1) Should the wound be managed in the operating room? (2) Are there associated injuries related to the wound (fractures or injuries to tendons, fascia, muscle, nerves, or vascular injuries)? (3) Can the wound be closed primarily, or should it be managed by delayed primary closure or by healing through secondary intention? (4) Should preventative antibiotics be given? (5) Does the patient need tetanus or rabies immunizations and/or prophylaxis?

The third phase of the algorithm relates to techniques of closure and the type of dressing. This is the last phase due to the utmost importance of the first two phases. Almost all truly poor or bad outcomes related to management of wounds can be linked to errors of judgment rather than to technique.

Wound Management in the Operating Room Versus the Emergency Center (Table 50-3)

Factors influencing the decision about whether or not to manage a wound in the operating room relate to the size of the wound, degree of contamination, presence of devitalized or ischemic tissue, anatomic location, associated injuries, and patient-specific factors.

The associated injury to an adjacent structure or cavity may be more important than the wound itself. The goals of traumatic wound management are to avoid infection, assist in hemostasis, and provide the safest closure technique; in addition, it is also important to consider the aesthetics of the wound.

Classification of Wounds

Surgical site infection events occurring following an operative procedure that takes place in an operating room are reportable events within the Centers for Disease Control and Prevention National Healthcare Safety Network. Important to this reporting is the initial classification of the wound. Wounds are divided into four classes, as listed in the following sections.

TABLE 50-3: Conditions for Wound Management in the Operating Room

Large or complicated soft tissue injury
Extensive amount of necrotic or ischemic tissue
Heavy contamination
Associated injury
Vascular
Tendon or fascia
Nerve
Fracture
Viscera
Intra-articular
Perineal wounds
Compartment syndrome
High-pressure injection injuries
Patient factors
Age
Length of sedation
Volume of topical anesthetic
Physiologic status
Mental/psychological status

CLEAN

A clean wound is an uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tracts are not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. Operative incisional wounds that follow nonpenetrating (blunt) trauma should be included in this category if they meet the criteria.

CLEAN-CONTAMINATED

Clean-contaminated wounds are operative wounds in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered.

CONTAMINATED

Contaminated wounds are open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (eg, open cardiac massage) or gross spillage from the gastrointestinal tract and incisions in which acute, nonpurulent inflammation is encountered, including necrotic tissue without evidence of purulent drainage (eg, dry gangrene), are included in this category.

DIRTY OR INFECTED

Dirty or infected wounds include old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation.

Management of the Wound

Once the critical associated injuries have been excluded or addressed, the decision is made about adjuncts to wound management, such as antibiotics and tetanus prophylaxis, skin preparation, irrigation methods, and type of wound closure. Additionally, the history should document the following: the event, environment, and time of the injury, and location, width, length, and depth, including the tissues involved such as subcutaneous fat, fascia, muscle, tendon, bones, nerves, and vascular structures. The appearance of the wound edges, wound bed, and the neurovascular and functional status should also be documented.

When deciding if antibiotics are needed, several factors need to be considered, including host factors such as age, comorbidities, and immunocompromised states, and wound characteristics and location (Table 50-4). In regard to the latter, the thigh and leg have the highest infection rate, whereas the scalp has the lowest (Table 50-5).

A meta-analysis conducted to determine whether prophylactic systemic antibiotics prevented infection in patients with nonbite wounds managed in the emergency department found that patients treated with antibiotics had a slightly greater incidence of infection compared to untreated controls (odds ratio, 1.16; 95% confidence interval, 0.77–1.78). Thus, from the nine randomized trials analyzed, it was concluded that there is no evidence the prophylactic antibiotics offer protection against infection of nonbite wounds in patients treated in emergency departments.[36] However, patients with wounds with high risk for infection due to location, contamination, tissue destruction, delayed presentation, and high-risk patient factors should receive antibiotics

TABLE 50-4: Characteristics That Indicate Need for Antibiotics

Host characteristics	Wound characteristics
Age	Crush/devitalized
Comorbidity	Stellate laceration
Diabetes mellitus	Contamination

at presentation and potentially an additional dose prior to debridement and closure if this time is prolonged from over the half-life of the initial dose (Table 50-6). The less time that elapses between injury and the administration of antibiotics, the lower is the risk of infection, especially in open fractures. Patients with open fractures receiving antibiotics within 3 hours of injury had decreased infection rates compared to those who received antibiotics beyond 3 hours (4.7% vs 7.4%).[37] In most settings, a first-generation cephalosporin, antistaphylococcal penicillin, or macrolide is adequate. If the wound has an intraoral component, a penicillin is appropriate. For more austere contamination and unusual incidents involving lakes, ponds, rivers, natural disasters (earthquakes, tornadoes), or agricultural or combat injuries, more resistant organisms should be considered, including nonfermenting gram negatives (*Acinetobacter*, *Pseudomonas*), *Enterobacter*, *Serratia*, and yeast or fungi (mucormycetes, *Apophysomyces*, *Aspergillus*). In these situations, additional agents such as quinolones, extended-spectrum penicillin, and antifungals should be considered and tailored to postculture findings and sensitivities.[38,39]

Tetanus immunization should be reviewed when a patient presents with an acute injury or wound, and prophylaxis administered as indicated (Table 50-7). Administration of the diphtheria–tetanus–acellular pertussis (DTaP) vaccine is routinely recommended in adolescents, with a single booster dose of a vaccine containing tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap, Adacel, or Boostrix 0.5 mL intramuscularly [IM]) recommended for 11- to 12-year-olds, followed by tetanus toxoid and the reduced diphtheria toxoid in the form of Td recommended at 10-year intervals throughout life. In the United States, a tetanus and diphtheria toxoids (Td) vaccine (0.5 mL IM) is recommended every 10 years for all adults with complete prior immunization against tetanus and diphtheria. The Advisory Committee on Immunization Practices also recommends a single dose of a vaccine containing tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) for all adults age 19 years and older who have not received Tdap previously. When indicated, Tdap should be administered regardless of the interval since the last dose of Td. The subsequent Td booster can be resumed 10 years after the Tdap administration. Adults who have not been previously vaccinated against tetanus and diphtheria should receive a series of three vaccines (one Tdap and two Td vaccines).[40] The preferred schedule is a Tdap vaccine dose followed by a Td vaccine dose 4 weeks later and another Td vaccine dose 6 to 12 months later. In addition to tetanus immunization, human tetanus immune globulin is indicated in individuals who have sustained a wound that is more severe than a clean and minor wound (eg, wounds contaminated with dirt, feces, soil, or saliva; puncture wounds; avulsions; wounds resulting from missiles, crushing, burns, or frostbite) and who have either received fewer than three doses of tetanus toxoid previously or in whom the number of previous doses is unknown.

The process and type of skin preparation for wound closure must be considered to decrease trauma to the wound and decrease the incidence of infection. Use of a depilatory or clippers to remove hair from the area is preferred over shaving to decrease infection[41] and foreign body contamination to the wound. If the wound can be closed without disruption of the surrounding hair or tissue, that would be most preferable; if not, limited removal for adequate closure is acceptable. The most common antiseptics—povidone-iodine solution (betadine), chlorohexidine gluconate solution (Hibiclens), and hydrogen peroxide—are all cytotoxic, have antibacterial activity, and have been shown to inhibit wound healing. These wound antiseptics should be restricted to the intact skin surrounding the wound and not in contact with the wound itself, unless at very dilute concentrations. Chlorhexidine gluconate is a potent broad-spectrum germicide that is effective against nearly all nosocomial bacteria and yeasts,[42] and bacterial resistance to chlorhexidine is rare. Chlorhexidine has a low skin irritancy and sensitization potential, has a strong affinity for the skin, and demonstrates prolonged duration of antimicrobial effect. Unlike povidone-iodine, the antibacterial activity of chlorhexidine persists for hours after topical application. In contrast to iodine-containing compounds, chlorhexidine is not neutralized by contact with proteinous solutions, such as blood. Chlorhexidine should not be used in the facial region due to risk of contact injury to the cornea.

Wound irrigation and removal of debris are probably the most important steps in wound preparation for closure. Methods include mechanical, biological, technical, and surgical. Each method has different potential benefits and risks. The advantages of all irrigation methods are removal of debris, hydration of the wound, and assistance in visualization of structures for repair or control. The classic techniques include bulb syringes, syringes with attached cannulas, puncturing holes in the cap of liter bottles of normal saline, gravity flow irrigation from intravenous solution bags, and a number of commercial devices on the market that provide high-pressure or alternating pulsatile pressure irrigation. The optimal irrigation pressure is unknown. There

remains ongoing debate given concern that if the pressure is too high, tissue destruction will occur and that low pressure fails to remove the debris and bacterial load, leading to a higher infection rate. Management should be based on the location, characteristics, injury environment, available equipment, and location of treatment.[43] A 2015 study in the orthopedic literature has shed a little more light on irrigation, showing that very-low-pressure irrigation (1–2 pounds per square inch [psi]) had similar complication rates, including infection, and was acceptable compared with low-pressure irrigation (5–10 psi) and high-pressure irrigation (>20 psi).[44] Thus, no method was superior to the other. High-pressure and alternating pulse irrigation systems have been noted to be associated with soft tissue damage and deeper bacterial propagation into the soft tissues. A study comparing high-pressure pulse lavage (HPPL) of greater than 20 psi, bulb irrigation, and suction irrigation noted that HPPL caused significantly more soft tissue damage and that bulb irrigation and suction irrigation were capable of removing more inorganic contamination than HPPL.[45] This supports the concept that sharp debridement and low-pressure irrigation, as opposed to high-pressure irrigation systems, may be the treatment of choice for most wounds. Judgment of the wound, including whether it is heavily contaminated, and concerns regarding soft tissue damage should dictate the use of higher pressure systems.

The solution for irrigation should be nontoxic and allow adequate assessment of the wound during the irrigation process. As previously noted, antiseptic solutions, such as povidone-iodine, chlorhexidine, hydrogen peroxide, and sodium hypochlorite (Dakin's solution) may be toxic to the tissues and impede wound healing. An additional agent used for open fracture management, castile soap, had a higher reoperation rate when compared to saline irrigation.[44] Normal saline has been the primary solution favored for wound irrigation given that it is isotonic, available, and does not interfere with normal wound healing processes. A recent review has reported no evidence that using potable (drinking/tap) water to cleanse an acute wound increases infection rates and some evidence that it reduces infection rates.[46] Thus, this may be an option if more sterile solutions are not available.

Wound Closure

The "golden period" for primary wound closure, defined as less than 6 hours from the time of injury, has been called into question. The initial recommendation of 6 to 8 hours was based on laboratory and clinical studies on the doubling time of bacteria and from clinical outcomes demonstrating decreased risk for infection after debridement during that period. Exceptions to this rule were the scalp and face, given the lower incidence of infection (Table 50-5). Quinn et al[47] reported that diabetes, wound contamination, length greater than 5 cm, and location on the lower extremity are the most important risk factors for wound infection. The time from injury to wound closure is not as important as previously thought. Improvements in irrigation, debridement, and decontamination over the past 30 years may have led to this change in outcome.[47] Wound closure may be performed immediately with sutures, tapes, tissue adhesives, or staples to allow healing by primary intention. Staples are most commonly used in areas less prone to cosmetic considerations such as the scalp, trunk, and extremities. Sutures are used in most other locations, with the type dependent on the location, wound tension, complexity, and possibly compliance of the patient to return for removal. In the latter population, fast-absorbing gut or other absorbable sutures may be appropriate for an interrupted or subcuticular closure. Complex wounds may be closed in multiple layers, using an absorbable suture to approximate fascia or the dead space of the soft tissues. The technique for skin closure should allow precise alignment of the skin edges, with the minimum amount of foreign material in the wound. For a cosmetic closure of facial wounds, 6-0 monofilament suture with 1- to 2-mm bites in either a running or interrupted fashion is used. These sutures are usually removed in 3 to 5 days to minimize suture marking (Table 50-8).

In the area of the mouth, the repair should approximate the vermillion border of the lip. Tissue adhesives are less painful and quicker to apply but may be associated with more dehiscence than sutures. The most frequent areas of use of these adhesives are for low-tension wounds, especially on the face. Adhesive tapes for closure must have a dry surface for best result, work best in areas of low tension, and can be associated with premature removal, traction blisters, and wound dehiscence. Patient compliance should be considered with tissue adhesive and adhesive tape closures.

Wounds with significant contamination, ischemia, or tissue loss may be left open to heal on their own by secondary intention. Wounds in this category may also need repetitive returns to the operating room for serial debridement of nonviable tissue as determined by the color, consistency, and circulation, and when evaluating muscle viability, contraction is also an important component. Wounds are treated with various methods of debridement, including excisional, abrasive, or nonexcisional, and with the use of irrigation or hydrosurgery. Surgical debridement involves the excision of necrotic tissue with the use of scalpels, scissors, curettes, rongeurs, saws, or burrs. Bleeding is common in this approach, which is usually performed in the operating room. Hydrosurgery,

TABLE 50-8: Timing for Suture removal

unlike high-pressure lavage, consists of a waterjet that passes parallel to the wound that debrides tissue, which is captured by a suction evacuator system. The system simultaneously irrigates and debrides tissue.[48,49] There is debate regarding whether hydrosurgery is cost effective for debridement and wound bed preparation.[50,51]

Wound dressings for open wounds treated by secondary closure are additionally variable. One of the traditional dressings for open wounds has been a moist gauze application and a dry gauze as a cover to wick away any exudate and remove debris—the traditional wet to dry dressing. The goal of newer dressings is to produce a moist but not macerated wound that is free of infection, toxic chemicals, and foreign material while maintaining an optimum temperature and pH. Wound dressings can be broken down into several major groups, which include gauze, semipermeable film dressings, foam dressing, alginates, and hydrocolloids (Table 50-9).

A number of dressing types are appropriate in a granulating wound, and the amount of wound exudate often guides wound care recommendations. Dabiri et al[52] published a practical guideline for dressing use in *Advances in Wound Care* in 2016. In granulating wounds with mild to moderate exudate, a hydrocolloid dressing will maintain granulation tissue and aid in epithelialization by absorbing liquid and exudate by formulating a soft gel. Foams are recommended for wounds with moderate exudate due to their hydrophilic component. Calcium alginates, hydrofibers, and polymeric membrane dressings are also useful in exudate wounds. Fibrinous wound beds require dressings that aid in slough removal, such as wet to dry dressings and proteolytic, enzymatic, or autolytic products. Finally, iodine-based and silver-releasing agents have been formulated into nontoxic antimicrobial dressings to assist in wound healing and enhance bactericidal properties.[53] The current recommendations for silver dressings is a 2-week period of use followed by reevaluation; if there is improvement, the dressings are continued, and if not, an alternative technique should be considered.[54]

Negative-pressure wound therapy (NPWT), also known as vacuum-assisted closure or microdeformational wound therapy, uses a dressing that applies continuous or intermittent

TABLE 50-9: Wound Dressing Materials

Classification	Material	Functions	Use	Examples	Disadvantages	Advantages
Gauze	Cotton gauze	Absorbs fluid, removes exudate with changes	Open or infected wounds, fibrinous wounds	Kerlex fluffs 4×4	Frequent changes, foreign body in wound, desiccation	Readily available
Hydrocolloid	Hydrophilic colloidal particles with adhesive matrix	Maintains moist wound environment with optimum temperature and pH, adherence without adhesion, promotes granulation and epithelialization, seals and protects wound, wound debridement by autolysis	Full- or partial-thickness wounds, decubitus ulcers, primary dressing for closed wounds	Duoderm NuDerm Comfell Hydrocol Cutinova Replicare Tegasorb Granuflex Intrasite Biofilm	Some seepage with heavy exudate, difficult-to-seal wounds with complex shape, malodorous yellow gel formation	Optimal wound environment, improved healing of some wounds, infrequently needs changing, decreased pain, no foreign body residual
Alginates	Calcium alginate fibers	Absorbs fluid and exudate, maintains moist wound environment	Open or infected wounds	Algiderm Algisite Algisorb Kaltostat Curasorb Sorbsan Melgisorb SeaSorb Kalginate	Painful removal when minimal exudate, require a secondary dressing	May be used in infected or contaminated wounds, infrequent dressing changes

Polymeric membrane dressings (PMD)	Hydrophilic polyurethane membrane matrix with a continuous semipermeable film backing	Contain ingredients that continuously cleanse wounds and expedite healing	Donor graft sites and superficial abrasions	Polymem		Nonadherent, may decrease wound pain
Silver dressings	Silver ions incorporated into a dressing	Silver ions bind and disrupt bacterial cell walls, intracellular and nuclear membranes, denature bacterial DNA and RNA	Infected wounds for 2 weeks, if improvement continues	Silvasorb Aquacel Ag Mepilex Ag Silvercel Algicate Ag SilverAlginate Dynaginate AG Suprasorb Ag Acticoat Medifoam Silver Allevyn Ag Polymem Silver	Must be moist to release the active agent	Multiple products with additional wound treatment advantages

negative pressure to a wound. NPWT, similar to the previously discussed dressings, provides wound coverage, prevents desiccation, facilitates wound drainage, and contributes to decreasing the wound bacterial burden. It is not an alternative to debridement, and in fact, if necrotic tissue is present, this mandates additional excisional debridement to assist in healing. NPWT has been shown to decrease hospital length of stay and cost of wound care, improve time to wound closure, and decrease overall complication rates.[55,56] The mechanisms by which NPWT facilitates wound contraction and closure are complex. The negative pressure draws out the excess fluid from the wound and may be a means of clearing excessive quantities of inflammatory mediators, which, it is believed, may preclude the natural progression of the wound healing pathways. Further, edema fluid exerts an adverse compressive effect on the microcirculation; thus, drawing the edema fluid from the wound may improve perfusion and oxygenation to the wound. NPWT has also been shown to decrease bacterial burden within the wound[57] and to act via mechanosensing and mechanotransduction effects, applying traction forces that promote the central migration of factors essential for wound coverage, including wound fibroblasts.[58,59] Keratinocytes, endothelial cells, and fibroblasts have all been shown to respond to the mechanical forces generated by NPWT upon the wound. NPWT also induces production of proangiogenic factors including vascular endothelial growth factor (VEGF) and fibroblast growth factor-2 (FGF-2), and this modifies endothelial morphology and proliferation with an associated improvement in angiogenesis, vessel formation, and ultimately wound perfusion.[60,61] Although the amount of collagen in the wound does not appear to be affected by NPWT, it is clear that NPWT improves collagen organization within the wound. It appears that the cytokine milieu of the wound is changed by the application of NPWT,[62] as evidenced by reduction in tumor necrosis factor levels,[63] whereas IL-8, a potent chemokine and regulator of neutrophil and macrophage migration, was noted to be elevated in the wound without a concomitant elevation of systemic IL-8 levels.[61]

In essence, the NPWT devices commercially available involve placement of a foam or interface material of varying porosity and chemical composition on a wound and then connection to a suction device. Polyurethane ether (PE) black foam is hydrophobic, whereas polyvinyl alcohol (PA) white foam is hydrophilic, and both are used with commercially available NPWT devices. PE is used for fluid drainage and to promote granulation, whereas the PA sponge is used over delicate tissues such as vasculature, tendons, or bowel. Modifications of NPWT devices include the ability to instill a variety of solutions, including antibiotics, through the device into the wound. NPWT has been used in conjunction with other wound healing modalities including being applied over a split-thickness skin graft as well as in combination with processed allogenic materials. NPWT induces macrodeformation of the wound through the centripetal force exerted upon the wound edges and microdeformation forces that are exerted upon the individual cells at the edges and within the body of the wound. This combined effect has the overall effect of transitioning a large complex wound into a smaller wound that may be manageable with lesser surgical reconstructive techniques.[64,65]

In wounds healing by secondary intention, excessive granulation tissue may form preventing epithelialization. The excess granulation tissue may need to be removed by surgical, cauterization (heat or silver nitrate), or laser techniques versus hypertonic NaCl dressings, permeable nonocclusive dressings, or topical steroids.[66] Wounds that heal by secondary intention either contract and epithelize, or if the wound is too large to completely epithelize, once the surface is appropriate a skin graft may be used.

The final choice in wound management may be to leave the wound open following debridement to viable tissue with a planned delayed primary closure. The wound is inspected periodically over the next several days until it is determined that there is no further devitalized tissue or inflammation, and then closed. Most wounds are closed within 48 to 72 hours, but some are closed after up to 5 to 7 days. The goal is to decrease infection and simplify wound care following closure; occasionally, as a result of dead space issues, drains will be placed in the depths of the wound. These wounds will need monitoring for secondary infection, and if this occurs, they need to be opened and allowed to heal by secondary intention. The benefit of this method is that the entire wound may not need to be opened, decreasing final time to healing and closure.

BITES

Human Bites

Mammalian bites are a significant health issue worldwide. In the United States alone, there are approximately 2,000,000 to 5,000,000 bites per year, accounting for 1% of all emergency department visits.[67,68] Human bites are the third most common cause of bite wounds seen in hospital emergency departments, behind dog and cat bites, and account for approximately 2% to 20% of all bite wounds. Human bite wounds are classically underreported and are notorious for causing infection at the site of injury; they also pose a risk for transmission of infectious diseases.

EPIDEMIOLOGY

Human bite wounds can result from incidental (nail biting) or purposeful injury. Studies have found that human bites are more common in males, with the peak incidence occurring in individuals between the ages of 10 and 34 years old.[69] Human bites can be classified according to mechanism, including occlusive bites and clenched-fist injuries (fight bite). Clenched-fist injuries occur predominantly in males, whereas occlusive injuries occur with equal frequency in males and females.[69,70] Human bites are often multiple, located on the upper extremity, and associated with both the greatest loss of function and risk of infection.

PATHOPHYSIOLOGY

Human bites can be classified by mechanism of injury into occlusion bites and clenched-fist injuries. Occlusion bites are similar to animal bites and occur when the teeth close over the skin with sufficient force to breach the integrity of the skin. Human occlusive bites are usually seen as a semicircular or oval area of ecchymosis or erythema that usually compresses tissue rather than avulses it, as is more common in animal bites. This classic pattern is caused by positive pressure from the closing teeth that first disrupts blood vessels and by the negative pressure from suction and tongue thrusting.[69,71] Clenched-fist injuries are not true bites but are clinically similar to bite wounds because the skin is disrupted by teeth. Clenched-fist injuries occur when a closed fist makes impact with another individual's teeth, classically leaving an injury over the dorsal aspect of the third, fourth, or fifth metacarpophalangeal joints. Although clenched-fist injuries are quite small, they are highly prone to infection given the proximity of skin over the knuckles to the joint capsule and the relative avascular nature of these structures.

CLINICAL EVALUATION AND MANAGEMENT

Most human bite wounds can be treated in the emergency department, with approximately 1% to 2% requiring hospitalization. The key components of initial evaluation and management of mammalian bites include a history, thorough physical examination, irrigation, debridement, and closure if indicated. Early treatment, appropriate antibiotic prophylaxis, and surgical evaluation if indicated are the key to achieving optimal outcomes for this vulnerable class of wounds. The first step in evaluation is an accurate history, and the essentials to elicit include both the timing and circumstances surrounding the bite event, location of bite wounds, any treatment rendered, significant past medical history that could alter the host response, tetanus vaccination status, and HIV or hepatitis carrier status of the person inflicting the bite if known (Table 50-10).[69] Occlusive bites in women should give concern for the possibility of domestic or sexual abuse, and although occlusive bites in children are often related to other children, the possibility of abuse needs to be considered.

TABLE 50-10: Essentials of Patient History After Human, Dog, or Cat Bites

Time and location of bite event
Circumstances surrounding bite
Anatomic location
Prehospital treatment (irrigation)
Type of dog or cat and health status (health, rabies vaccination history, behavior, known location)
HIV and hepatitis status of person inflicting human bite if known
Patient factors
• Tetanus status
• Rabies vaccination history
• Immunocompromised state
• Diabetes
• Peripheral vascular disease

TABLE 50-11: Clinical Management After Human, Dog, or Cat Bites

Inspect all bite wounds
• Depth
• Range of motion (very important for hand bites to identify occult injury)
• Associated devitalized tissue
Irrigate all wounds thoroughly with saline
Debride necrotic tissue
Obtain cultures: blood and wound if clinical signs of infection (abscess, cellulitis, sepsis)
Obtain radiographic studies if indicated (identify associated fractures)
Initiate prophylactic antibiotics if indicated
Assess tetanus status and administer if indicated
Assess need for rabies postexposure prophylaxis
Assess need for postexposure prophylaxis and counseling for potential HIV/hepatitis exposure
Hospitalization
• Fever
• Severe cellulitis
• Edema
• Sepsis
• Significant crush injury

Physical examination should include a measurement of vital signs and careful inspection of every bite wound to identify the depth of penetration, the presence of devitalized tissue, neurovascular involvement, and any signs of infection including surrounding erythema, edema, and purulent drainage (Table 50-11). Local anesthesia is usually necessary for an adequate physical examination to minimize patient discomfort. Occlusive or clenched-fist injuries on the hand or fingers are particularly prone to infection as penetration into deeper tissue including the underlying extensor mechanism, joint capsule, or deeper connective tissue is noted to occur in as many as 75% of clenched-fist injuries to the hand.[72] In hand bites of any etiology, it is critical to perform a complete assessment of extension and flexion of the hand and fingers to adequately examine the underlying structures in their natural state, minimizing missed injuries. Although this assessment may be painful for the patient, it is essential and includes recreating the clenched fist to examine the wound and underlying tendons and tissue, which can retract and/or be masked by viewing only in the relaxed position. A thorough exam, although important for every bite, is crucial in this vulnerable anatomic subset of wounds that are prone to infection and devastating complications if diagnosis or management is delayed.

Physical examination is crucial in determining appropriate ancillary studies in patients who present with human bite wounds. Routine laboratory studies, including a white blood cell count, C-reactive protein, and erythrocyte sedimentation

rate, may be elevated but do little to either rule out or rule in infection and are not indicated. Aerobic and anaerobic blood cultures are only indicated in patients who present with physical exam findings consistent with an infected bite wound and signs of systemic infection prior to initiation of antibiotic therapy (Table 50-11). Empiric wound cultures of the noninfected bite wound are not clinically indicated, and the results from those cultures do not correlate with the likelihood of infection or the pathogen that is present if the wound subsequently becomes infected.[73,74] Plain x-rays are indicated in wounds near joints to evaluate for fractures and evidence of foreign bodies and in wounds with signs of marked infection to detect fractures, subcutaneous gas, and changes associated with osteomyelitis (Table 50-11).

Key to achieving optical outcomes is expedient treatment. Irrigation and debridement of necrotic tissue are the most important means of infection prevention and are most important in treating bite wounds to the hand (Table 50-11). Irrigation should proceed with isotonic sodium chloride irrigation under pressure; approximately 100 to 200 mL of irrigation solution per square inch appears to be an adequate rule of thumb.[69,75] For most bite wounds, a 19-gauge blunt needle and 35-mL syringe provide adequate pressure and volume. If surgical sharp debridement is needed, it should include devitalized, infected, and necrotic tissue. Delayed presentation and treatment leads to worse outcomes, particularly in closed-fist injuries where delay beyond 8 days is associated with an amputation rate of 18%.[76] Although an important part of infection prevention, care should be taken when debridement is necessary in order to avoid unnecessary enlargement of the wound preventing potential closure, particularly in areas of cosmetic concern.

A majority of human bite wounds are left open to heal by secondary intention due to the high risk of infection. This is most important for bites to the hand. Primary closure can be considered on clinically uninfected facial wounds less than 24 hours old where cosmesis is paramount and infection is uncommon secondary to the excellent blood supply to the face. This has been anecdotally reported, but a paucity of evidence is present in the literature. In one study of a limited number of patients with primary closure of facial human bites after irrigation and debridement, despite the duration of injury being delayed up to 4 days, wound healing was complete in 90% of patients at the time of suture removal.[77]

Appropriate prophylaxis is of paramount importance in minimizing complications in patients who suffer human bite wounds. All patients with human bite wounds that penetrate the dermis, regardless of appearance of the wound, should undergo antibiotic prophylaxis because of the higher risk of infection. One randomized controlled trial that studied the utility of antibiotic prophylaxis in human bite injuries to the hand found that 47% of patients in the placebo group developed infection versus none in the antibiotic prophylaxis group.[78] It is of particular importance in occlusive and clenched-fist injuries to the hand, wounds near a bone or joint, wounds with associated crush injury, wounds requiring surgical repair, and wounds in immunocompromised patients. Patients receiving antibiotic prophylaxis should receive the first dose as soon as possible after the injury and continue the antibiotic course for 3 to 5 days. Antibiotic prophylaxis should include activity against the common human bite wound pathogens, including *Streptococcus* species, *Staphylococcus aureus*, *Eikenella*, *Fusobacterium*, *Peptostreptococcus*, *Prevotella*, and *Porphyromonas* species (Table 50-12). In addition to antibiotic prophylaxis, tetanus prophylaxis should be administered if indicated (Table 50-7). Transmission of HIV and hepatitis C through saliva is rare, and routine HIV testing after human bites is not necessary; however, counseling regarding postexposure prophylaxis may be appropriate in certain settings (Table 50-11).[79-81] Rates of transmission of hepatitis B virus are higher, and administration of an accelerated course of hepatitis B virus vaccine is recommended.

TABLE 50-12: Antibiotic Guidelines After Dog, Cat, or Human Bites

Infection not established

- Amoxicillin + clavulanate (child, 22.5 + 3.2 mg/kg up to 875 + 125 mg) orally, 12 doses hourly for 5 d
- If commencement of above is likely to be delayed, procaine penicillin (child, 50 mg/kg up to 1.5 g) intramuscularly, as 1 dose, followed by above

Infection established

- Metronidazole (child, 10 mg/kg up to 400 mg) orally, 12 doses hourly for 14 d + EITHER
- Cefotaxime (child, 50 mg/kg up to 1 g) intravenously daily for 14 d OR
- Ceftriaxone (child, 50 mg/kg up to 1 g) intravenously daily for 14 d OR
- Piperacillin + tazobactam (child, 100 + 12.5 mg/kg up to 4 + 0.5 g) intravenously, 8 doses hourly for 14 d OR
- Ticarcillin + clavulanate (child, 50 + 1.7 mg/kg up to 3 + 0.1 g) intravenously, 6 doses hourly for 14 d

For patients with immediate penicillin hypersensitivity

- Metronidazole (child, 10 mg/kg up to 400 mg) orally, 12 doses hourly for 14 d + EITHER
- Doxycycline (child > 8 y, 5 mg/kg up to 200 mg) orally for the first dose, then 2.5 mg/kg up to 100 mg orally, 12 doses hourly OR
- Trimethoprim + sulfamethoxazole (child, 4 + 20 mg/kg up to 160 + 800 mg) orally, 12 doses hourly OR
- Ciprofloxacin (child, 10 mg/kg up to +500 mg) orally, 12 doses hourly

COMPLICATIONS

The most feared complication following human bite wounds is the development of infection. Human bites are a challenging problem given the wide variety of bacteria (>50) and the number of organisms, with almost 10^8 microbes/mL found in saliva.[68,82] Higher rates of infection are seen in human bites with delayed presentation, bites on the hand, or bites on relatively avascular structures (ear cartilage). When infections do

occur, they tend to be polymicrobial, and common organisms include *Streptococcus viridans*, *Staphylococcus* species, *Eikenella corrodens*, *Bacteroides* species, and microaerophilic streptococci. Antibiotics should cover the most common pathogens and provide broad anaerobic coverage. In addition, they should include a β-lactamase inhibitor because 50% to 80% of *Prevotella* species and staphylococci isolated from human bite wounds were β-lactamase producers.[68,83] Antibiotic prophylaxis, as mentioned previously, should be continued for 3 to 5 days and extended if infection is present during follow-up or on initial presentation if delayed. This course is extended for 10 to 14 days when cellulitis is present, for 3 weeks for tenosynovitis, for 4 weeks for septic arthritis, and for 6 weeks for osteomyelitis (Table 50-12).

Dog Bites

Dog bites are the most common animal bites seen in the emergency department in the United States each year (60%–90%), and the medical costs for the treatment of dog bites alone is estimated to be $1 billion per year in the United States. In addition, dog bites cause between 20 and 35 deaths each year in the United States, primarily in infants and young children.[69]

EPIDEMIOLOGY

Dog bites are frequently caused by animals known to the victim. Dog bite wounds are more common in males and in children, with the highest incidence in males between the ages of 5 and 9 years. The age of the dog bite victim is indicative of location of injury. The most common sites of dog bites are to the head and neck in children through the age of 9 years. In children older than 10 years and adults the most common location of dog bites is to the arms, particularly the dominant hand, and legs.[84-86]

PATHOPHYSIOLOGY

Dogs can cause a wide range of injuries, from relatively minor wounds, including scratches and abrasions, to complicated wounds, including deep puncture wounds and lacerations, tissue avulsions, and crush injuries. The severity of injury is most commonly related to the size of the dog, with the jaws of larger dogs capable of generating 200 to 450 psi. The substantial pressures exerted on tissue during the bite result primarily in significant crush injuries and avulsions.

CLINICAL EVALUATION AND MANAGEMENT

As discussed thoroughly in the previous section, the key components of initial evaluation and management of mammalian bites include a history, thorough physical examination, irrigation, debridement, and closure if indicated (Tables 50-10 and 50-11). Dog bites have markedly lower rates of infection than bites from humans or cats. Despite the lower risk of infection, dog bites require copious irrigation. Facial dog bite wounds are usually closed, whereas wounds in other locations are managed with delayed primary closure or healing by secondary intention.

Although the infection risk is lower in dog bites than in human or cat bites, prophylaxis should be considered in patients who present more than 8 hours after the bite or patients who have moderate or severe wounds, diabetes mellitus, an immunocompromised state, hand bites, or deep puncture wounds. Common infecting organisms include *Pasteurella multocida*, *S viridans*, *Bacteroides* species, *Fusobacterium*, and *Capnocytophaga*. Antibiotics should cover the most common organisms; ampicillin plus a β-lactamase inhibitor provide reasonable empiric coverage. Treatment for empiric coverage should be 3 to 5 days and should be extended if infection is present during initial presentation or in follow-up (Table 50-12). As with most bite wounds, treatment can occur mainly as an outpatient; however, if significant infection or debridement is warranted, the patient may require hospital admission and utilization of intravenous antibiotics. Tetanus and rabies prophylaxis should be administered if indicated in all patients presenting with a dog bite (Tables 50-7, 50-13, and 50-14).

Cat Bites

Cat bites are the second most common type of animal bite in the United States, accounting for approximately 5% to 20% of animal bite wounds.

EPIDEMIOLOGY

Cat bites occur with an estimated annual incidence of approximately 400,000 and usually present in a delayed fashion after complications develop.[87] Cat bites occur most commonly in females and the elderly over the age of 75.[88] Over two-thirds of cat bites occur on the upper extremities, with decreasing incidence on the lower extremities, head and neck, and trunk. Similar to human bites, cat bites are heavily contaminated with bacteria.

PATHOPHYSIOLOGY

Cat bites do not carry as much force as seen in dog bites and thus are not associated with the same degree of crush and soft tissue injury. Due to their sharp and narrow teeth, cat bites present with small puncture wounds that can be deceptively deep.

CLINICAL EVALUATION AND MANAGEMENT

The evaluation and management of cat bites are similar to other bite wounds and include a history, thorough physical examination, irrigation, and debridement (Tables 50-10 and 50-11). Closure is not indicated in cat bites. As mentioned previously, cat bites are heavily contaminated, and the wounds they inflict, although small, can be deep. Thorough exploration of the depth of penetration is extremely important, because deep abscess and osteomyelitis are more common in cat bites.

As mentioned previously, cat bites are prone to infection. Common organisms include *Pasteurella multocida* and *Staphylococcus* species. Antibiotic prophylaxis that includes

TABLE 50-13: Treatment Recommendations and Estimates of the Risk of Rabies According to Type of Exposure and Geographic Area

		Treatment recommendations[b,c]		Cases of rabies/10,000 untreated exposures[c]	
Geographic area	**Animals[a]**	**Bite**	**No bite**	**Bite**	**No bite**
Group 1: Rabies endemic or suspected in species involved	Bats anywhere in the United States; raccoons, skunks, foxes, mongooses in Puerto Rico, dogs in most developing countries and in the United States along the Mexican border (3%–80% rabid)	Treat	Treat	150–5000	0.3–160
Group 2: Rabies not endemic in species involved in the exposure, but endemic in other terrestrial animals in the area	Most wild carnivores (wolves, bobcats, bears) and groundhogs (2%–20% rabid)	Treat	Treat or consult	10–1200	0.2–40
	Dogs and cats (0.1%–2% rabid)	Observe or consult	Observe or consult	0.5–120	0.01–4
	Rodents and lagomorphs except groundhogs (0.01% rabid)	Consult or do not treat	Do not treat	0.05–0.6	0.001–0.02
Group 3: Rabies not endemic in species involved in the exposure or in other terrestrial animals in the area	Dogs, cats, many wild terrestrial animals in Washington, Idaho, Utah, Nevada, and Colorado (0.1%–0.01% rabid)	Consult or do not treat	Consult or do not treat	0.05–6	0.001–0.2

[a]Percentages are the approximate proportions of indicated species found rabid when submitted and tested in state health department laboratories.
[b]"Consult" denotes consultation with a state or local health department. If the risk of rabies in the species involved in the exposure is low and the animal's brain is available, treatment is sometimes delayed up to 48 hours pending the results of laboratory testing. A healthy domestic dog or cat that bites a person should be confined and observed for 10 days. Any illness in the animals should be evaluated by a veterinarian and reported immediately to the local health department. If signs suggestive of rabies develop, treatment is begun immediately. If the animal is a stray or unwanted cat or dog, it should be killed immediately and the head removed and shipped under refrigeration for examination by a qualified laboratory.
[c]Rabies develops in 50% to 60% of untreated humans bitten by a rabid animal and in 0.1% to 2% of those exposed to rabid animals but not bitten (scratched or licked on an open wound or mucous membrane). The number of cases per 10,000 untreated patients was derived by multiplying the prevalence of rabies in a geographic area by the proportion of untreated humans in whom rabies would be expected to develop after exposure to a rabid animal.

Source: Adapted from Fishbein D, Robinson L. Rabies. *N Engl J Med.* 1993;329:1636. Adapted from Centers for Disease Control and Prevention. Rabies Prevention—United States, 1991. Recommendations of the Immunization Practices Advisory Committee (ACIP). *MMWR.* 1991;40(RR03):1-19. Table 2.

ampicillin and a β-lactamase for 3 to 5 days is indicated, with extended duration for established infection. Tetanus and rabies prophylaxis should be given if indicated (Tables 50-11 and 50-12). It is important to remember when evaluating and managing cat bites that approximately 6% of cat bites will require hospital admission.

Rabies

Rabies is a vaccine-preventable viral disease primarily caused by the bite of a rabid animal. A number of different strains of highly neurotropic viruses cause rabies infection. Most of the viruses belong to a single serotype in the genus *Lyssavirus*, which belongs to the Rhabdoviridae family, and induce a rapidly progressive encephalitis. There is no known effective treatment once infection is established, and rabies has the highest per-case fatality rate of any infectious disease.

EPIDEMIOLOGY

Rabies has a worldwide distribution and is found on every continent except Antarctica.[89] A majority of rabies cases are acquired through exposure to saliva from an animal bite. A minority of cases can occur via nonbite exposures, including aerosolized virus in bat caves, handling virus in laboratories, and transplantation of tissue or organs from a donor with unrecognized disease. The World Health Organization estimates that between 30,000 and 70,000 people die of rabies each year, with a majority of these occurring in Asia and Africa. Dogs are the main source of human rabies deaths, accounting for over 99% worldwide.[90] In the United States, vaccination programs have been responsible for a dramatic decline in rabies acquired from domestic cats and dogs. Since the late 1960s, rabies exposures in the United States have been most commonly linked to wild animals, including bats (most common), raccoons, skunks, and foxes (Table 50-13).[91-93]

TABLE 50-14: Schedule of Prophylaxis Recommended in the United States After Possible Exposure to Rabies

Vaccination status	Regimen[a]
Not previously vaccinated	
Local wound cleansing	Immediate cleansing with soap and water.
Rabies immune globulin	20 IU/kg of body weight (if anatomically feasible, up to half the dose should be infiltrated around the wound or wounds and the rest should be administered intramuscularly in the gluteal area. Never give more than the recommended dose. Do not use the syringe used for vaccine or inject into the same anatomic site.)
Vaccine	1.0 mL of HDCV or RVA intramuscularly in the deltoid area[b] on days 0, 3, 7, 14, and 28.
Previously vaccinated[c]	
Local wound cleansing	Immediate cleansing with soap and water.
Rabies immune globulin	Should not be given.
Vaccine	1.0 mL of HDCV or RVA intramuscularly in the deltoid area[b] on days 0 and 3.

[a]The regimens are applicable to all age groups, including children.
[b]The deltoid area is the preferred site of vaccination for adults and older children. For younger children, the outer aspect of the thigh may be used. Vaccine should never be administered in the gluteal area.
[c]"Previously vaccinated" indicates previous vaccination with HDCV or RVA, or any other type of rabies vaccine and a documented history of antibody response.

HDCV, human diploid cell vaccine; RVA, rabies vaccine adsorbed.

Source: From Fishbein D, Robinson L. Rabies. *N Engl J Med*. 1993;329:1636. Adapted from Centers for Disease Control and Prevention. Rabies Prevention—United States, 1991. Recommendations of the Immunization Practices Advisory Committee (ACIP). *MMWR*. 1991;40(RR03):1–19. Table 2.

In the United States, there are approximately two to three reported cases of human rabies per year.[94-96]

PATHOPHYSIOLOGY

The rabies virus has a predilection for neural tissue and spreads via peripheral nerves to the central nervous system. Rabies has a prolonged average incubation period of 1 to 3 months, with reports ranging from several days to 7 years. The relatively slow replication in the infected muscle or peripheral nerve allows for marked immune system evasion. Once in the central nervous system, the virus replicates rapidly and travels to the salivary glands, where productive viral replication and shedding occur. There are many host factors that influence the susceptibility to rabies infection. Host factors that increase susceptibility include virus variant, amount of viral inoculum, degree of innervation at the site of the bite, and host immunity and genetics.[97,98]

CLINICAL EVALUATION AND MANAGEMENT

In humans, established disease is almost always fatal. The dismal prognosis of rabies encephalitis emphasizes the importance of appropriate use of the vaccine and immunoglobulin preparations to prevent infection when indicated in humans presenting with animal bite wounds. The risk of acquiring infection depends on the probability of rabies infection in the animal and the amount of inoculum delivered into the wound. It is of utmost importance for treating physicians to be familiar with the local incidence of rabies in their region and to integrate this knowledge into the patient history of present illness. In general, low-risk bites include those from immunized animals and healthy cats and dogs in nonendemic areas. The risk of rabies inoculation is increased in domestic animals when the bite was unprovoked or if the animal was behaving erratically prior to the bite. Patients who present with bites from wild animals including bats, skunks, raccoons, and foxes should be considered high risk for rabies, and prophylaxis should be given. Tables 50-13 and 50-14 summarize the risk of transmission of rabies and treatment. Upon initial presentation, all bite wounds should be thoroughly cleansed with soap and water. This treatment alone has been shown to protect 90% of experimental animals from infection following inoculation of rabies virus into a wound.

The mainstay of treatment is a high index of suspicion and administration of postexposure rabies prophylaxis upon initial presentation, as the early symptoms are often mild. Early symptoms are subtle and vague, consisting of mild fatigue and behavioral changes. Overt symptoms, occurring approximately 7 days from the bite, include pain at the bite site, dysphagia, pharyngeal spasms, excessive muscle movements or flaccidity, and dysautonomia. Neurologic deterioration continues rapidly and includes progressive motor paralysis and death, usually within 3 days of the presence of overt symptoms. Rabies infection is uniformly fatal in humans; therefore, postexposure prophylaxis is critical. Although rabies prophylaxis is costly, there has been no recorded failure of the cell-based postexposure prophylaxis since 1970 if promptly administered.[99,100]

Spider Bites

Spider bites are very rare medical events. There are thousands of spider species, and only a few cause problems in humans. All spiders have a venomous component to their bite, which is essential for neutralizing and killing their prey, but only a few species have muscles powerful enough to penetrate human skin and have venom that affects mammalian tissues.

EPIDEMIOLOGY

There are many common disorders that mimic a spider bite, so the incidence is often exaggerated and overreported. The two most common species of spiders dangerous to humans in the continental United States include the brown recluse spider (*Loxosceles reclusa*) and the black widow (*Latrodectus mactans*). Brown recluse spiders are limited to the midwestern

and southern portions of the United States, and the black widow spider is found in warm climates worldwide.

CLINICAL EVALUATION AND MANAGEMENT

A presumptive diagnosis of a spider bite is often based on history and clinical presentation. Most patient reports are unreliable, and the spider was never visualized. The diagnosis of a spider bite can only be considered definitive if a spider was observed inflicting the bite; the spider was recovered, collected, and properly identified; and a skin lesion or systemic finding typically associated with the type of spider bite is present.[101] Physicians evaluating patients with suspected spider bites should be knowledgeable about spiders indigenous to their area and offer tetanus prophylaxis when indicated.

The brown recluse spider can be identified as a brown spider with three pairs of eyes and a violin-shaped carapace on its body, although this may be difficult to see.[102] Initial symptoms are often very mild and cause little pain. In up to 40% of cases, local tissue ischemia progresses and a very painful necrotic wound can develop. Aggressive surgical management is contraindicated, and allowing for definitive demarcation can minimize wound size and tissue loss. Rarely, wounds resulting after debridement will require skin grafting. Systemic symptoms are mild and respond well to supportive care.

The black widow spider can be identified as a large black shiny spider with a red hourglass on the underside of the abdomen. Only the female black widow spider has enough venom to envenomate a human. Bites by the black widow spider are characterized by a systemic toxic reaction. Symptoms of envenomation are rapid and usually occur within 1 hour of the bite and include pain, muscle rigidity, altered mental status, and seizures. The pain is often intense but resolves within 72 hours. The treatment is mainly supportive; however, there are commercially available antivenoms that can be given to patients unresponsive to supportive care. Antivenom appears to reduce pain duration and severity and the need for hospitalization.[103,104] The mortality rate for black widow spider bites has been reported as 5%.

Snakebites

Snakebites are a significant problem in the United States. Successful treatment requires prompt definitive medical evaluation, careful clinical assessment, and timely administration of antivenom in selected patients. Consultation with a medical toxicologist or other clinician with experience in poisonous snakebites is recommended. There are approximately 120 known snake species that are indigenous in the United States, but only 40 of these species are believed to be venomous to humans. Approximately 5000 snakebites are reported to the American Association of Poison Control Centers annually.[105] Most of these occur in adult males. Clinical effects are more severe in children and in victims of rattlesnakes or water moccasin (cottonmouth) envenomation. Most snakebites occur in the summer months when snakes are most active. Southern and western states with warmer climates report the greatest

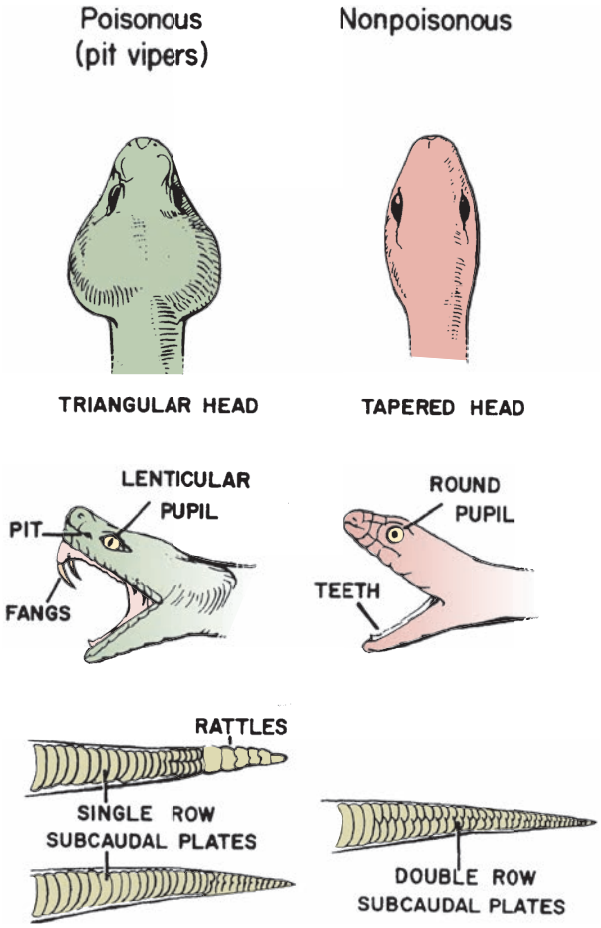

FIGURE 50-2 Characteristics of poisonous versus nonpoisonous snakes.

number of venomous snakebites, including Texas, Florida, California, Arizona, Louisiana, Georgia, and North Carolina.

The Viperidae and Elapidae families are primarily responsible for all venomous bites to humans (Fig. 50-2). The Elapidae family includes the king cobra, the world's longest venomous snake, measuring up to 18 ft in length. Elapids possess a pair of fangs through which they can inject their venom, a potent neurotoxin that induces paralysis, making elapid bites potentially lethal. Coral snakes are also members of the Elapidae family, and these snakes are relatively small and are known for their bright distinctive coloration forming rings around the body of the snake. The venomous coral snakes may be distinguished from a similarly appearing benign snake by the sequence of the coloration. If a red band is adjacent to a yellow band, then this is a venomous snake, whereas if the red band touches a black band, then the snake is lacking venom. This has led to the oft-stated idiom "Red on yellow, kill a fellow; red on black, venom lack"; however, this association of coloration and presence of venom only applies to coral snakes found in North America. Coral snakes have short fangs, which may have difficulty penetrating thick clothing, and bites from these snakes are relatively rare due to their rather reclusive, burrowing, and nonaggressive nature.

TABLE 50-15: Crotalinae of North America

Genus	Common name	Characteristics	Range
Agkistrodon	Moccasins, copperheads	No rattles, large plates on crown	North America, southeastern Europe, Asia
Crotalus	Rattlesnakes	Rattles, small scales on crown	North, Central, and South America
Sistrurus	Massasaugas and pygmy rattlesnakes	Rattles, large plates on crown	North America

Despite their timid behavior and limited fangs, coral snakes possess some of the most potent venom among snakes in North America; thus, they should not be taken lightly or else significant morbidity and mortality may ensue.

Rattlesnakes, water moccasins (cottonmouths), and copperheads are members of the family Viperidae, subfamily Crotalinae (Table 50-15). They are also commonly called pit vipers, a name that refers to the heat-sensing pit located behind the nostrils. Rattlesnakes, water moccasins (cottonmouths), and copperheads are the most numerous and cause the most snakebites in the Unites States. Elapids (coral snakes) and imported exotic snakes cause a smaller number.[106] Characteristic features of copperheads include a broad triangular head with a thick body and facial pits. Rattlesnakes possess the characteristic rattles often heard before an attack, and these may aid in distinguishing a rattlesnake attack.

An understanding of the effects of snake venom and US distribution of snakes is important when assessing and treating patients. Symptomatic Crotalinae (rattlesnake, water moccasin, or copperhead) envenomation is best considered as an envenomation syndrome.[107] Local tissue damage consists of ecchymosis and progressive tissue swelling. Nonspecific systemic effects are nausea, vomiting, diarrhea, weakness, lightheadedness, diaphoresis, and chills. Coagulopathy and rhabdomyolysis with nephrotoxicity can also occur. Increased vascular permeability, tachycardia, tachypnea, and hypotension can also be seen, as well as neurotoxicity.[108]

The venom of the Viperidae, and subspecies of rattlesnakes, water moccasins, and copperheads described earlier, often induces tissue necrosis because the venom possesses over 50 active components, including considerable amounts of metalloproteinases, phospholipases, and inflammatory mediators.[109] Symptoms of Viperidae envenomation include pain, especially with movement, swelling, erythema, and nausea. Moderate to severe envenomation is associated with tissue destruction from the enzymes present in the venom, vomiting, and bleeding with resultant tachycardia. Tissue destruction is related to matrix metalloproteinases (MMPs), phospholipases, and the inflammatory mediators inducing vascular endothelial damage as well as activation of platelets and complement. The MMPs in snake venom have been shown to be diverse and have a variety of adverse effects upon the coagulation/fibrinolytic pathways in humans, and may progress to a severe consumptive coagulopathy.[105,110] The degree of local destruction is considered a marker of the degree and nature of the envenomation. The cause of death from viper envenomation is commonly from cardiovascular collapse. The degree of tissue destruction and severity of the bite may vary considerably and are dependent on numerous factors including duration from bite to treatment, dose of venom in the wound, anatomic location of the wound, and the victim's immunologic response to either the venom or the antivenin. Greater consideration for possible extensive tissue necrosis must be given when the victim of the snake bite is a child, given the smaller volume of distribution in children for the same volume of injected venom.

All patient snakebite assessments begin with consideration of whether an envenomation has occurred. Examining for the presence of fang marks is very helpful, as the lack of fang marks effectively rules out a possible envenomation, but even if fang marks are identified, envenomation will have occurred in only 25% of bite victims. The following measures are recommended for US snakebite victims prior to definitive hospital care: remove the patient from the snake's territory, and keep him or her warm, at rest, and calm. Immobilize the injured body part in a functional position at the level of the heart initially.[111,112] Placing the extremity below the level of the heart may lead to increased tissue damage in some patients but may be appropriate in patients who have systemic effects of envenomation.[105] In contrast, elevation of a swollen extremity to prevent acute swelling in patients without systemic symptoms may subsequently increase systemic venom absorption but may be acceptable if the time to definitive care, including antivenom administration, is short.[111] Remove any rings, watches, or constrictive clothing; do not apply pressure immobilization, tourniquets, or constrictive dressings; cleanse the wound; and withhold alcohol and drugs that may confound clinical assessment. Transport the patient in the supine position to the nearest medical facility as quickly as possible, preferably using emergency medical services. In addition, attempts to identify the snake should not endanger the patient or rescuer and should not delay transport to a medical facility.[106]

Clinical evaluation begins with an assessment of the wound site and the adjacent tissues. "Dry bites," in which no venom was injected, occur in approximately 25% of snakebites in the United States and show only minimal local irritation. True Crotalinae envenomation produces swelling, pain, ecchymosis, and blister. Proximal spread of these signs suggests progressive toxicity. Systemic reactions, such as nausea, vomiting, abdominal pain, paresthesia, and dizziness, suggest more severe envenomation. Hypotension and altered mental status are ominous findings.[113] Elapidae envenomation, such as with Mojave rattlesnakes, does not typically produce significant local tissue reaction, and neurologic findings are pathognomonic. Onset of neurologic findings can

be delayed up to 12 hours.[114] Because symptoms of Elapidae envenomation rarely occur immediately, as the neurotoxins circulate, the effects manifest as tingling and numbness in the extremities, dysarthria, lethargy, and shallow respirations. Patients with suspected Elapidae envenomation who present with neurologic symptoms should be transported to a center of care capable of offering critical care, since these neurotoxic effects may progress to respiratory failure and the need for intubation and mechanical ventilation. Given the fact that the effects of Crotalinae envenomation have a relatively fast onset of action, it is reasonable to assume that a lack of symptoms upon arrival at a care center is highly associated with a lack of envenomation, and thus practitioners may withhold antivenin treatment or other advanced treatment options and follow with close clinical examination. It is important, however, to remember that the neurologic effects of Elapidae envenomation can be delayed up to 12 hours.[114]

The initial response to a snakebite, whether in the prehospital setting or following arrival to a definitive care center, should be focused on minimizing further harm from "therapeutic maneuvers." A spectrum of commonly employed measures undertaken at the scene may worsen the clinical situation; thus, field management of snakebites now focuses on rapid and expedient transport to a medical facility rather than attempting care in the field.[115,116] Methods such as tourniquets, incisions and oral suction, mechanical suction devices, stun gun therapy, immersion of the affected limb in ice, cryotherapy, surgery, and electric shock therapy have been tried in the past but are no longer recommended[117] (Fig. 50-3).

Incision and attempted aspiration of possible venom is fraught with potential harm, as this is likely occurring prehospital outdoors with nonsterile hunting equipment by an individual with very limited knowledge of anatomy. Given the fact that 25% of snakebites will result in little or no envenomation, the risk of creating a potentially serious soft tissue infection far outweighs any potential theoretical benefit. Venom removal by mechanical suction is minimal and only reduces the total body venom burden by 2%.[118] Electric shock therapy administered from a stun gun, largely advocated by investigators from Ecuador, has also been proven to be ineffective as both clinical data and animal studies have demonstrated no benefit of electric shock therapy in snakebite wounds. Placing the affected limb into ice was considered a potential therapeutic option based on decreasing the temperature and diminishing the activity of the enzymes contained within the venom; however, not only has this been shown to be ineffective, but it has also led to considerable numbers of snakebite victims having the whole extremity immersed in ice with significant ice-related tissue loss and destruction with no evidence of actual envenomation. In addition to the previously mentioned therapies to avoid, another therapy that is no longer recommended is pressure immobilization. Patients with snakebites should not receive pressure immobilization. Pressure immobilization, originally described in 1979 for neurotoxic envenomation in Australia, remains controversial.[119] Pressure immobilization has failed to show a benefit in other regions of the world including in the United States, calling into question the Australian experience. In Australia, where travel to definitive care can involve traveling over vast areas and the rate of neurotoxin envenomation is considerably higher, this may theoretically work, but it has been discouraged in the United States where the predominance of true envenomation is tissue destructive rather than neurotoxic. Pressure immobilization refers to a procedure in which an elastic bandage is applied to the affected limb with a goal of achieving a bandage pressure of 55 to 70 mm Hg. This method may delay systemic absorption of snake venom by preventing lymphatic spread in the affected limb; however, this may cause increased tissue damage, especially with Crotalinae envenomation, due to ischemia from the pressure immobilization in combination with the local tissue damage caused by the venom.[117] No studies have demonstrated benefit in envenomated humans, and if anything, studies have shown worse outcomes due to sequestering the venom in the affected limb.[120] Furthermore, application of the pressure immobilization to ensure the correct pressure is exceedingly difficult to achieve. When incorrectly applied with elevated pressures, pressure immobilization becomes effectively an arterial tourniquet; thus, the use of a pressure immobilization is greatly discouraged.

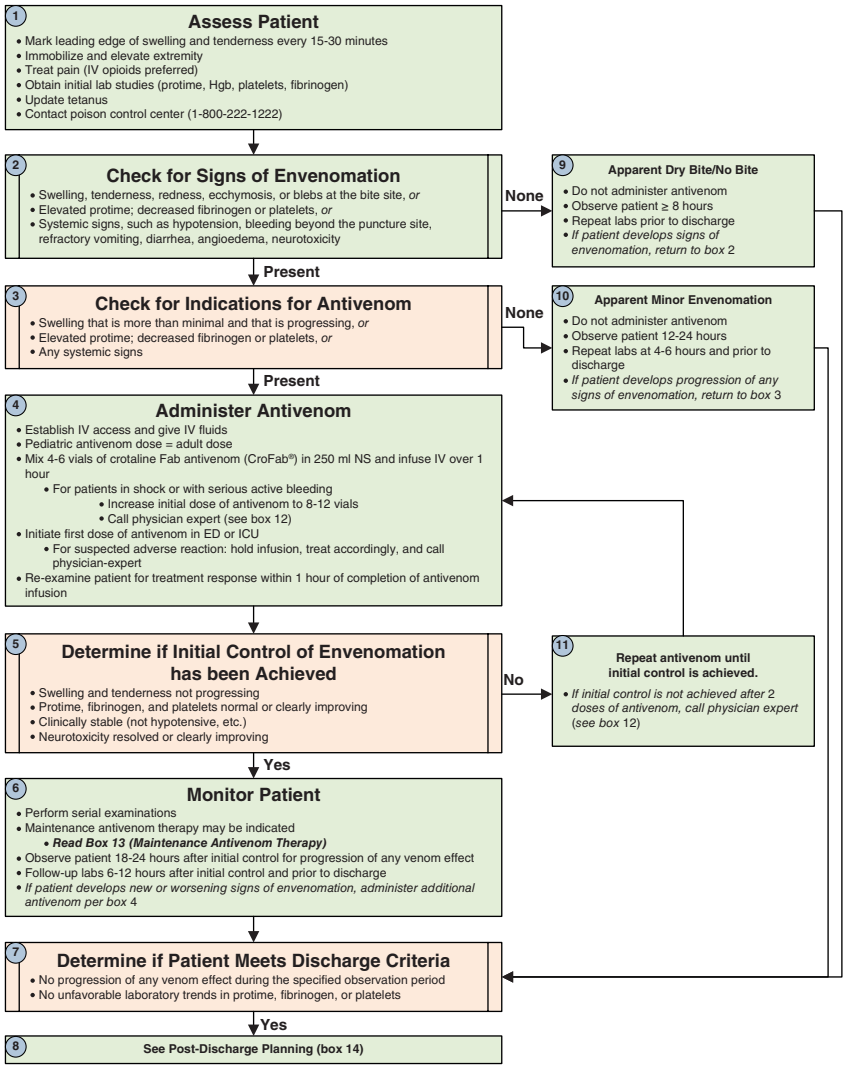
Tourniquet application has been advocated and employed by many first responders, but the application of an arterial tourniquet for greater than 2 hours may result in severe ischemic damage to the extremity with potential limb loss from the tourniquet.[113] Venous tourniquets, loosely applied, have the potential theoretical benefit of impairing venom outflow while allowing arterial inflow to perfuse the extremity; however, these tourniquets are often difficult to correctly apply in the field due to lack of knowledge or experience. The proper application of a tourniquet in this situation is loose enough to allow the passage of one to two fingers while also being tight enough to impede venous return, but it should be noted that animal models showing a theoretical benefit have not been proven in clinical studies.[113] Furthermore, it is postulated that containing the venom in a restricted region may increase the potential for local tissue destruction; therefore, the application of a tourniquet is best avoided in all cases of snakebites.

Once the patient arrives at the site of definitive care, care should commence with supportive measures such as gaining intravenous access, fluid resuscitation, pain control, and a clinical assessment and good documentation of the presence and/or extent of tissue injury, which will aid in following for progression of tissue loss. Lab work should be sent (including complete blood count, serum electrolytes, creatinine, blood urea nitrogen, serum creatine kinase, prothrombin time, partial thromboplastin time, international normalized ratio, D-dimer, fibrinogen, and urinalysis) and electrocardiogram performed to help identify coagulopathy, rhabdomyolysis, and acute kidney injury.

Ongoing supportive care should encompass fluid resuscitation, pain control, administration of tetanus prophylaxis, and correction of coagulopathy. Although the mouth of a snake is colonized with bacteria like all animals, infection

Emergency Department and Hospital Management of Pit Viper Snakebite

Includes: Rattlesnakes, Copperheads, and Cottonmouths (Water Moccasins)



12 When to Call a Physician-Expert

Direct consultation with a physician-expert is recommended in certain high-risk clinical situations:

- **Life-threatening envenomation**
  - Shock
  - Serious active bleeding
  - Facial or airway swelling
- **Hard to control envenomation**
  - Envenomation that requires more than 2 doses of antivenom for initial control
- **Recurrence or delayed-onset of venom effects**
  - Worsening swelling or abnormal labs (protime, fibrinogen, platelets, or hemoglobin) on follow-up visits
- **Allergic reactions to antivenom**
- **If transfusion is considered**
- **Uncommon clinical situations**
  - Bites to the head and neck
  - Rhabdomyolysis
  - Suspected compartment syndrome
  - Venom-induced hives and angioedema
- **Complicated wound issues**

If no local expert is available, a physician-expert can be reached through a certified poison center (1-800-222-1222) *or the antivenom manufacturer's line* (1-877-377-3784).

13 Maintenance Antivenom Therapy

- Maintenance therapy is additional antivenom given after initial control to prevent recurrence of limb swelling
  - Maintenance therapy is 2 vials of antivenom Q6H x 3 (given 6, 12, and 18 hours after initial control)
- Maintenance therapy may not be indicated in certain situations, such as
  - Minor envenomations
  - Facilities where close observation by a physician-expert is available.
- Follow local protocol or contact a poison center or physician-expert for advice.

14 Post-Discharge Planning

- Instruct patient to return for
  - Worsening swelling that is not relieved by elevation
  - Abnormal bleeding (gums, easy bruising, melena, etc.)
- Instruct patient where to seek care if symptoms of serum sickness (fever, rash, muscle/joint pains) develop
- Bleeding precautions (no contact sports, elective surgery or dental work, etc.) for 2 weeks in patients with
  - Rattlesnake envenomation
  - Abnormal protime, fibrinogen, or platelet count at any time
- Follow-up visits:
  - Antivenom not given:
    - PRN only
  - Antivenom given:
    - Copperhead victims: PRN only
    - Other snakes: Follow up with labs (protime, fibrinogen, platelets, hemoglobin) twice (2-3 days and 5-7 days), then PRN

15 Treatments to Avoid in Pit Viper Snakebite

- Cutting and/or suctioning of the wound
- Ice
- NSAIDs
- Prophylactic antibiotics
- Prophylactic fasciotomy
- Routine use of blood products
- Shock therapy (electricity)
- Steroids (except for allergic phenomena)
- Tourniquets

16 Notes:

- **All treatment recommendations in this algorithm refer to crotalidae polyvalent immune Fab (ovine) (CroFab®).**
- This worksheet represents general advice from a panel of US snakebite experts convened in May, 2010. No algorithm can anticipate all clinical situations. Other valid approaches exist, and deviations from this worksheet based on individual patient needs, local resources, local treatment guidelines, and patient preferences are expected. **This document is not intended to represent a standard of care.** For more information, please see the accompanying manuscript, available at www.biomedcentral.com.

FIGURE 50-3 Algorithm for the management of a pit viper snakebite. ED, emergency department; ICU, intensive care unit; IV, intravenous; NS, normal saline; PRN, as needed; Q6H, every 6 hours. (Reproduced with permission from Lavonas EJ, Ruha AM, Banner W, et al. Unified treatment algorithm for the management of crotaline snakebite in the United States: results of an evidence-informed consensus workshop. *BMC Emerg Med.* 2011;11:2.)

following a snakebite is rare. In a placebo-controlled trial, there was no difference in infectious outcomes with routine administration of an antimicrobial agent following snakebites; thus, routine prophylactic antimicrobial agents are not indicated.[121] Secondary bacterial infections are much more likely to occur in patients who had their wound manipulated in the field in an attempt to "extract" the venom. Antibiotics should only be administered for established infections or for heavily contaminated wounds.[106] Tetanus prophylaxis should be administered to snakebite patients according to the recommended immunization schedule (Table 50-7).

Coagulopathy is a more frequent complication of envenomation and should be corrected based on laboratory values of clotting times and blood products levels as well in response to evidence of bleeding. The coagulopathy associated with Crotalinae (rattlesnake, water moccasin, or copperhead) envenomation is due to thrombin-like glycoproteins within the venom as well as thrombocytopenia.[107] This is in contrast to true disseminated intravascular coagulation where fibrinolysis is activated by increased levels of endogenous thrombin. Transfused platelets and coagulation factors in fresh frozen plasma are inactivated by Crotalinae venom and should be avoided in patients with envenomation-induced coagulopathy unless significant bleeding occurs that is uncontrolled by high-dose antivenom administration.[107] Thus, antivenom administration, and not coagulation factor replacement, is the primary treatment for Crotalinae-induced coagulopathy.

Tissue destruction caused by snake envenomation may lead to muscle cell breakdown (rhabdomyolysis) with significant risk for renal failure. Patients with rhabdomyolysis typically present with the triad of pigmented granular casts in the urine, a red to brown color of the urine supernatant, and a marked elevation in the plasma level of creatine kinase. Primary treatment goals consist of fluid repletion and evaluation for significant electrolyte abnormalities (hyperkalemia, hyperphosphatemia, hypocalcemia).[113]

The surgical management of envenomation has changed over the past 20 years, as excising the region of the bite attempting to remove the venom-laden fangs combined with empiric fasciotomy has fallen out of favor. Now, surgical intervention is limited to debridement of necrotic or devitalized tissue and wound care. Elevated tissue or compartment pressures may complicate Crotalinae bites. Any dressing, constrictive band, splint, cast, or other restrictive covering should be removed. Venom is usually introduced into the subcutaneous tissues, and edema occurs in this space. Tissue pressures may increase because of the massive amounts of subcutaneous tissue fluid and because the skin has limits of elasticity. Swelling, pain, and paresthesia may occur in patients after Crotalinae snakebites even in the abscesses of elevated tissue compartment pressures.[113] Thus, surgical intervention based on clinical findings alone is inappropriate. Increased compartment pressures result from extrinsic pressure and can be reduced with the administration of adequate amounts of antivenom and elevation. Elevation is usually avoided in true compartment syndromes and prior to antivenom administration in patients with venomous snakebites. After antivenom administration, however, elevation results in the drainage of subcutaneous edema and contributes to the reduction of the source of increased tissue pressure.[106] The prior rationale for early aggressive operative intervention lay in the postulation that the tissue destruction was a local effect amenable to locally excising the infused venom with the surrounding necrotic muscle and decompressing the adjacent healthy tissues pending resolution of the inflammation.[122] However, it has been clearly demonstrated that empiric operative intervention or empiric fasciotomy is not indicated for envenomation and that muscle necrosis is more likely the result of the ongoing venom rather than the presence of compartment syndrome.[123] Although the risk of compartment syndrome is low, it still occurs. There is a wide range in the literature on the rate of rattlesnake envenomation progressing to require fasciotomy and decompression (0%–15%), but it is estimated that the incidence of true compartment syndrome needing fasciotomy rather than just "prophylactic fasciotomy" is considerably lower, at approximately 1% to 2%.[124,125] Compartment syndrome is more likely to occur in the anterior leg, fingers, or hand and is usually associated with deeper bites. True compartment syndromes may result from direct compartmental injection of venom, particularly with the anterior tibial compartment, which is very close to the skin. In these instances, antivenom and elevation may still reduce compartment pressures by the reduction of extrinsic pressure, but persistent intercompartmental pressures may remain high. The indications for fasciotomy in this context are unclear. An animal model of direct compartmental injection of venom demonstrated improved outcomes with antivenom alone versus antivenom plus fasciotomy.[126] In this model, fasciotomy was performed immediately after venom injection. The diagnosis of compartment syndrome may be difficult given the overlap in clinical findings, such as pain with passive motion, pain out of proportion to findings, swelling, and firmness to exam, between severe local tissue inflammation and true compartment syndrome. Thus, it is highly recommended to base the decision to intervene surgically on objective measures of the compartment pressures rather than exclusively on physical examination.[124] Therefore, surgical intervention for elevated compartment pressures following Crotalinae snakebites is controversial and should be guided by a medical toxicologist and surgeon with extensive experience caring for victims with snakebites.[127] With fasciotomy, acute debridement is to be discouraged, as injured muscle may improve with the concomitant administration of antivenin and supportive care. Despite the infrequency of progression to fulminant tissue necrosis and/or compartment syndrome, snakebites should still be considered a potential surgical disease, and early surgical consultation is critical given the consequences of missing progression to compartment syndrome.[128]

It must be recognized that the majority of snakebites that occur in the United States are nonvenomous, and given the potential for adverse reactions to antivenin, an attempt should be made to identify the snake, preferably by an individual trained in herpetology. Originally created in 1954, commercial Crotalinae antivenin has undergone extensive

modifications over the years to minimize its side effects. The original antivenin contained whole immunoglobulin G including the Fc fragment, which led to severe hypersensitivity reactions including bronchospasm and cardiovascular collapse. Anaphylactic reactions were reported to occur in as many as 50% of administrations, and much higher rates of serum sickness were also noted.[127] This early product was also limited in its ability to work against the rapidly spreading neurotoxin or in controlling the coagulopathic and hemorrhagic components of the envenomation. Modifications in antivenin design allowed for cleavage of the Fc and the Fab segments, isolating the Fab preparations for the final antivenin, which minimized its side effects, with serum sickness being reported in about 15% of patients. Polyvalent Crotalinae ovine immune Fab (FabAV, Crofab, Protherics) is the antivenom currently commercially available in the United States for Crotalinae (rattlesnake, water moccasin, or copperhead) envenomation.[127] Equine F(ab)2 antivenom (Anavip) has been used successfully to treat US pit viper envenomation in one study and may reduce the risk of late coagulopathy, and is now available for clinical use. FabAV consists of the purified Fab fragments of sheep immunoglobulin (IgG) raised against the venom of four snakes.[127,129] When infused, these Fab fragments bind venom in the intervascular space and are renally excreted. The half-life of FabAV is shorter than that of Crotalinae venom substances. Thus, recurrent toxicity is possible despite initial control of local and systemic effects and may necessitate repeated FabAV administration. It is most effective when given within 6 hours of envenomation.[130]

It is recommended that patients with Crotalinae bites (rattlesnake, water moccasin, cottonmouth, or copperhead bites) and moderate to severe toxicity or with bite sites that present a significant possibility for airway obstruction from local tissue swelling (bites to the face or neck) receive FabAV therapy.[113] In these patients, the benefits of treating life-threatening toxicity clearly outweigh the potential risk of hypersensitivity. Guidelines have suggested that patients with mild envenomation not receive antivenom, but some evidence suggests that it may provide short-term benefit, primarily a more rapid return to normal function of the involved limb.[117,131] The use of antivenin is discouraged in cases of mild envenomation, and antivenin should not be administered to individuals with a history of allergic reactions to antivenin or in settings where a severe life-threatening allergic reaction cannot be managed.[132] Administration should be through slow infusion while watching for an allergic reaction and stopping immediately upon detecting any hypersensitivity. Antivenin treatment, although ideally administered before injury, remains effective if given up to 6 hours following the envenomation, but there have been anecdotal reports of effective antivenin therapy when administered later. In life-threatening envenomation, antivenin has been administered up to 24 hours following the bite with variable benefit.[132]

Even when used correctly, many of the existing antivenins are associated with considerable allergic side effects that, on occasion, may induce severe organ failure. Even with milder cases of allergic reactions to antivenin, the adverse effects may last up to several months.[132,133] The dose of antivenin administered remains empiric and is based on a clinical judgment of the amount of venom delivered from the bite; thus, adults and children are dosed based on the amount of venom from the bite and not on patient weight. Multiple administrations may be necessary, with 10 vials or more potentially required for patients with large exposures and severe envenomation. In patients with progressive clinical manifestations, repeat doses may be required.[113] Thus, the use of antivenin for patients with mild envenomation should be individualized on a case-by-case basis with input from a medical toxicologist or other snakebite expert. For patients with Crotalinae envenomation but minimal and nonprogressive swelling, pain, or ecchymosis, and in whom the decision is to withhold antivenom, we suggest close observation for 12 to 24 hours to ensure that progression of toxicity, as indicated by worsening local or systemic effects, does not occur. All patients who receive antivenom should receive close observation for recurrent toxicity over the first 24 hours after antivenom administration.[134] Recurrent toxicity may occur despite initial control with antivenom. This is related to the short half-life of Fab fragments or possibly dissociation of Fab fragment–venom complexes.[135] As a result, guidelines suggest that those who receive FabAV administration with moderate-severe envenomation should receive scheduled doses of 2 g every 6 hours for three doses to prevent recurrent toxicity.

The clinician should immediately stop antivenom infusion in patients who experience signs of acute hypersensitivity (anaphylactic shock, oropharyngeal swelling, bronchospasm, and urticaria). These patients should receive treatment for anaphylaxis. Because acute reactions are often nonimmunologic in nature, the antivenom infusion may be resumed cautiously and completed at a lower infusion rate once initial signs of acute hypersensitivity have been treated.[113] Allergic reactions can be secondary to venom sensitivity, particularly in those who have been bitten before. In all cases of anaphylaxis, cessation of antivenom administration is part of the management of anaphylaxis. Once anaphylaxis is controlled, restarting the antivenom should be based on risk-benefit analysis, and if the decision is made to restart, then it should be administered at a lower infusion rate.[132] Again, consultation with a medical toxicologist experienced in the management of snakebites is strongly recommended for these patients.

Considerable limitations have developed over the past 10 years with respect to coral antivenin since its production has ceased in the United States due to the rare incidence of coral snake envenomation. Production of coral antivenin in the United States ceased in 2003, and most stocks of coral antivenin in the United States expired roughly 5 years later. Although licensing and expiration dates have been amended several times, there is no longer any coral snake antivenin available.

Overall the use of antivenin has increased over the past 15 years, but this may change as stocks of antivenin expire and are not being reproduced. Despite increasing awareness of the potential benefit of antivenin, many institutions do not

stock, or are unaware of the availability of, the appropriate antivenin.[113]

STINGS

Venomous Fish

The seas and oceans contain several potential stinging or biting hazards to humans. These include venomous fish, jellyfish, sea snakes, coral, sea urchins, and stingrays. These envenomations are painful. The degree of pain is largely determined by the amount of venom injected and the animal encountered. The puncture wounds associated with marine envenomation often have retained foreign bodies and are frequently contaminated. Most wounds are superficial, although stingrays can cause deep penetrating injuries. Marine envenomation may induce a spectrum of manifestations including allergic reactions, neurotoxic effects such as paralysis, and cardiac depression due to cardiotoxins.[136]

Coral are cnidarians, like jellyfish, and members of the class of Anthozoa.[137] Stings and lacerations are common among snorkelers, surfers, and scuba divers who touch or step on coral.[138] Coral stings are usually only mildly toxic with local pain and erythema. The sting is caused by venomous capsules called nematocysts and can be treated similarly to jellyfish stings. Lacerations from coral are prone to secondary infection, including cellulitis, lymphangitis, fever, and ulceration of the wound within a few days of injury.[137,139]

Sea urchins are echinoderms and the most significant member of this phylum in the United States. Other members include starfish and sea cucumbers, which have no venom apparatus (poisonous rather than venomous). Sea urchins have long, sharp spines made of calcium carbonate that easily penetrate flesh, rubber-soled shoes, or wetsuits and can break off in the wound. Some species of sea urchins have venom-producing glands at the tips of the spines and thus are venomous.[140] Clinical findings include redness, swelling, bleeding, and intense pain, which can last up to 24 hours.[138] Discoloration of the wound can indicate retained sea urchin spines. If this discoloration resolves in 48 hours, it is unlikely that a spine is still lodged in the skin.[141] Imaging can help identify retained foreign body.

There are over 150 species of stingrays worldwide, accounting for thousands of injuries every year.[137] Stingrays are flat, cartilaginous fish with a long, tapered whiplike tail with a furrowed, serrated spine containing secretory venom cells and sacs. This tail is noted to contain multiple barbs containing venom, and this venom is noted to be cardiotoxic. It also contains proteolytic and hyaluronidase activities, which may contribute to tissue necrosis and skin loss around the site of the sting. The flat-shaped nature of the stingray body allows it to easily burrow under a shallow layer of sand and thus remain unexposed and difficult to visualize, leading to stings; however, gentle agitation of the sand will disturb the stingrays, prompting them to move away, as stingrays are not aggressive by nature. When a stingray is stimulated or frightened, it flings the barbed tail upward, embedding the spine in the victim, which releases the venom.[142] Most stingrays possess one or more barbed stingers located on the tail that are loaded with venom and are used by the stingray as a defense mechanism; thus, these animals should be left alone in order to minimize the likelihood of a sting.[137] Most stings occur from accidentally stepping on a stingray while walking in the surf and wading at shallow ocean depths. Injuries to the upper limbs are less common but can occur when stingrays are removed from fishing lines. Thoracoabdominal trauma can occur rarely to divers. Although most stingray stings are not fatal, they do induce considerable pain from both the site of the sting as well as from venom-induced muscle cramps.[142] Pain may radiate up the limb and usually persists for hours. The wound may be erythematous and dusky. There is also usually significant bleeding, which depends on the site of injury. Although numerus systemic effects are reported, they are uncommon and usually related to the systemic response to pain.[136] The size and length of the stingray spine will dictate the extent of injury, and larger spines increase the risk of trauma and secondary infection. Death or severe injury may occur if the spine penetrates a major blood vessel, heart, or other vital organ.[143] Thoracoabdominal injuries should be managed like major penetrating trauma but have the additional risk of foreign body retention and infection; as such, those wounds that extend through the chest or abdominal wall will need exploration in the operating room.[144] Imaging is undertaken to assess for possible remaining fragments of the barb, and wound exploration should be completed as the barb from the tail may break off and remain lodged in the stung extremity. Stingray wounds should be left open to heal by secondary intention, and surgical debridement may be indicated in cases of significant necrosis. Prophylactic antimicrobial agents are administered given the relatively high rate of infection. Tetanus prophylaxis should be updated, but currently there is no available stingray antivenin.[136]

Venomous fish have a specific apparatus designed to inject poison. Stings occur in the marine and freshwater environment and also from private aquariums.[145] Spines cover integumentary sheaths, which contain venom glands. When the spine penetrates the victim's skin, the surrounding integument covering the spine ruptures and venom is injected into the wound. There are two families of venomous spiny fish; the Scorpaenidae include stonefish and lionfish, and the Trachinidae contain the weeverfish.[136] Stonefish and weeverfish usually cause injuries when they are stepped on by swimmers or divers because they are bottom-dwellers, and lionfish usually cause envenomation of the hands or fingers during routine care and feeding by their handlers.[146] Lionfish are often kept as part of home aquariums, which increases the incidence of stings caused by this tropical fish, and stings from lionfish are the most common marine-related sting called in to poison centers in the United States. The pain of these venomous fish stings may resolve over 1 hour in minor injuries, but with more severe stings, the pain may persist for over 24 hours and may radiate. Systemic effects have been reported in more severe cases, including nausea, vomiting, headache, sweating, hypotension, and syncope. However, these are most

likely secondary to the severe pain. Most patients experience moderate to severe pain at the sting site, and stings from lionfish may induce significant skin necrosis.[147] Stonefish toxins may induce local tissue necrosis, severe muscle contracture, and neurotoxicity and may even induce cardiotoxicity with severe cardiac depression and death.[146] The weeverfish inhabits the waters of Europe and the Mediterranean and can inflict a painful sting, typically to the foot or ankle due to humans stepping on them at low tide. These stings require local wound care only, and there are no confirmed fatalities due to this fish.[148] Fatalities have been attributed to many kinds of venomous fish; however, they are usually due to septicemia from secondary infection.

Sea snakes reside in a variety of tropical regions, including the warmer portions of the Indian and Pacific Oceans from the east coast of Africa to the west coast of the United States and Central and South America. They are found close to land in coral reefs or along islands.[149] The bite is often painless with limited local tissue injury; however, after a dormant period that can last up to several hours, systematic effects become apparent, including muscle pain, tenderness, trismus, weakness, rhabdomyolysis in severe cases, acute kidney injury, and hyperkalemia.[150] Sea snake envenomation may warrant treatment with antivenom depending on severity.

Cnidaria comprise four different classes including Cubozoa (box jellyfish), Scyphozoa (true jellyfish), Anthozoa (anemone), and Hydrozoa (Portuguese man-o-war). All species of Cnidaria have hollow, sharp-pointed, coiled thread tubes surrounded by venom called cnidae. The jellyfish and sea anemones do not cause puncture wounds. After a jellyfish sting, a linear red urticarial lesion typically develops a few minutes later, although these lesions sometimes do not appear for several hours. "Tentacle prints" may be seen on examination of the skin. Nematocysts can be obtained by skin scrapings or by applying sticky tape to the sting site when diagnosis is unclear. Sea anemone stings present as circular and painful urticarial lesions, which may have a central pallor. Most jellyfish stings induce an acute dermatitis and are self-limiting; however, box jellyfish, residing mainly off the coast of Australia, are the deadliest of jellyfish and some have contended that box jellyfish may be the world's most venomous creature. Most reported cases of box jellyfish stings involve painful lesions that may progress to skin necrosis within 12 to 18 hours. Although the exact mechanism of action of the venom is largely unknown in humans, it is postulated that the venom causes cellular pore formation, leading to massive and swift sodium and calcium fluxes into cells with rapid cellular compromise. This venom leads to rapid hypotension, cardiovascular collapse, and death, which has been reported to occur in as little as 60 seconds after the sting. Treatment of all jellyfish stings involves nematocyst removal using seawater and gentle rubbing. It is not recommended to immerse in cool fresh water or vigorously rub the wound because this will cause the nematocysts (tentacles) to fire. After their removal, it is recommended that the pain from the stings of the box jellyfish and bluebottle jellyfish (man-of-war) be treated with hot water immersion, acetic acid, or papain meat tenderizer. Hot water immersion should be for approximately 20 minutes.[151]

Fire Ants

Fire ants, both red (*Solenopsis invicta*) and black (*Solenopsis richteri*), were originally imported into the southern United States in the 1920s, but these insects continue to march forward, and colonization has extended across vast areas of the United States. Red imported fire ants are the most abundant and damaging species.[152] The habitat of the black imported fire ant is relatively limited. Stings occur most frequently in the summer and typically on the lower extremities. Off-season stings often do not cause as much pain and may go unnoticed. This may reflect seasonal differences in fire ant venom.[153] Fire ant bites will not sting through fabric, stockings, or tights.[154] Thus, wearing shoes with socks and long pants is a helpful avoidance measure. Hands and arms should be covered with gloves and sleeves when gardening or doing outdoor work. Insect repellents are not effective. Approximately 5% of victims of fire ant bites will require medical attention, and of those, approximately a fifth will have systemic allergic reactions.[155] The fire ant is capable of multiple stings during one attack if not removed quickly, leading to a characteristic pattern of bites in a circular or linear pattern of pustules on the victim. The victim experiences an immediate, intense burning and itching at the sting site. The multiple stings in succession give the feeling of "fire" along the site, and the majority of the fire ant venom is composed of nonprotein piperidine alkaloids, which lead to the characteristic pustules following the stings. The venom is 95% water-insoluble alkaloids by volume, with the remaining 5% being an aqueous solution of proteins. The alkaloids cause the sterile pustule but are not allergenic. The allergenic portion of the venom is the protein component.[156] Following a fire ant sting, immediate washing of the stung area will help to reduce the venom load. Akin to other stings, the effects can be classified as local, local large, or systemic, with about 2% of patients presenting after a fire ant sting with a severe systemic reaction. Patients manifesting systemic symptoms require prompt medical attention since these reactions may progress to full-blown anaphylaxis.[155] If a patient develops a severe local reaction to the bite or survives a systemic reaction to the venom, then referral to an immunologist for workup of a fire ant venom allergy, possible skin testing, and immunotherapy to minimize the response to repeat exposure to fire ant venom is warranted.

Bee Stings

Hymenoptera species that sting humans include bees, wasps, yellow jackets, hornets, and imported fire ants. Most people develop only minor local reactions, but patients with venom allergy are at risk for systemic allergic reactions (anaphylaxis), which can be severe and is the leading cause of death from stings. There are also several uncommon and delayed types of reactions that may develop after Hymenoptera stings, such as serum sickness.[157] Hymenoptera generally sting people in

self-defense or to protect their nests or hives. Their stings are acutely painful. Identification of the species can be difficult after the sting since the resultant lesions are similar in appearance. Bees (and some yellowjackets) have a barbed stinging apparatus that can lodge in the skin and rip away, along with the venom sac, from the insect's body.[158] Venom is released almost immediately, so if the stinger can be removed immediately, it may help limit the amount of venom injected. After this, immediate stinger removal is not critical, because the venom will have already been fully expelled.[159] Honey bees differ from wasps in that the stinging mechanism of the bee is strongly barbed and is designed to remain in the flesh, whereas wasp stings are not intended to remain in the victim, which facilitates multiple stings. The presence of a retained stinger distinguishes bee and wasp sting, aiding in identifying those who will benefit from allergic reaction therapies.[160] Local reactions consist of symptoms that are confined to the tissues contiguous with the sting site. Stings from bees and wasps are relatively common during the warmer months of the year, and the vast majority of these remain unreported, requiring only local wound care or topical analgesics. They are usually mild and transient, although some patients develop large local reactions or rarely secondary bacterial infections.[161] Ten percent of individuals who sustain a wasp or bee sting develop a large local reaction, and approximately 1% to 3% of individuals who are stung will display a life-threatening allergic reaction.

Stings from bees can be categorized as minor local, major local, or systemic. Local symptoms include pain and erythema, but the presence of symptoms distal to the site of the sting defines a systemic response. A typical local reaction to a Hymenoptera sting is redness and an area of painful swelling (1–5 cm) at the site of the sting that develops within minutes and resolves within a few hours. Occasionally, swelling may last 1 to 2 days. Uncomplicated local reactions may be treated with cold compresses. Large local reactions result in exaggerated redness and swelling at the site of the sting that gradually enlarges over 1 to 2 days. These reactions peak at approximately 48 hours and then gradually resolve over 5 to 10 days. The area of swelling typically measures about 10 cm in diameter.[162] Treatment of a large local reaction is based on symptoms and includes cold compresses, elevation, oral prednisone as a single dose or rapid taper, nonsteroidal anti-inflammatory drugs, and oral antihistamines.[163] Hymenoptera stings are considered "clean" for the purposes of tetanus vaccination. Large local reactions and anaphylaxis are believed to be immunoglobin E mediated. Systemic symptoms include nausea, vomiting, and bronchospasm, and ultimately may progress to anaphylaxis and cardiovascular collapse. The incidence of anaphylactic reaction and deaths from bee stings is exceedingly rare yet constitutes more deaths per year than from all other venomous animals. Anaphylaxis may be defined as a serious allergic reaction that is rapid in onset and may cause death.[164] A single sting is sufficient to precipitate a severe reaction in a venom-allergic individual, and insect stings are a leading cause of fatal anaphylaxis, requiring multiple doses of epinephrine.[164] The reported deaths from bee stings are usually related to anaphylaxis and a delay in seeking medical care once the symptoms start. Small children are especially at risk of larger allergic reactions since the venom load is consistent among the bee population and is not based on the weight of the victim. Immunoprophylaxis is available, but there are several limitations for its use.[164] Any person who has exhibited bee sting anaphylaxis should be equipped with an emergency allergy kit and epinephrine pen and should be referred for consideration of immunoprophylaxis (Table 50-16).

TABLE 50-16: Treatment for Anaphylaxis

1. Airway control.
2. Epinephrine, 0.5 mg SQ (may be given IV with major anaphylactic reaction). May be repeated every 20 min.
3. Volume expansion.
4. H_1 antagonists (diphenhydramine, 25–50 mg IV or IM).
5. H_2 antagonists (ranitidine, 50 mg IV).
6. Glucocorticoids (hydrocortisone, 125 mg IV). No effect for several hours, but may prevent recurrence of symptoms.
7. Inhaled β_2-agonist for recurrent bronchospasm (albuterol, 0.5 mg).
8. Removal of bee stinger.

IM, intramuscularly; IV, intravenously; SQ, subcutaneously.

Burns and Radiation

Benjamin Levi • Gary A. Vercruysse

KEY POINTS

- Early resuscitation after burn injury is key to mitigate shock. Follow the Parkland formula for resuscitation in burns greater than 20% total body surface area (TBSA).
- Use lactated Ringer's solution, not normal saline, as a resuscitation fluid to avoid hyperchloremic metabolic acidosis.
- Do not administer bolus intravenous fluids during initial burn resuscitation. This can lead to abdominal compartment and secondary extremity compartment syndromes.
- Consider early use of colloid (packed red blood cells, fresh frozen plasma, or albumin) in patients with low urine output despite adequate fluid resuscitation.
- Communicate with local burn center before performing escharotomy.
- Intubate prior to transfer in patients with extensive head, neck, or facial burns; elevated carbon monoxide levels (>30%), large burns (>40% TBSA), obtundation, or symptoms of early airway obstruction.
- In austere conditions, resuscitate orally when possible, graft only full-thickness burns and in small aliquots, and minimize ventilator use.

BURNS

Introduction

Approximately 1.25 million people are burned annually in the United States, of whom 30,000 are admitted to burn centers and 3400 succumb to their injury.[1,2] Traditionally, the highest incidence of burn injury occurs at the two extremes of age. During the first few years of life, burns are primarily due to liquid scalds and then, after the age of 60, injuries are commonly due to both flame and scald burns.[2-4]

Between 1971 and 1991, burn deaths decreased by 40% with a concomitant 12% decrease in deaths associated with inhalation injury.[5] Since 1991, burn deaths per capita have decreased 25% according to the Centers for Disease Control and Prevention (https://www.cdc.gov/injury/wisqars/index.html). These improvements are in part due to prevention strategies resulting in fewer burns of lesser severity as well as significant advances in treatment, particularly in children. Current reports indicate a 50% mortality for 98% total body surface area (TBSA) burns in children age 14 years and younger.[6] A healthy child with any size burn can be expected to survive.[7] The same is not true for those age 45 years or older, where improvements have been more modest, particularly in patients over 65 years of age, in whom a 35% TBSA burn still results in a 50% mortality.[8]

Burn Center Referral Criteria

The decision for in-hospital care of a burned victim varies with burn size, age, premorbid conditions, the patient's home situation, and access to local expertise. Patients with larger burns may benefit from treatment in specialized burn centers. These centers have dedicated resources and the required multidisciplinary approach to maximize outcomes from such devastating injuries.[9] The American Burn Association and the American College of Surgeons Committee on Trauma have established guidelines to identify patients who should be transferred to a specialized burn center, and these include the following[10]:

- Partial-thickness burns greater than 10% TBSA
- Burns that involve the face, hands, feet, genitalia, perineum, or major joints
- Third-degree burns in any age group
- Electrical injury, including lightning injury
- Chemical burns

- Inhalation injury
- Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
- Any patient with burns and concomitant trauma in whom the burn injury poses the greatest risk of morbidity or mortality
- Burned children in hospitals without qualified personnel or equipment for the care of children
- Burn injury in patients who will require special social, emotional, or rehabilitative intervention

In an effort to mitigate unnecessary transfer of minor burns, efforts are underway by the American Burn Association to create consultative criteria, rather than transfer criteria, so that minor burns can be cared for at nonburn centers with burn center input, follow-up, and transfer as necessary. This patient-centered approach is designed to provide optimal patient care without the added expense of unnecessary transfers. If successful triage can be accomplished, a great opportunity for savings in the health care system can be achieved while still rendering safe and effective burn care.[3,4,11] In the past several years, advances in video-based consultation using smartphone technology have allowed for accurate initial consultation. This can then be used to facilitate appropriate triage decisions and guide initial care to a significant proportion of the patients previously triaged to burn centers.[12-14]

Pathophysiology

Burns are classified into six causal categories, three zones of injury, and five depths of injury (Table 51-1). The causes include fire, scald, contact, chemical, electrical, and radiation. Fire burns can be further divided into flash and flame burns, whereas scald burns can be divided into those caused by liquids, grease, or steam. Liquid scald burns can be due to spill or immersion scalds.

Flame, scald, and contact burns cause cellular damage primarily by the transfer of energy that induces coagulative necrosis. On the other hand, direct damage to cellular membranes is the cause of injury in chemical and electrical burns.

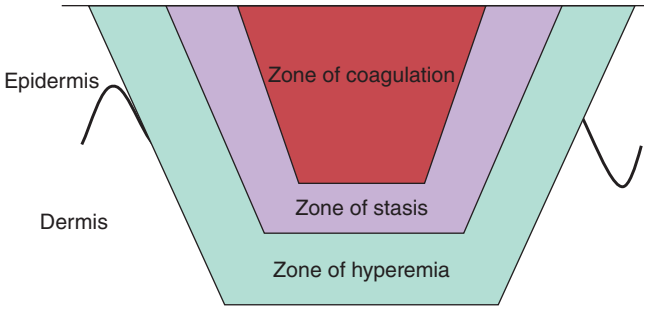

FIGURE 51-1 Zones of injury after burn. Factors likely to affect the zone of stasis determine the extension of injury from the original zone of coagulation.

The skin generally provides a barrier to limit transfer of heat energy to underlying tissues; however, after the source of burn is removed, the response of local tissues can lead to further injury. The necrotic area of a burn is termed the *zone of coagulation*. The area immediately surrounding the necrotic zone has a moderate degree of injury that initially causes a decrease in tissue perfusion. This area is termed the *zone of stasis* and, depending on the environment of the wound, can progress to coagulative necrosis if local blood flow is not maintained. Thromboxane A_2, a potent vasoconstrictor, is present in high concentrations in burn wounds, and local application of thromboxane inhibitors has been shown to improve blood flow and may decrease this zone of stasis.[15,16] Antioxidants and inhibition of neutrophil-mediated processes may also improve blood flow, preserve tissue, and decrease the depth of injury.[17,18]

Endogenous vasodilators such as calcitonin gene-related peptide and substance P, whose levels are increased in the plasma of burn patients, may also play a role.[19] Practically, the most important factor to minimize conversion of zones of stasis into zones of coagulation is adequate fluid resuscitation. The last area, the *zone of hyperemia*, is formed as a result of vasodilation from inflammation surrounding the burn wound. This zone contains clearly viable tissue from which the healing process begins (Fig. 51-1).

TABLE 51-1: Definition of Burn Types, Zones, and Depth of Injury

Burn	Categories	Zones of injury	Burn depth
Fire	Flash	Zone of coagulation	First degree (superficial)
	Flame		
Scald	Liquid	Zone of stasis	Superficial second degree (superficial partial thickness)
	Spill		
	Immersion		
	Grease	Zone of hyperemia	Deep second degree (deep partial thickness)
	Steam		Third degree (full thickness)
Contact			Fourth degree (deep organ involvement)
Chemical			
Electrical			
Radiation			

Inflammatory Response

There is a profound hypermetabolic response and massive release of inflammatory mediators following burns. This hypermetabolism is associated with alterations in blood glucose as well as lipids and typically occurs in the ebb phase (first 14 hours) and flow phase (until 5 days after burn).[20,21] Many mediators have been proposed to explain the changes in permeability after burns, including prostaglandins, catecholamines, histamine, bradykinin, vasoactive amines, leukotrienes, and activated complement.[22] Mast cells in the burned skin release histamine in large quantities immediately after injury, causing a characteristic response in venules by increasing the space in intercellular junctions.[23,24] The use of antihistamines in the treatment of burn edema, however, has had limited success with the possible exception of H_2-receptor antagonists.[25] In addition, aggregated platelets release serotonin, which plays a major role in the formation of edema. This agent acts directly to increase pulmonary vascular resistance and indirectly aggravates the vasoconstrictive effects of various vasoactive amines. Serotonin blockade has been shown to improve cardiac index, decrease pulmonary artery pressure, and decrease oxygen consumption after burns.[26]

Another mediator likely to play a major role in vascular hyperpermeability and tone is thromboxane A_2. Levels of thromboxane increase dramatically in the plasma and wounds of burn patients.[27,28] This potent vasoconstrictor leads to platelet aggregation in the wound, contributing to expansion of the zone of stasis. Also, it causes prominent mesenteric vasoconstriction and decreased blood flow to the gut in animal models with compromised gut mucosal integrity and immune function.[29]

Patients with major burn injury have the highest metabolic rate of all critically ill or injured patients.[30] The metabolic response to a severe burn injury is characterized by a hyperdynamic cardiovascular response, increased energy expenditure, loss of lean body mass and body weight, accelerated breakdown of glycogen and protein, lipolysis, and immune depression.[31] This response is mediated by increases in circulating levels of catabolic hormones including catecholamines, cortisol, and glucagon.[32]

Pharmacologic agents have been used to attenuate catabolism and stimulate growth after burn injury. To further minimize erosion of lean body mass, administration of anabolic hormones such as growth hormone, insulin, oxandrolone, fenofibrate, and catecholamine antagonists such as propranolol has been studied. These agents contribute to maintenance of lean body mass and promote wound healing.[33-38]

Changes in Organ Function

Major burn injury affects multiple organs. Cardiac effects include marked loss of plasma volume, increased peripheral vascular resistance, and decreased cardiac output; pulmonary effects include a decrease in pulmonary static compliance, and these changes are associated with mild direct cardiac damage.[39-41] Renal blood flow decreases with a fall in glomerular filtration rate, which may result in renal dysfunction. Metabolic changes are characterized by an early depression followed by a marked sustained increase in resting energy expenditure as well as increased lipolysis, proteolysis, and oxygen consumption. This is driven, in part, by an increase in production of catecholamines, cortisol, and glucagon.[42] Increased peripheral lipolysis results in hepatic steatosis, and a fatty liver is caused by breakdown of triglycerol into free fatty acids. Like steatosis, peripheral lipolysis contributes to morbidity and mortality through fatty infiltration of various organs. Burn-related metabolic responses can last more than 2 years after burn.[21] There is a generalized impairment in host defenses, with depressed production of immunoglobulin, decreased opsonic activity, and depressed bactericidal activity.[43] This leads to an increased susceptibility to infections.

Initial Care

The patient should be removed from the source of the burn to stop the burning process, and clothing and jewelry taken off. The patient should be kept warm by wrapping in a clean sheet or blanket. Upon arrival to the emergency department, the immediate treatment of a burn patient should proceed as with any trauma patient to include the ABCDEs (airway, breathing, circulation, disability, exposure), and any potential life-threatening injuries should be identified and treated.

Airway and Breathing

Assessment starts with the airway, as upper airway obstruction can occur after burn injury. In most patients, there is a 4- to 6-hour period of time before postburn edema will compromise the airway. It is important make the decision for intubation in a relatively elective fashion. Oral tracheal intubation is preferred. It is important to place as large an endotracheal tube (ETT) as possible because burn patients frequently require pulmonary toilet via bronchoscopy, and smaller tubes can become occluded. It is not possible to perform bronchoscopy on an adult with an ETT smaller than a size 7, or a 4.5 in a child. Once placed, it is important to carefully secure the ETT to avoid dislodgement. Stridor, wheezing, tachypnea, and hoarseness indicate impending airway obstruction due to an inhalation injury or edema, and immediate treatment is required. Severe hypoxemia can result from flame burns, so oxygen should be administered and saturations closely monitored. Refractory hypoxemia or labored breathing also signal the need for intubation. In-line stabilization of the neck should be maintained if injury to the cervical spine is suspected.

Hypoxemia can also result from an elevated carbon monoxide (CO) following prolonged smoke exposure. Arterial blood gas and carboxyhemoglobin (COHb) levels should be obtained when inhalation injury is suspected. CO has an

affinity for hemoglobin that is over 200 times that of oxygen, and COHb can falsely elevate oxygen saturation levels determined colorimetrically. Therefore, use of a pulse oximeter may not be effective because patients with CO poisoning may show falsely normal oxygen saturation levels. Use of a pulse CO-oximeter enables measurement of absorption at several wavelengths to distinguish oxyhemoglobin from COHb saturation and determines blood oxygen saturation more reliably.[44] Levels of CO higher than 30% to 40% are indicative of severe exposure. The treatment for CO inhalation is 100% oxygen. This will decrease the half-life of CO from 4 to 6 hours at room air to 40 to 80 minutes with 100% oxygen. In three atmospheres absolute 100% oxygen in a hyperbaric chamber, the half-life decreases further to 15 to 30 minutes.

Full-thickness circumferential burns of the chest can interfere with ventilation, and bilateral expansion of the chest should be observed to document equal air movement. If the patient is ventilated, airway pressure and P_{CO_2} should be monitored. Rising airway pressure and P_{CO_2} indicates compromised ventilation, and a chest wall escharotomy should be performed. This is preferably performed at a burn center.

Managing the airway of an acute burn patient is one of the most difficult aspects of initial burn care. In general, intubation should strongly be considered for the following: elevated COHb associated with depressed mental status and/or persistent metabolic acidosis; burns greater than 40% TBSA, especially in children; burns with a perioral full-thickness facial component of more than 50%; full head burns (face and scalp); and clinically significant smoke inhalation. Relative indications for intubation include the following: change in voice or hoarseness, carbonaceous sputum, partial-thickness burns to the face, and extremes of age (<1 or >75 years of age). Neither chest x-ray findings nor the presence of singed nasal hairs is particularly helpful. Singed nasal hairs can occur with a flash burn or burn in an enclosed space. Bronchoscopic findings are relatively unhelpful if there is no history of inhalation injury and no spontaneously expectorated carbonaceous sputum.

Circulation

All patients with significant burns should have large-bore intravenous (IV) lines placed for resuscitation. If an IV cannot be placed in the field, an intraosseous line can be placed in the humeral head, proximal tibia, or sternum. If required, IVs can be placed through the burned skin for initial resuscitation. Because noninvasive measurement of blood pressure may be difficult in patients with burned extremities, there should be early consideration of an arterial line.

Disability and Exposure

Patients should undergo the standard trauma evaluation with complete exposure to allow all areas of skin to be examined. Burned areas should be cleansed with soap and warm water or Hibiclens solution if available, and then dressed with antibiotic cream (bacitracin or gentamycin ointments, silver sulfadiazine, or Sulfamylon) and wrapped in gauze or other clean dressing material. A Foley catheter should be placed for large (>10% TBSA in children or >20% TBSA in adults) burns or burns to the genitalia. During this process, it is important to avoid hypothermia. Resuscitation areas and IV fluids should be warmed, exposure minimized, and warm blankets and thermal coverings employed. Finally, tetanus status should be updated as necessary.

Determination of Burn Size

Accurate determination of burn size is critical to ensure treatment and resuscitation are performed properly. The most commonly used method of determining the burn size in adults is the "rule of nines" (Fig. 51-2). Each upper extremity and the head and neck are 9% of the TBSA. Each lower extremity, the anterior trunk, and posterior trunk are 18% each. Finally, the perineum and genitalia are 1% of the TBSA. Another method of estimating burn size is using the patient's open hand including the digits, which is approximately 1% TBSA. Many burn centers will use the Lund-Browder chart, which adjusts for differences based on age (Table 51-2). Regions should be marked for burn depth with the understanding that this may change with time. Children have a relatively larger portion of body surface area in the head and neck and a smaller surface area in the lower extremities. Infants have 21% of the TBSA in the head and neck and 14% in each leg, which incrementally approaches adult proportions with increasing age. These are estimates for the initial fluid rate. Subsequent adjustments are based on the patient's response to resuscitation.

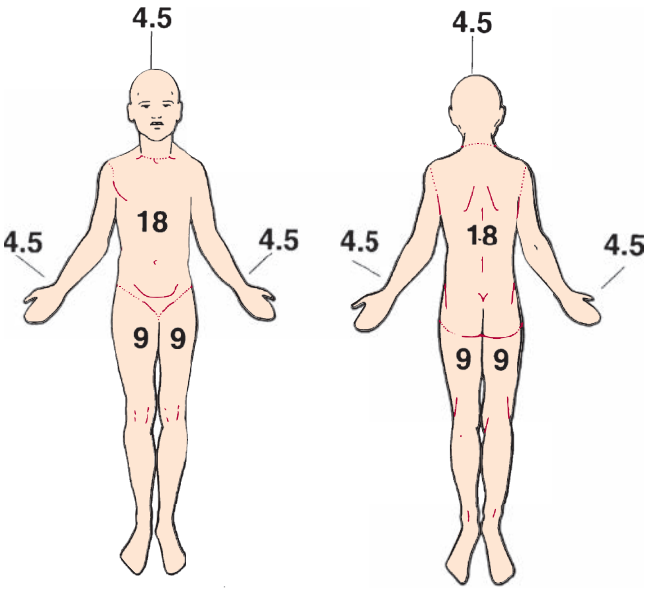

FIGURE 51-2 Determining burn size by the "rule of nines."

TABLE 51-2: Lund-Browder Chart for Estimation of Burn Size in Children

Area	1 y	1–4 y	5–9 y	10–14 y	15 y
Head	19	17	13	11	9
Neck	2	2	2	2	2
Anterior trunk	13	13	13	13	13

Leg	5	5	5.5	6	6.5
Foot	3.5	3.5	3.5	3.5	3.5

FIGURE 51-3 Right hand showing superficial partial-thickness burn after the typically occurring blister has been removed. Superficial partial-thickness burn has a wet, pink, and moist appearance.

Determination of Burn Depth

Clinical manifestations of burn injury are determined by depth and breadth of tissue destruction. The two independent systems of describing the depth of burn injury include degree and thickness. Both are interchangeable.

SUPERFICIAL BURN (FIRST-DEGREE BURN)

Superficial burns do not penetrate the epidermis. Similar to a sunburn, the skin is warm, erythematous, and painful. It is also dry without blisters or eschar. The epithelium remains intact but may slough over time. These burns are self-limited and have no potential for scar. Treatment is primarily related to comfort.

PARTIAL-THICKNESS BURN (SECOND-DEGREE BURN)

Partial-thickness burns penetrate into but not through the dermis. These burns appear wet, weeping, and erythematous, and are exquisitely painful, with blisters or sloughing of the epidermal remnant. They are further divided into two categories based on the depth of dermal penetration.

Superficial Partial-Thickness Burn. These burns involve the epidermis and papillary dermis. They blanch to touch and often form blisters, which may not occur for some hours following injury (Fig. 51-3). Typical healing occurs in about 2 weeks with appropriate wound care, and they are low risk for scar and pigment changes. These can be managed conservatively with dressing changes or xenograft to facilitate healing.

Deep Partial-Thickness Burn. These burns involve the epidermis, papillary dermis, and reticular dermis. They are nonblanching, less painful, pink or pale, and require more than 3 weeks to heal (Fig. 51-4). These burns are frequently managed surgically because they are at high risk of hypertrophic scar and pigment change. Outcomes may be improved by early tangential excision and grafting.

FULL-THICKNESS BURN (THIRD-DEGREE BURN)

Full-thickness burns destroy the dermis and penetrate into the subcutaneous fat. These burns are dry, leathery, waxy, nonblanching, and insensate, and eschar is frequently shades of brown, white, gray, or black (Fig. 51-5) The transition from adjacent partial-thickness burn is clear by the lack of tissue edema. These burns will not heal alone without significant scarification and contracture, and warrant surgical excision with skin grafting or tissue transposition. Despite early excision and grafting, a large full-thickness burn is still at risk for sequelae such as contractures and hypertrophic scars.[45] It is now common practice to surgically debride third-degree burns within the first 3 to 5 days after burn to avoid

FIGURE 51-4 Left hand showing deep partial-thickness burn, typically with mottled pink or white areas.

FIGURE 51-5 Third-degree burn of the abdominal wall. Full-thickness burns destroy the dermis and penetrate into the subcutaneous fat. These burns are dry, leathery, waxy, nonblanching, and insensate, and eschar is frequently shades of brown, white, gray, or black.

cellulitis and burn wound sepsis, especially in large burns. Fourth-degree burns refer to burns that extend into muscle, tendon, or bone. They have a charred appearance that usually results from high-voltage electrical injury or from prolonged duration of contact with fire or a heated object. Skin grafting alone is not adequate treatment for burns of this severity, and limb loss may occur.[46]

Burn Resuscitation

Burn resuscitation is essential for large burns, defined as greater than 10% TBSA in those younger than 5 or older than 50 years of age and 20% TBSA in those 5 to 50 years of age. Patients with smaller burns who can tolerate oral intake including oral rehydration do not require supplemental IV fluids.[47]

With larger burns, there is a systemic capillary leak that increases with burn size. Capillaries usually begin to regain competence after 18 to 24 hours if resuscitation has been successful. Lactated Ringer's is the fluid of choice in adults. Normal saline will predictably result in a severe hyperchloremic metabolic acidosis and should be avoided. Children less than 2 years of age should receive fluids containing 5% dextrose, such as 5% dextrose in half-normal saline, to prevent hypoglycemia. This can be accomplished by giving 5% dextrose as maintenance fluid and lactated Ringer's solution as resuscitation fluid.

Different formulas have been devised to assist the clinician in determining the proper amount of resuscitation fluid. Early work by Baxter[48] formed the basis for modern fluid resuscitation protocols. His work showed that edema fluid in burn wounds is isotonic and contains the same amount of protein as plasma. Additionally, the greatest loss of fluid is into the interstitial fluid compartment. Various volumes

TABLE 51-3: Resuscitation Formulas

Formula	Crystalloid volume	Colloid volume	Free water
Parkland	4 mL/kg/% TBSA burn	None	None
Brooke	1.5 mL/kg/% TBSA burn	0.5 mL/kg/% TBSA burn	2.0 L
Galveston (pediatric)	5000 mL/m^2 burned + 1500 mL/m^2 total	None	None

TBSA, total body surface area.

of intravascular fluid were tested in a canine burn model to determine the optimal delivered amount in terms of cardiac output and extracellular volume. These findings led to the Parkland formula in resuscitating burn patients (Table 51-3); Baxter also concluded that colloid solutions should not be used in the first 24 hours after burn until capillary permeability returns closer to normal. Others have argued that normal capillary permeability is restored somewhat earlier after a burn (8 hours), and thus colloids could be used earlier.[49] Some burn centers are now in fact using oncotic fluids such as albumin or plasma.[50,51]

The late colonels John A. Moncrief and Basil A. Pruitt, Jr. studied the hemodynamic effects of fluid resuscitation in burns, which resulted in the Brooke formula (Table 51-3). They showed that fluid loss in moderate burns results in an obligatory 20% decrease in both extracellular fluid and plasma volume during the first 24 hours after injury. In the second 24 hours, plasma volume returns to normal with the administration of colloid. Cardiac output is low on the first postburn day despite resuscitation but subsequently increases to supernormal levels as the flow phase of hypermetabolism is established.[52] Since these studies, it has been found that much of the fluid needs are due to capillary leak that permits passage of large molecules and water into the interstitial space. Intravascular volume follows the gradient into the burn wound and nonburned tissues. Approximately 50% of fluid resuscitation needs are sequestered in nonburned tissues in patients with 50% TBSA burns.[53]

Most burn centers use guidelines similar to the Parkland or Brooke formulas, with varying amounts of crystalloid and colloid solutions being administered for the first 24 hours after burn. These formulas are guidelines to the amount of fluid necessary to maintain adequate perfusion. All of them calculate the amount of volume given in the first 24 hours, with half being given in the first 8 hours and the other half being given over the next 16 hours.

In pediatric burns, the commonly used formulas are modified to account for changes in surface area–to–mass ratios. Compared to adults, children have a larger body surface area relative to their weight and generally have greater fluid needs during resuscitation. The Galveston formula for children based on body surface area uses 5000 mL/m^2 TBSA burned for resuscitation plus 1500 mL/m^2 TBSA for maintenance in the first 24 hours (Table 51-3). This formula accounts for

both the resuscitation fluid requirements and maintenance needs of children with burns.

An alternative resuscitation formula popularized in the military is the Rule of Ten.[54] Burn size is estimated to the nearest 10% TBSA. The initial fluid rate for patients who weigh 40 to 80 kg is %TBSA × 10. For patients who weigh more than 80 kg, the rate should be increased by 100 mL/h for every 10 kg.

The main indicator of the adequacy of resuscitation in burn patients remains the hourly urine output. In general, the goal for urine output in these patients should be 0.5 mL/kg/h in adults and 1 mL/kg/h in children. Fluid rates should be adjusted to match the desired urine output. If urine output is greater than the stated goal, the fluid rate can be adjusted down 20% per hour until urine output is within the goal range. To avoid oliguria, it is not recommended to decrease the fluid rate below the maintenance rate. If urine output is less than expected, fluid rates should be adjusted up by 20% per hour until urine output goals are met.[55] Patients at risk of low urine output due to heightened needs for resuscitation are those with deep burns, smoke inhalation, alcohol intoxication, or associated injuries, and children.[50] In addition to urine output, standard measures of resuscitation, such as lactate, base deficit, pulse pressure variation, and CVP, should be monitored. Crystalloid boluses should be avoided because these will only contribute to resuscitation morbidity and potentially lead to increased pulmonary edema or secondary extremity or abdominal compartment syndromes.[56-59]

Fluids should be decreased by one-third after the first 24 hours and can be divided between colloid and crystalloid. This will help to mitigate unnecessary interstitial edema.[60] Patients with chronic renal failure will clearly not meet the normal targeted urine output and may require some type of objective measure to guide resuscitation to avoid fluid overload.

Resuscitation morbidity is a consequence of overresuscitation. Excessive fluid administration can lead to abdominal compartment syndrome, which, in the burn patient, is associated with a greatly increased mortality, especially when a decompressive laparotomy is required.[61] Additional complications of fluid overload include extremity compartment syndrome, airway edema, and malperfusion of burn wounds. This constellation of complications associated with excessive fluid administration has been coined "fluid creep."[57]

Escharotomies

With circumferential constricting burns to an extremity, peripheral circulation to the limb can be compromised. Development of generalized edema beneath a nonyielding eschar impedes venous outflow and will have a tourniquet effect on the arterial inflow to the distal beds. This can be recognized by numbness and tingling in the limb and increased pain in the digits. Arterial flow can be assessed by pulse oximetry and determination of Doppler signals in the digital arteries and the palmar and plantar arches in affected extremities. Capillary refill should also be assessed. Escharotomies may be needed for patients with deep second-degree and third-degree burns that are circumferential around the chest, extremities, abdomen, penis, or neck.[62-64] In the extremity, the release of a burn eschar is performed by making lateral and medial incisions on the affected extremity using electrocautery. The entire constricting eschar must be incised to relieve the obstruction to blood flow. If the hand is involved, incisions should be made as they would for a fasciotomy. These include over the index and ring finger metacarpal and along the thenar and hypothenar eminence at the junction of the glaborous and nonglaborous skin. If needed in the fingers, the incisions should be placed at the border of the glaborous and nonglaborous skin. Chest wall escharotomies are made in the lateral chest bilaterally with a connecting incision across the chest to relieve constriction and allow adequate ventilation. Incision placement for commonly required escharotomies is shown in Fig. 51-6.

An overview of burn triage and initial care is presented in Fig. 51-7.

Inhalation Injury

Inhalation injury occurs in 8% of cutaneous burn injuries and remains a significant predictor of outcome following massive burns. There has been improved survival over the past few decades, which is attributed to early diagnosis, better airway management, gentle ventilation, and pulmonary hygiene.[65]

In most inhalation injuries, damage is caused primarily by inhaled toxins. Heat is generally dispersed in the upper airways, whereas cooled smoke particles and released toxins are carried distally into the bronchi and alveoli. The injury is principally chemical in mechanism, and the response is an immediate increase in blood flow in the bronchial arteries with formation of edema and increases in lung lymph flow. The resulting edema is associated with an increase in lung neutrophils, and it is postulated that these cells may be the primary mediators of pulmonary damage with this injury.[66] Neutrophils release proteases and reactive oxygen species that can produce conjugated dienes by lipid peroxidation. High concentrations of these conjugated dienes are present in the lymph and pulmonary tissues after inhalation injury, suggesting that increased neutrophils are active in producing cytotoxic materials.[67]

Another hallmark of inhalation injury is separation of the ciliated epithelial cells from the basement membrane followed by formation of exudate within the airways. The exudate consists of proteins found in the lung lymph and eventually coalesces to form fibrin casts.[68] Clinically, these fibrin casts can be difficult to clear with standard airway suction, and bronchoscopy is often required. These casts can also add barotrauma to localized areas of the lung by forming a "ball valve." During inspiration, the airway diameter increases, and air flows past the cast into the distal airways. During expiration, the airway diameter decreases, and the casts effectively occlude the airway, preventing the inhaled air from escaping. Increasing volume leads to localized increases in pressure that are associated with numerous complications, including pneumothorax and decreased lung compliance. Therapy is aimed at clearing the airway and minimizing complications from hyperinflation.

Patients with smoke inhalation often present with a history of exposure to smoke in a closed space. Signs and symptoms include stridor, hoarseness, wheezing, carbonaceous sputum, facial burns, and singed nasal vibrissae. Each of these findings has poor sensitivity and specificity[69]; therefore, the diagnosis is often established with bronchoscopy. Bronchoscopy can reveal early inflammatory changes such as erythema, edema, ulceration, sloughing of mucosa, and prominent vasculature in addition to infraglottic soot.[70] Mechanical ventilation may be needed to maintain gas exchange, and repeated bronchoscopies often reveal continued ulceration of the airways with the formation of granulation tissue and exudate, inspissation of secretions, and edema.

Management of an inhalation injury is directed at maintaining open airways, clearing secretions, and maximizing gas exchange while the lungs heal. An awake patient with a strong cough and patent airway can clear secretions very effectively, and efforts should be made to treat patients without mechanical ventilation when possible. If respiratory failure is imminent, intubation should be instituted early, with frequent chest physiotherapy and suctioning as needed. Pharmacologic treatment of inhalation injury includes β-agonists, nebulized acetylcysteine and heparin, and nebulized racemic epinephrine.[71-73]

Alternative ventilator therapies such as high-frequency percussive ventilation have been used in patients who fail conventional ventilation strategies. High-frequency percussive ventilation minimizes barotrauma, enhances secretion clearance by loosening inspissated secretions, and recruits alveoli at lower airway pressures. It combines standard tidal volumes and respiratory rates (ventilator rates 6–20 breaths/min) with smaller high-frequency respirations (200–500 breaths/min); however, there are no data that this method is superior over basic lung-protective ventilation strategies.

Electrical Burns

The two kinds of electrical burns are arc and current. Arc burns are flash burns produced by heat generated by an electrical arc. These types of burns are much more common than current burns. There usually is no history of tetany in involved muscle groups. The neurologic exam of the affected extremity is normal. There is no entrance or exit wound and no deep tissue damage. Arc burns are treated the same as thermal burns.[74]

Current burns are caused by electricity passing through the body, leading to tissue destruction. They are characteristically deep and well circumscribed, with visible entrance and exit wounds that are typically on widely different areas of the body (eg, entrance at hand and exit at foot). There is usually a history of tetanus muscle contracture. The neurologic exam of the involved extremity is usually abnormal.[75] An acute neuropathy is common and may be permanent. Development of cataracts is also common after severe electrical current burns and may be delayed for months; therefore, close ophthalmologic follow-up is necessary. Patients with current burns are at risk for a compartment syndrome, which would require a fasciotomy, not escharotomy, to decompress the affected extremity. If myoglobin is present in the urine, a brisk urine output should be maintained. Current burns are debrided surgically much like necrotizing soft tissue infections. Most of the patients will need operative debridement within 48 hours of admission and will require multiple surgeries.

Chemical Burns

It is important to accurately identify the chemical, how the exposure occurred, and type and duration of exposure. Prompt treatment is imperative in minimizing tissue damage in chemical burns, and the area of the burn should be copiously irrigated with water. Care must be taken to direct the drainage of the irrigating solution away from unburned areas to limit the area of exposed skin. Contaminated clothing should be removed and disposed of, and care should be taken not to get any chemical on providers. If the chemical composition is known, monitoring the irrigated solution pH will give an indication of the effectiveness of the irrigation. Attempts at neutralization of either acidic or basic solutions can result in heat production and extend the injury. Generally, acids cause coagulative necrosis and are confined to the skin, while basic solutions cause liquefactive necrosis and extend further into tissues. After the chemical injury has been controlled, the remaining burn is treated in the same way as thermal injuries. Assessment of burn depth is often difficult but is typically deeper than it appears. For chemical exposures to the eyes, a visual acuity test and fluorescein dye test should be performed following irrigation. Ophthalmology should be consulted on any patient with a significant eye chemical exposure.

HYDROFLUORIC ACID

Hydrofluoric acid (HF) is used in chrome and rust cleaners and in industry for etching glass. It is corrosive, and the fluoride ion penetrates deeply into tissues to cause progressive tissue destruction.[76] Burns are usually seen when HF concentrations are greater than 20%. Even small amounts of HF swallowed, inhaled, or absorbed through the skin can cause systemic symptoms. The fluoride ion precipitates calcium and may cause systemic hypocalcemia; however, the classic physical signs of hypocalcemia do not usually occur. Instead, patients will have severe pain at the site of exposure (typically hands), and over time, if untreated, patients will develop ventricular arrhythmias that are resistant to pharmacologic therapy and tend to recur after cardioversion. The arrhythmias occur even after the abnormalities in calcium and magnesium have been corrected. It is thought that the fluoride ion is directly cardiotoxic.[77] In addition to undergoing copious irrigation of the burned area, the exposed skin should be treated with 2.5% calcium gluconate gel to provide pain relief and limit the spread of the fluoride ion. Magnesium and ionized calcium levels should be followed closely. Patients who present with acute HF burns that are obviously full thickness and are greater than 1% TBSA should be taken immediately to surgery to excise the wound and thus remove the toxin.

Inhaled HF causes severe pulmonary edema and destruction of lung parenchyma. Aerosolized calcium gluconate has been used with mixed results.

HF hand burns are typically seen after direct exposure to industrial-strength cleaning solutions. As for all HF burns, 2.5% calcium gluconate gel can be applied topically. For more severe burns (tissue blanching or bleb formation) not on the digits, 10% calcium gluconate solution can be injected into the subcutaneous tissues (0.5 mL/cm^2 of burned area). If HF digital burns progress to bleb formation or blanching, intra-arterial calcium infusion has been advocated. These burns will rarely be severe enough to need palmar or digital fasciotomies.[78]

WHITE PHOSPHORUS BURNS

White phosphorus is an incendiary agent used in fireworks and military ammunitions. It is found in certain bullets, mortars, rockets, improvised explosive devices, and bombs. White phosphorus burns as long as oxygen is available. It is highly lipolytic, which allows it to continue to penetrate into deep tissues producing systemic effects. If still burning, soft tissue may need rapid debridement until all visible white phosphorus has been removed. Wounds should be soaked with saline or water to avoid exposure to oxygen; then 2% copper sulfate solution should be applied if available. Calcium and phosphorus levels should be monitored as the exothermic reaction generated by burning white phosphorus releases phosphates and oxidates, which bind calcium. Sudden death from electrolyte abnormalities has been seen for burns greater than 10% TBSA.[79,80]

PHENOL BURNS

Phenol is a solvent used by industry that acts as a topical anesthetic, so that delayed recognition of the burn is possible. The burned area should be cleansed with polyethylene glycol (PEG 300 or 400), propylene glycol, or vegetable oil to remove the phenol, followed by application of a topical antibiotic such as silver sulfadiazine. Phenol can be rapidly absorbed through the skin, resulting in systemic toxicity such as renal failure, intravascular hemolysis, and hepatic dysfunction.[81,82]

Care of the Burn Wound

ANTIMICROBIAL AGENTS

Care of the burn wound is based on burn depth. In general, after initial debridement of the epidermis, topical antimicrobial dressings should be applied with the goal to limit bacterial overgrowth.

Silver sulfadiazine cream (Silvadene) (SSD) combines the agents sulfonamide and silver ion. It is the most common ointment used for initial wound care. It can also be used for care of donor sites.[83-85] SSD is applied only once a day and has fair eschar penetration. It should not be used on the face or ears. SSD has good gram-positive, gram-negative, and antifungal properties. It is painless but can cause leukopenia that is self-limited. Its use is contraindicated in patients with true sulfa allergies. The sulfonamide component of SSD can be absorbed through the skin. This is especially true in small children who have a greater area-to-mass ratio. In addition, sulfonamides can cause kernicterus in newborns. For these reasons, SSD is contraindicated in children under 2 months of age. Instead, gentamicin or bacitracin ointment should be used.

Mafenide acetate (Sulfamylon) is used as a 2% solution, penetrates eschar well, is painful when applied, and is rapidly absorbed. Sulfamylon has broad-spectrum antimicrobial qualities and is bactericidal. It has good gram-positive and gram-negative activity, including *Clostridium* species, but has little antifungal activity. Sulfamylon is a strong carbonic anhydrase inhibitor, causing loss of bicarbonate in the urine.[86] If used on large-percent TBSA burns, pH should be monitored, and often supplemental bicarbonate is needed. Sulfamylon is safe for use on ear burns and can prevent auricular chondritis.[87]

Silver nitrate solution (0.5%), although rarely used today, is safe for patients with sulfonamide allergies, does not penetrate eschar, and is minimally absorbed. Broad-spectrum antimicrobial resistance is uncommon. Disadvantages include the use of large bulky dressings to keep wounds moist, and black staining of all exposed surfaces. It can also cause hyponatremia and hypokalemia as well as methemoglobinemia.[88-90]

Bacitracin ointment is typically used on the face or in children where keeping dressings in place is a challenge. It is useful for superficial partial-thickness burns or clean donor sites.

Nystatin is a polyene antibiotic structurally similar to amphotericin B. It binds ergosterol in the fungus cell membrane. It has a broad-spectrum antifungal effect but little antibacterial effect. It is used with SSD in cases of heavy fungal colonization of the burn wound or in invasive fungal burn wound infections. It is not systemically absorbed, and resistance is rare.

BASIC BURN DRESSINGS

The application of topical antimicrobials is an effective method of decreasing skin colonization, but dressing changes are painful. Recently, silver nylon or foam dressings (Silverlon, Silverseal, or Mepilex Ag) are being used once the burn wounds have been determined to be clean, stable, and likely to heal. The main advantages of these types of dressings are ease of application, elimination of painful daily dressing changes, and documented antimicrobial effectiveness. In some cases, this will allow home care rather than inpatient burn wound care.

Surgical Management of the Burn Wound

Deep partial-thickness burns may not heal and full-thickness burns will not heal in a timely fashion without autografting. Early excision and skin grafting of these wounds are now standard. For wounds less than 20% TBSA, skin grafts are either unmeshed or meshed, with a narrow ratio (2:1 or less). The advantage of unmeshed is that there is less contraction. In major burns, widely expanded autograft skin (4:1 or greater ratio) is needed. Although widely meshed skin is applicable for most large burn wounds, cosmetically important areas such as the hands, face, and neck should be grafted with non-meshed sheet grafts to optimize appearance and function.

Cultured epidermal autograft is a process by which a patient's own keratinocytes are cultured in vitro and then used as a graft to cover wounds.[91] The potential for donor coverage is potentially unlimited, but the process is time consuming and expensive. This technique can be used as rescue in patients with very large burns and limited donor sites, and works best when applied over a 6:1 meshed autograft.[92] Prolonged drying time is required each day, adherence is as low as 15%, and the grafts are subject to significant degradation by mechanical forces as well as by colonizing bacteria.[93] Recently, the FDA has approved cultured epidermal autografts which can be sprayed over the excised burn wound within the same operation of the harvest. Like cultured epidermal autografts, outcomes are better if the cells are sprayed over widely meshed autograft.

Wounds that cannot be covered with meshed autograft skin due to a scarcity of available donor skin can be temporarily covered with an allograft. Porcine xenograft or human allograft (cadaveric) has the advantage of being readily available. These temporary dressings may also be used for coverage of partial-thickness wounds to reduce pain and maintain joint mobility while allowing the wound to heal. Dermal substitutes such as Integra (Integra LifeSciences Corporation, Plainsboro, NJ) and Alloderm (LifeCell Corporation, The Woodlands, TX) are also being used. They remain in place for approximately 2 weeks, after which time the outer silastic layer is removed and a thin allograft is placed over the underlying neodermis.

Nutritional Management of Burn Patients

As previously noted, profound hypermetabolism is a physiologic response unique to burn injuries. This hypermetabolism is characterized by increased body temperature, glycolysis, gluconeogenesis, proteolysis, lipolysis, and prolonged substrate cycling.[94,95] Overall, the basal level of glucose is elevated despite a high insulin state, which can complicate outcomes and exacerbate muscle catabolism. Lipolysis also occurs at a rate that is higher than normal due to abnormal substrate cycling. This results in an accumulation of triglycerides causing steatosis. There has been a report that propranolol will decrease this peripheral lipolysis.[96] Proteolysis is also increased in burn patients compared to nonburn patients. This is due to a combination of increased muscle breakdown and increased plasma protein production by the liver. As wound healing requires an increase in protein synthesis, early enteral nutrition with supplemental proteins is recommended. Protein requirements are typically from 2 to 2.5 g protein/kg/d, and calorie needs may be as high as 40 kcal/kg/d, although these will vary with metabolic demand, age, and percent TBSA. The use of anabolic agents, particularly oxandrolone, can reduce catabolism and improve muscle mass after burn injury.[97]

Special Problems Seen in Burn Patients

STRESS ULCERS

Since the near-universal use of histamine type 2 receptor blockers or proton pump inhibitors in burn patients, stress ulcers, or Curling ulcers, are now rarely seen. Some centers have advocated for conservative use of stress ulcer prophylaxis in small burns, but this has not been well studied.

BURNS OF THE EAR

The ear is unique in that it contains cartilage that is just under a thin layer of skin. Because cartilage has a poor blood supply, it is very susceptible to infection following burns. Sulfamylon penetrates into the cartilage better than other topical antibiotics and is recommended for use on ear burns. If auricular chondritis does develop, it should be promptly treated. Signs and symptoms include pain, tenderness, and erythema and an increase in the auriculocephalic angle such that the ear may protrude laterally. Chondritis usually occurs 2 to 6 weeks after the burn, often after the patient has been discharged from inpatient care. The most common organism seen in auricular chondritis is *Pseudomonas aeruginosa*, but gram-positive infections are possible, and cultures should always be sent. Treatment includes antibiotics, drainage of any abscesses, and debridement of necrotic cartilage. Infections can be challenging to eradicate, and they often recur.[98]

TAR BURNS

Tar or pitch blend is used in sealing roofs or repairing roadways. Burns are usually on the hands and forearms. Significant pain and loss of skin will result if the tar is simply peeled off of the skin. Petroleum ointment or other emulsifying agents will adhere to the tar, solubilize, and then dissolve the tar. Underlying burns are then treated with SSD or another topical antibiotic.[99,100]

Care of the Burn Patient in Austere Conditions

Caring for victims of burns in austere conditions such as the military environment or after natural disasters or other humanitarian crises can be challenging. Evacuation to a burn center or other treatment facility may not be feasible. The following are practical and safe alternatives to care in such settings. For additional information related to combat casualty care, see Chapter 53.

For patients who can be evacuated, care should be optimized prior to long flights or travel in suboptimal medical conditions.[101] Patients should undergo dressing changes each day prior to and including the day of transport. Prior to departure, the patient should be wrapped in clean sheets and blankets, with Bair Huggers, fluid warmers, and ancillary warming devices used when possible to help maintain normothermia during transport. Other than an escharotomy, operative burn care should not be undertaken prior to evacuation.

Burn patients who cannot be evacuated face additional challenges. Recent US military experience treating burn casualties abroad has led to clinical practice guidelines citing 40% to 45% TBSA as the largest survivable burn size. Resuscitation capabilities and blood are limited, dressing supplies

are precious, infection control is rudimentary, supplemental nutrition may not be available, and physicians, nurses, and physical therapists (if available) may have variable to no burn experience. When a burn patient arrives, burn evaluation, cleansing, and dressing should ideally be performed in the operating room. Field lines should be changed, and assessment of burn wound depth and extent should be performed as per normal care. Resuscitation is similar to civilian burns with a prescribed formula such as outlined in Table 51-3.[102] Smaller size burns may be amenable to primary excision and closure. Once larger burns have demarcated, excision and grafting of small portions of full-thickness burns can commence. This should be undertaken approximately every 3 days until all full-thickness sites are covered with graft and until all partial-thickness wounds are healing.

Reconstruction

As survival of patients with large surface area burns has increased due to acute burn care and improved critical care, surgeons care for an increased number of patients with secondary burn deformities. Hypertrophic scarring is a major complication after burn injury with several risk factors that contribute to its development including the following: location of the burn injury, burn depth, time to healing, and skin color.[103,104] Although the precise mechanism by which hypertrophic scarring occurs remains unclear, expression of transforming growth factor-β1 and its receptors has been associated with its development. Recent investigations have also identified the role of mechanotransduction through focal adhesion kinase as playing a central role.[105]

The key to improving hypertrophic scars is to relieve tension by either lengthening the scar through local tissue rearrangement or providing additional tissue through thick split-thickness grafts, full-thickness grafts, biologic substitutes, or free-tissue transfer. Z-plasty adds length to the scar at the expense of width and is a form of local tissue rearrangement to release linear burn scar contractures.[106,107] In addition to lengthening a scar, it is also useful in redirecting a scar, flattening a raised or depressed scar, and recreating a webspace.[45,46,108] The classic Z-plasty design incorporates angles of 60° with three equal limbs to achieve a theoretical 75% lengthening. This configuration balances the desired increase in length of the contracture by taking advantage of the laxity of lateral skin. The corner of the Z-plasty should be 90° to maximize blood flow and minimize the risk of skin necrosis, as shown in Fig. 51-8. Laser therapy can also be used to treat hypertrophic burn scars, including both pulsed dye lasers (PDLs) and fractional carbon dioxide lasers. PDLs increase vascularity and reduce redness, whereas carbon dioxide lasers improve pliability of the scar to permit increased range of motion.[109] Often, use of both PDLs and a fractional carbon dioxide laser is required.

Broad burn scar contractures will require a generous transverse release to restore structures to their normal anatomic positions for a proper correction. As a general rule, most burn scar contractures that cross a mobile structure, such as an eyelid or a joint, will require an incision across the entire axis of rotation and further than one might expect. Scar excision should rarely be contemplated as this will create an even larger defect, and the same forces will be present that led to the initial scar.

Autologous fat grafting involves transfer of fat from one area on the body to another. For burn reconstruction, it can aid in replacing tissue loss in a burned area. Fat is usually removed by liposuction, processed into liquid, and then injected into the scarred or grafted area. Fat grafting has shown promise to improve function and appearance. Also, flaps can be used to fill in a postburn tissue defect. They have the advantage of not having to rely on the blood supply of the recipient bed to survive. Flaps can also be used to cover exposed nongraftable structures such as tendon or bone.

Tissue expansion is a valuable tool for burn reconstruction when a large adjacent piece of skin is needed either as a full-thickness graft or flap. The basis for tissue expansion is the gradual placement of mechanical stress to the overlying skin. Complications of tissue expansion are common, especially in

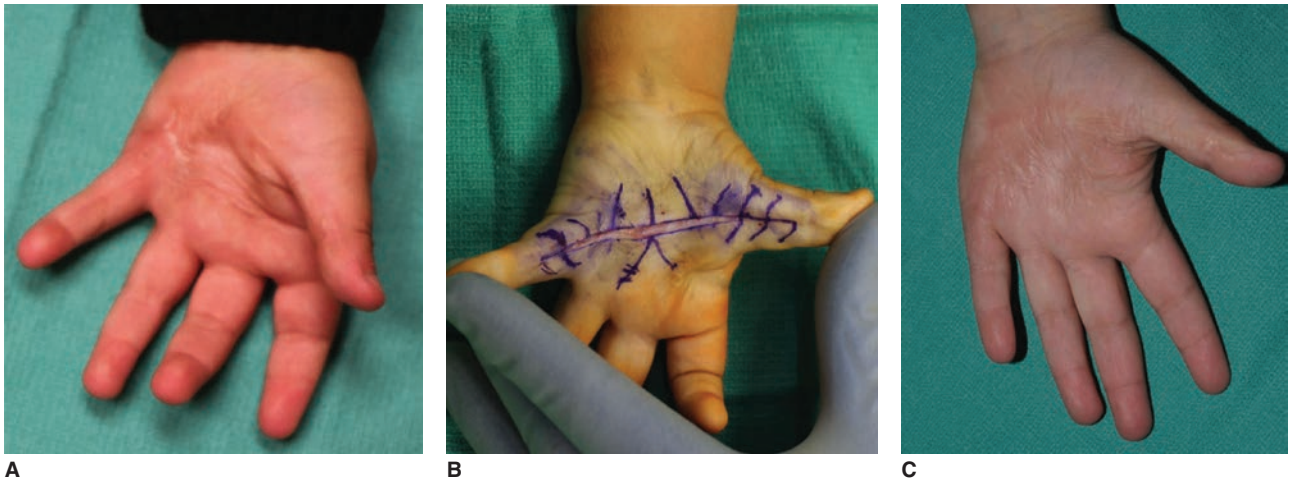

FIGURE 51-8 Series of Z-plasties with a central five-flap "jumping man" to relieve a palmar contracture. (**A**) Preoperative hand in extension. (**B**) Intraoperative markers. (**C**) Postoperative hand in extension.

the extremities, and include infection, implant exposure, and flap ischemia.

RADIATION

Therapeutic Radiation

Ionizing radiation therapy has become a central component of cancer treatment. In radiation-treated areas, close to 85% of patients will have a moderate to severe skin reaction, known as acute radiation dermatitis, that can lead to blistering, ulceration, and erosion.[110] There is a grading system developed by the National Cancer Institute to classify radiation dermatitis, and it includes four stages. Grade 1 injuries have faint erythema or dry desquamation. These are treated with hydrophilic moisturizers, while pruritus/irritation is treated with low-dose steroids. Grade 2 injuries have moderate to brisk erythema with patchy desquamation confined to creases and skin folds. Grade 3 injuries have moist desquamation outside skin folds with pitting edema and bleeding from minor trauma. Grades 2 and 3 injuries are treated with a hydrogel dressing and hydrocolloids with the goal of decreasing infection. Grade 4 injuries are characterized by full-thickness skin necrosis or ulceration with spontaneous bleeding. These wounds may be treated like full-thickness burn injuries and can require debridement with skin grafts or flaps.

Measuring Exposure to Radiation

Radiation consists of both particles (α, β, and neutrons) and photons (γ- and x-rays), which have specific energies and tissue penetrance (Table 51-4). The potential for biological injury for each of these depends on the amount of energy transmitted by the particle or photon when it interacts with the target. Each type of radiation has different qualities, and each is absorbed into tissue to varying degrees. Distance, time, and shielding are the ways to reduce exposure from a radiation source. Dosimetry is the measurement of radiation exposure by detectors that indicate the type, quality, flux, and rate of exposure dependent on the distance of the detector from the source.

Pathophysiology

Cell damage from radiation is caused by the transfer of kinetic energy from particles or photons to existing molecules, causing ionization of mostly oxygen and formation of free radicals such as the hydroxyl radical. These highly toxic compounds react with normal biologic molecules to cause cellular damage, primarily to phospholipid membranes and deoxyribonucleic acid.[111] Different cell types have different sensitivities to radiation. Cells with high proliferation rates are the most sensitive, while those with low proliferation rates are relatively resistant (Table 51-5).

The overall effect depends on the extent of cellular mass exposed, the duration of exposure, and the homogeneity of the radiation field. Radiation injuries are either localized or whole body, depending on the circumstances of the exposure. The term *localized radiation injury* refers to an injury involving a relatively small portion of the body that does not lead to systemic effects.[112] This is mostly associated with local exposure to low-energy radiation.

The dose of exposure determines injury severity. The onset of vomiting is useful for estimating the dose received from a single exposure. Vomiting in the first 10 minutes of the exposure means that the dosage was more than 8 Gray (unit of ionizing radiation dose, or Gy), vomiting within 10 to 30 minutes, 6 to 8 Gy; within 1 hour, 4 to 6 Gy; within 1 to 2 hours, 2 to 4 Gy; and over 2 hours, less than 2 Gy.[113] Aside from vomiting, erythema of the skin can be an initial sign of exposure, with the sooner the appearance of erythema, the higher the dose of exposure. Depilation, or hair loss, is another way to determine the extent of localized injury and may occur as early as 7 days after exposure.

TABLE 51-4: Types of Radiation, Relative Energies, Penetrance, and Relative Hazard

	Relative energy (MeV)	Penetrance into tissue (cm)	Relative hazard
α	1–5	0.0007–0.004	Low
β	0.2–1.0	0.017–0.34	Moderate
γ	0.1–10	20–150	High

TABLE 51-5: Radiosensitivity of Human Cell Types

Radiosensitivity	Cell types
Very high	Lymphocytes
	Hematopoietic cells
	Intestinal epithelium
	Spermatogonia, ovarian follicular cells
High	Urinary bladder epithelium
	Esophageal epithelium
Intermediate	Endothelium
	Fibroblasts
	Pulmonary epithelium
	Renal epithelium
	Hepatocytes
Low	Hematopoietic stem cells
	Myocytes
	Chondrocytes
	Neural cells

Acute Radiation Syndrome

Detonation of a nuclear device can result in enough radiation exposure to cause immediate death for individuals within the lethal area of the blast. The severity of injury from acute

TABLE 51-6: Four Phases of Acute Radiation Syndrome

Prodromal phase	Nausea, vomiting, fever
Latent phase	Symptom-free interval following acute nausea/vomiting
Manifest phase	Symptoms of hematopoietic, gastrointestinal, and neurologic injury
Recovery phase	Variable

radiation exposure is directly related to the effective dose of radiation to the whole body. Radiation exposure less than 1 Gy is associated with minimal symptoms and no mortality, but exposure to greater than 8 Gy has a 100% mortality.[114] The hematopoietic and gastrointestinal systems are particularly affected by radiation because they have rapidly dividing cells. Therefore, loss of stem cells and rapidly dividing cells from hematopoietic and gastrointestinal tissues can lead to bleeding, infection, and diarrhea.

Acute radiation syndrome has four phases of severity of signs and symptoms (Table 51-6). Onset of the prodromal phase is related to the total dose of radiation received. It can be minutes, if a lethal dose is received, to hours for lower doses. Fever, nausea, vomiting, and anorexia characterize this phase, which may last for 2 to 4 days or longer. When signs and symptoms regress, the latent phase starts. This symptom-free period may last a few hours to several weeks depending on the dose of radiation. As dose increases, the latent phase becomes shorter. Symptoms of hematopoietic, gastrointestinal, and neurologic syndromes are expressed in the third, or manifest, phase. Nausea, vomiting, diarrhea, and bleeding characterize this phase. Recovery is the last phase, is variable, and may last weeks to months. If the dose is high enough, death ensues.

Whole-Body Exposure

Effects of whole-body exposure depend on the dose of radiation absorbed by all tissues of the body. As opposed to local exposure to just the skin, whole-body exposure will lead to much more absorption of energy. Effects are primarily seen on the cardiovascular, hematopoietic, gastrointestinal, and central nervous systems. With relatively lower doses, bleeding, infection, and loss of electrolytes can occur from damage to the intestinal mucosa and blood cell components. Higher doses will cause cardiovascular collapse and circulatory failure.

The dose absorbed will lead to one of the three following courses:

1. *Hematopoietic syndrome*—Exposure to 1 to 4 Gy causes pancytopenia with an onset of 48 hours and a nadir at 30 days. Spontaneous bleeding can occur from thrombocytopenia, and opportunistic infections can occur from granulocytopenia.
2. *Gastrointestinal syndrome*—Exposure to 8 to 12 Gy will cause gastrointestinal symptoms in addition to pancytopenia. Severe nausea, vomiting, abdominal pain, and watery diarrhea occur within hours of the exposure. Once these symptoms resolve, the mucosa of the intestine sloughs and causes bloody diarrhea, loss of the intestinal barrier, and translocation of bacteria. Sepsis and massive fluid losses ensue with subsequent hypovolemia, acute renal failure, and death.
3. *Neurovascular syndrome*—Exposure to more than 15 Gy causes immediate total collapse of vascular tone that is superimposed on the preceding syndromes. This may be caused by the massive release of vasodilatory mediators or destruction of the endothelium, which progresses rapidly to shock and death.[115]

Assessment

Effective field triage, rapid evacuation of casualties, and appropriate decontamination are essential and should be performed as soon as possible.

During stabilization of the patient, information about the incident should be obtained, including the type of radiation, the duration of the exposure, the distance from the source, and whether direct contact with the source occurred. This information will be necessary to calculate the dose of radiation. Other important information is the background radiation level of the involved area at the time of the incident. The average radiation background in the United States is 360 mrem/y (rem = the quantity of any ionizing radiation that has the same biologic effectiveness as 1 rad of x-rays). Any radiation above the background level is considered contamination.

The individual radiation dose is assessed by determining the time to onset and severity of nausea and vomiting, rate of decline in absolute lymphocyte count, and appearance of chromosomal aberrations in peripheral lymphocytes. Documentation of clinical signs and symptoms affecting the hematopoietic, gastrointestinal, neurovascular, and cutaneous systems over time is essential for triage of victims, selection of therapy, and assignment of prognosis.

A complete blood count with differential should be performed with particular attention to the total lymphocyte count (TLC), which is the most accurate indication of radiation injury. The rate of decrease in TLC varies inversely with the dose of radiation and, therefore, portends the prognosis. Increases in serum amylase and diamine oxidase (specific to enterocytes) may be helpful in determining injury to the intestinal mucosa.

TRIAGE

Like other disaster situations, major radiation accidents and exposures can quickly overwhelm any response system. Treatment facilities may be destroyed, supply distribution may be hampered, and health care workers can be among the injured. For these reasons, triage with resources directed toward those likely to survive is paramount to limit casualties. Unfortunately, the extent of radiation injury may not be initially apparent.

Victims should be evacuated as quickly as possible to limit exposure. The patient's injuries, including burn or traumatic injury, should be treated, and then symptomatic treatment for the radiation illness should commence.

Thermal burns are likely to occur in combination with radiation injury, which can be a lethal combination. With the addition of a significant radiation injury, survival following burns is reduced and only those individuals with relatively small (<30% TBSA burns) burns may be expected to survive.[116] Under most circumstances, the immediate resuscitation and treatment of life-threatening injuries supersede treatment for radiation exposure, as the effects of radiation are relatively delayed.

DECONTAMINATION

The first priority in the treatment of radiation injury is the stabilization of the patient. Once the resuscitation has begun and the initial assessment is complete, decontamination should be started and occur before access to the treating facility. Removal of clothing and jewelry and irrigation or washing of the body is an effective way of removing any radioactive contamination. Open wounds should be covered with a clean dressing. These wounds are assumed to be contaminated with radioactive material and should be gently irrigated with copious amount of water, saline, or 3% sodium hydroxide solution. The irrigant should be rinsed to a safe drain with the goal of diluting any radioactive particles without spreading them to adjacent uncontaminated areas. Irrigation is continued until the area indicates a steady-state absence of radiation with a Geiger counter or reaches the background radiation level.

Attention should then be turned to the intact skin, where decontamination involves gentle scrubbing of the contaminated sites with a soft brush under a steady stream of water. Following this, povidone-iodine or hexachlorophene solution is applied. This should be repeated until the skin has a steady-state level of radiation. After two rounds of the preceding treatment, a diluted mixture of one part commercial bleach to 10 parts water can be used to remove further radioactive particles.

Management of Local Injuries

Local injuries to the skin evolve very slowly over time, and symptoms may not occur for days to weeks after the exposure. Mild erythema should be treated conservatively with dressings, if needed. The lesion may progress to ulceration or chronic radiodermatitis.

Management of Whole-Body Injuries

The management of whole-body irradiation is aimed primarily at symptoms of cellular loss. Except for removal of internal radiation, no treatment can interrupt the process. Antiemetics are given to provide symptomatic relief from nausea and vomiting. Resuscitation may be needed to maintain euvolemia because of volume losses.

Gastrointestinal bleeding, diarrhea, infection, anemia, and diffuse bleeding from pancytopenia may occur with varying degrees of severity. If the exposure is more than 2 Gy, a bone marrow transplant as a salvage maneuver may be considered.

Infections become problematic as these patients become profoundly immunosuppressed, and opportunistic organisms are often the cause. All blood products should be irradiated to prevent graft-versus-host disease. Transplants should be performed at the peak of immunosuppression, which is between 3 and 5 days after a high-dose exposure. The use of hemopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) can speed restoration of granulocytes.

SUMMARY

The treatment of burns and radiation injuries is complex. Knowledgeable physicians can treat minor injuries in the community; however, moderate and severe injuries require treatment in dedicated facilities with resources to maximize the outcomes from these often devastating injuries. The care of patients has markedly improved over the past 40 years, and most patients with massive injuries now survive. Challenges for the future will be in modulation of scar formation and in shortening the time to a functional and visually appealing outcome.

Temperature-Related Syndromes

Elizabeth R. Benjamin • Sydne Muratore • Kenji Inaba • Gregory J. Beilman

KEY POINTS

- The standard definitions of hypothermia are mild (>32°C), moderate (28–32°C), and severe (<28°C).
- Warming techniques to reverse hypothermia include passive, active and noninvasive, and active and invasive.
- Depressed platelet function, impaired platelet delivery, slowed activation of coagulation enzymes, activation of protein C, and activation of fibrinolysis occur in hypothermic patients.
- Initial hospital management of frostbite should include rapid rewarming of the affected body part, in a 38°C to 40°C water bath.
- Surgical debridement and amputation should be delayed until demarcation has occurred after a frostbite injury, unless the patient develops wet gangrene, overwhelming infection, or a necrotizing soft tissue infection.
- The normal core body temperature is maintained at approximately 37°C by conduction, convection, evaporation, and radiation.
- As heat exhaustion progresses, the cutaneous blood vessels paradoxically vasoconstrict and sweating stops in many, but not all, patients.
- In patients with heat stroke, rapid cooling improves morbidity and mortality.
- Cellular changes, including protein denaturation, begin to take place at approximately 41.6°C to 42.3°C.
- Malignant hyperthermia is caused by exposure of susceptible individuals with a unique genetic composition to halogenated anesthetic agents.

INTRODUCTION

Humans as homeothermic mammals must maintain a stable internal body temperature within narrow range to allow function of enzymes. Regional and seasonal variations in the environment mandate the ability to either lose or generate heat in order to maintain temperature within this range. Mechanisms to either conserve heat (surface vasoconstriction, shivering, and piloerection) or lose heat (surface vasodilation, sweating with evaporation) allow adaptation to a colder or warmer environment. Three specific adaptive behaviors permit existence in a cold environment and have allowed the spread of humankind across six of the seven continents. These are fabrication of clothing, shelter-building, and control of fire. However, environmental extremes, abnormal endocrine function, or infection and injury can result in the inability of the organism to maintain body temperature within the normal range, leading to significant functional disturbances.

HYPOTHERMIA

It is important to understand the distinction between environmental hypothermia (due to exposure to cold) and hypothermia associated with injury. Hypothermia due to exposure can be lethal when it is severe and ongoing (consider Napoleon's army during the retreat from Moscow[1]), but with modern medical care, hypothermia without injury has a significant survival rate even in the setting of cardiac arrest (50%).[2] In patients after injury, however, the effects of hypothermia are profound, with hypothermia being an important component of the "bloody vicious cycle" first described by Kashuk and

TABLE 52-1: Hypothermia and Associated Physiologic Changes

	System

colleagues.[3] In one large historical series, there were no survivors of hypothermia and serious trauma if initial core body temperature was less than 32°C.[4] This distinction mandates a different approach for patients with hypothermia and injury.

Definitions

The normal core body temperature for humans is 37°C, with a circadian variation of approximately 0.5°C to 1°C.[5] The standard definition of hypothermia, developed for environmental hypothermia, describes mild hypothermia as a core body temperature above 32°C, moderate from 28°C to 32°C, and severe less than 28°C. The lowest reported temperature for an adult survivor of hypothermia is 13.7°C. In trauma patients with hypothermia, the scale is shifted due to significant changes in mortality, with temperatures of 34°C to 36°C defined as mild, 32°C to 34°C as moderate, and less than 32°C as severe.

Measurement of temperature should be performed using a reliable technique. The most readily available and accurate techniques include a bladder catheter with thermistor tip or an esophageal monitor. Rectal temperature measurements are accurate but not as responsive to changes in core body temperature as the previously noted techniques. Tympanic thermometers are readily available and noninvasive but are of limited use at subnormal body temperatures. Oral and axillary temperature measurements are not reliable in hypothermic patients and should not be used.

Environmental Hypothermia

Environmental hypothermia (also known as accidental hypothermia) occurs if a normal person is exposed to cool temperatures with inadequate clothing or shelter. The incidence of environmental hypothermia in both the United States and Europe is increasing with risk factors including advanced age, mental illness, male sex, and alcohol intoxication.[6,7] Unsurprisingly, hypothermia is highly associated with the winter season.[7] Cooling is accelerated in the presence of windy conditions, and submersion in cold water can result in heat loss of more than 30 times that of the same air temperature.[8] Although exceptional athletes can swim for hours in cold water, an unconditioned person may become unconscious within 30 minutes of immersion in 4°C water. Case reports and small series suggest improved survival of children with cold water immersion undergoing cardiopulmonary resuscitation,[9] with a major issue being anoxic brain injury.[10,11]

The physiology of hypothermia is significantly dependent on the variation from normal body temperature[12] (Table 52-1). Initially there is an intense cutaneous vasoconstriction to reduce heat loss, and the exposed skin can rapidly cool to the ambient temperature. The patient experiences thermogenic shivering, which markedly increases oxygen consumption and depletes glycogen stores.[13] As the temperature drops, metabolism progressively slows and shivering ceases. The patient becomes confused, lethargic, and cold to the touch. Urine production is profuse due to impaired production of antidiuretic hormone (ADH) and increased vascular tone. The patient exhibits bradycardia, electrocardiogram (ECG) changes,[14] hypotension, hypovolemia, and metabolic acidosis with elevated blood lactate. Agitation, irrational behavior, and combativeness are replaced by obtundation and finally coma. When cardiac arrest occurs, death is not immediate but is inevitable without medical intervention.

MANAGEMENT OF ENVIRONMENTAL HYPOTHERMIA

Warming Techniques

There are a variety of techniques available for prevention and treatment of hypothermia. These include both passive and active warming techniques (Table 52-2). Passive techniques, consisting of warmed blankets and environment, are more applicable for prevention of hypothermia and for treatment of patients with cold stress (temperature >35°C). Specifically, ambient operating room temperature has been shown to have no effect on patient core temperature during emergency surgery and may in fact contribute to surgeon distraction.[15,16] Active methods can be defined as either external or internal. One of the most common external methods in use is forced-air rewarming (Bair-Hugger, 3M, St Paul, MN, or similar). Current broadly used internal methods include use of arterial-venous rewarming through catheters placed in femoral artery and vein with the blood passed through a fluid warmer, or continuous venovenous rewarming (using a continuous hemofiltration dialysis unit). A more recently developed option is use of a femoral venous catheter designed for therapeutic hypothermia (Thermogard XP, Zoll Medical, Minneapolis, MN), which circulates warmed or cooled fluid through the catheter. For unstable patients or those who have developed cardiac arrest, extracorporeal membrane oxygenation (ECMO) and cardiopulmonary bypass (CPB) are appropriate options.

For the responsive patient with a core temperature above 35°C, passive rewarming measures and supportive care are adequate. For patients with mild hypothermia (32–35°C), normal mentation, and preserved vital signs, passive or active external warming techniques can be effectively used. Trauma patients with mild hypothermia should be transported to a trauma center if feasible and should receive active warming. Patients with hypothermia should receive warmed parenteral fluids only. In patients with moderate hypothermia, a Foley catheter with an integral temperature probe is optimal to monitor core temperature and measure urine output. Urine output will typically remain brisk during rewarming and is *not* an indicator of adequate intravascular volume. Subclavian or internal jugular catheter placement is avoided because the guide wire can trigger ventricular fibrillation of the cold myocardium. Rewarming can be performed using either active internal or external techniques. Patients with severe hypothermia require endotracheal and nasogastric tubes to protect the airway and prevent aspiration. Irrigation of the chest and abdominal cavities with sterile warmed saline may be an effective warming technique in severe hypothermia. If any perfusing rhythm can be detected, administer pressor agents but avoid chest compressions that may trigger intractable ventricular fibrillation. In patients showing signs of severe hypothermia in the field (eg, unconsciousness, minimal vital signs), consideration should be given for transport to a center with the ability to perform ECMO or CPB, as these are the most effective techniques for both support of the cardiopulmonary system and rewarming, with survival in small series of 50% to 100%.[17,18] Figure 52-1 presents an algorithm of the previously discussed management strategies, adapted from a number of society guidelines.[19-21]

TABLE 52-2: Warming Techniques and Estimated Rates of Rewarming

Warming technique	Rate of temperature increase
Passive	
Blankets, warm room	0–0.5°C/h
Active noninvasive	
Forced air rewarming	1–2.4°C/h
Resistive heating blankets	1–2.5°C/h
Circulating water blanket	1.5–2°C/h
Active invasive	
Cavity lavage	1–4°C/h
Intravascular venous (Thermogard XP Catheter)	3–5°C/h
Cardiopulmonary bypass	2°C/5 min under optimal circumstances

The classic adage for the hypothermic trauma patient is that the patient is not dead until they are warm and dead; however, there are a number of identified markers strongly correlated with death despite aggressive resuscitation. These include elevated serum potassium of more than 12 mEq/L, lethal traumatic injury, core temperature less than 10°C, unwitnessed cardiac arrest, or chest wall too stiff to permit cardiopulmonary resuscitation.[20,21]

There are a number of potential complications associated with rewarming. These include core temperature afterdrop, rewarming-associated hypotension, pulmonary edema, hypoglycemia, electrolyte imbalances, renal failure, disseminated intravascular coagulation (DIC), and rhabdomyolysis.[22] An expected major sequela of rewarming of patients with hypothermic cardiac arrest is potential for anoxic brain injury.[23] A mortality of 0% to 50% is reported.[17,18,22,23]

Patients with hypothermia routinely present with an extremity temperature more than 15°C lower than the core temperature, so that even in a warmed environment, the core temperature can continue to fall, a phenomenon referred to as *afterdrop*.[24] Afterdrop may be clinically relevant in the setting of a patient with borderline severe hypothermia. In this setting, a further drop in cardiac temperature may result in cardiac arrest. An afterdrop of up to 5°C has been reported.[25] For this reason, until rewarming is achieved, patients with moderate or severe hypothermia should not be mobilized to minimize return of cold peripheral blood to the central circulation.

Hypothermia in Trauma

Hypothermia is associated with increased risk of death after serious trauma. A classic study performed by Jurkovich et al[4]

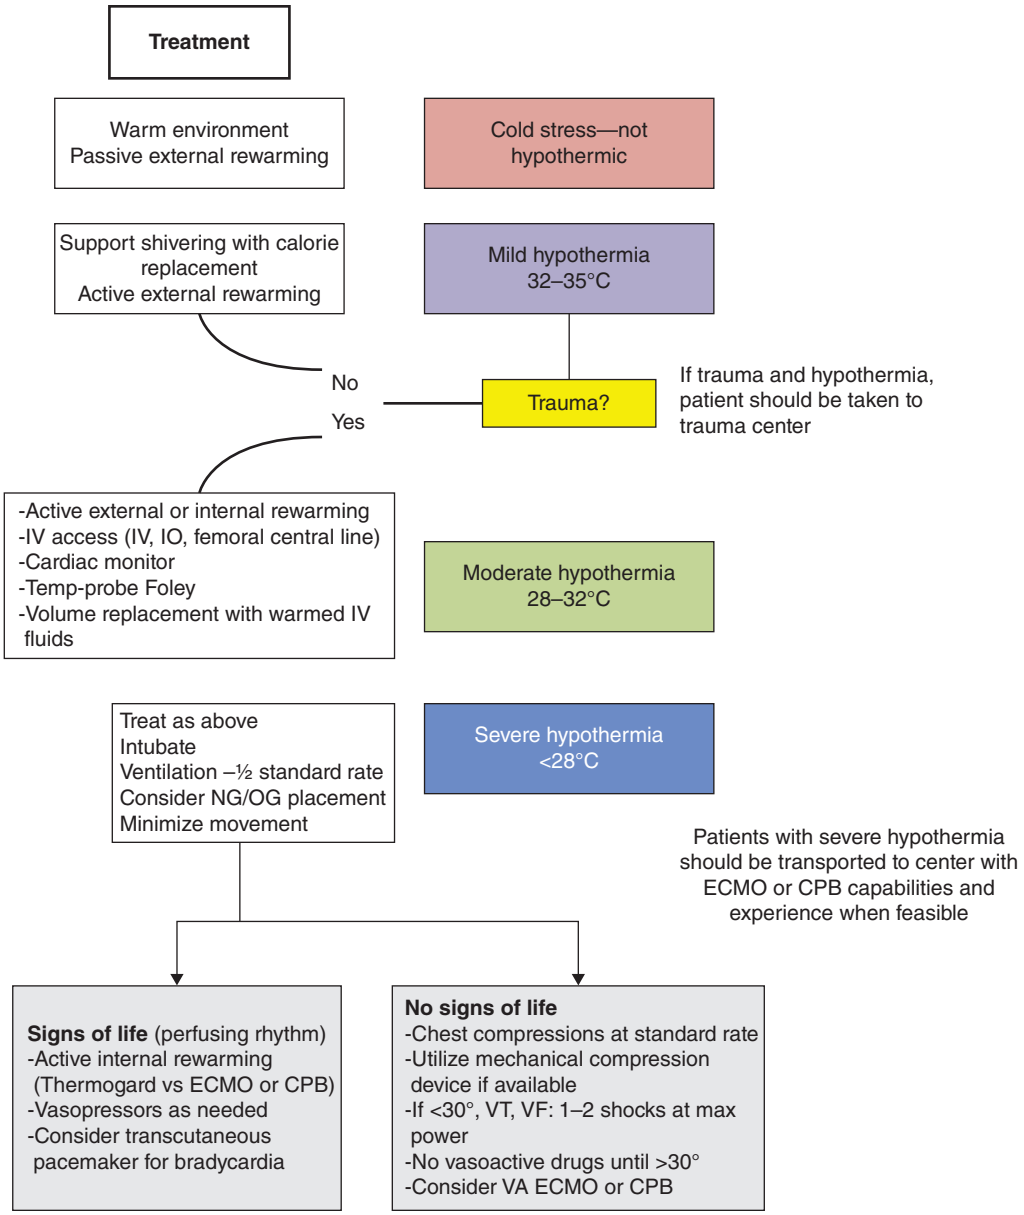

FIGURE 52-1 Algorithm for treatment of environmental hypothermia. CPB, cardiopulmonary bypass; ECMO, extracorporeal membrane oxygenation; IO, intraosseous; IV, intravenous; NG, nasogastric; OG, orogastric; VA, venoarterial; VF, ventricular fibrillation; VT, ventricular tachycardia.

in 1987 reported a 40% mortality in trauma patients with a core temperature less than 34°C, which increased to 100% in patients with a core temperature less than 32°C. Wang et al[26] reported data from analysis of 38,520 patients in the Pennsylvania Trauma Outcome Study, with an odds ratio for death of 3.03 associated with hypothermia. Similarly, postoperative hypothermia after cavitary surgery in severe trauma patients was also associated with increased mortality.[27] In an effort to determine whether or not hypothermia was a risk factor for death or a marker of complications, Shafi et al[28] evaluated nearly 40,000 patients in the National Trauma Data Bank and found that hypothermia was independently associated with increased mortality. In one large multicenter, prospective evaluation, hypothermia in severely injured trauma patients was found to be independently associated with multiple organ failure but not mortality.[29] In a randomized trial of active internal versus external rewarming techniques, Gentilello et al[30] noted improved early survival in patients receiving active internal rewarming; however, this early benefit did not lead to improved survival to discharge.

In contrast to these results in humans, there are a number of animal studies showing benefit to hypothermia in animal models of traumatic injury and shock.[31-33] The discrepancy between animal and human studies is initially puzzling but is

key to understanding the differences between accidental and traumatically induced hypothermia. The primary driver of hypothermia after injury is insufficient intrinsic heat generation due to mitochondrial anoxia during anaerobic metabolism, resulting in a drop of the organisms' core temperature toward that of the ambient environment. This is in distinction to induced hypothermia, which is sparing of adenosine triphosphate (ATP) levels, resulting in protection of the cellular environment during anaerobic conditions. For example, ATP levels are lower and remain depressed longer in hypothermic trauma patients compared to persons with hypothermia following elective surgery[34] or patients with therapeutic hypothermia induced under anesthesia.[35]

In the case of animal models, most involve induction of hypothermia over a short period of time, close to the time of injury/shock, and frequently in the setting of a standardized single-organ model, whereas in the human condition, hypothermia develops over a variable period of time, with the patient in shock, and with varied periods of transport and exposure to environmental cooling prior to arrival for definitive medical care. Until more evidence exists defining appropriate patient populations for therapeutic hypothermia, we recommend aggressively warming multiply injured patients to normothermic levels.

Hypothermia and Coagulation

Coagulation disorders are the most concerning physiologic abnormality in trauma patients, and hypothermia exerts profound effects on the coagulation system. It is difficult to separate the effects of hypothermia alone in the setting of the "bloody vicious cycle" of traumatic coagulopathy; however, the effects of hypothermia on the intrinsic and extrinsic coagulation systems, and their laboratory measures, have been extensively evaluated. Cosgriff et al[36] identified coagulopathy in massively transfused patients and noted in multivariate analysis that hypothermia was a significant risk factor, with an odds ratio of 8.7. These clinical results have been confirmed in a number of animal and human ex vivo studies,[37,38] demonstrating significant impairments of coagulation measurements with plasma or blood in cold conditions that resolve with warming of the plasma. In an in vitro study using viscoelastic testing to evaluate the individual roles of hypothermia, fibrinolysis, hemodilution, and acidosis in trauma-induced coagulopathy, hypothermia in the presence of fibrinolysis was found to have a significant effect on clot formation, clot strength, and lysis time.[38,39] Monitoring of coagulation parameters in the hypothermic patient is a challenge because decreasing temperature has been shown to have a significant inverse effect on prothrombin and activated partial thromboplastin time. This is relevant for clinicians, as coagulation tests are performed after warming of the plasma to 37°C, suggesting that these tests in hypothermic trauma patients are likely to underestimate the degree of coagulopathy. These results were confirmed clinically in a group of 112 seriously injured trauma patients in which core body temperature was correlated with coagulation studies.[40] It was noted that coagulation enzyme activity decreased below a threshold temperature of 34°C.

A host of additional mechanisms related to hypothermia have been implicated, including depressed platelet function, impaired platelet delivery, slowed activation of coagulation enzymes, activation of protein C, and activation of fibrinolysis.[41] Hypothermia plays a significant role in the coagulopathy of trauma and significantly complicates surgical management in these patients. In patients at high risk for coagulopathy, "damage control resuscitation" with component therapy to mimic whole blood should be used along with aggressive measures to rewarm the patient.[42] In patients requiring operative control of their injuries, damage control procedures should be used, with definitive correction delayed until the patient's coagulopathy, acidosis, and hypothermia have been corrected.[43]

THERAPEUTIC HYPOTHERMIA

There is increasing clinical evidence to support the use of therapeutic hypothermia (also known as targeted temperature management) in different clinical conditions. Hypothermia has a variety of physiologic effects that are potentially useful, including reduction in metabolic rate, inhibition of apoptosis, reduction of oxidative stress, inhibition of neuroexcitatory pathways, and decreased inflammation.[44] Since two landmark trials published in 2002 demonstrated a benefit in terms of neurologic outcomes after out-of-hospital cardiac arrest in patients treated with mild hypothermia,[45,46] there has been a growing literature suggesting potential benefit in a variety of other settings[47,48] (Table 52-3).

As a result of the two trials noted earlier, therapeutic hypothermia is included as a part of guidelines in the United States[49] and internationally for treatment of patients suffering out-of-hospital cardiac arrest with an initial cardiac rhythm of ventricular tachycardia or fibrillation. Data on its use in other

TABLE 52-3: Clinical Uses of Therapeutic Hypothermia and Type of Clinical Evidence

Clinical scenario	Efficacy	Evidence
Cardiac arrest	Effective	RCTs; cohort studies
Neonatal hypoxic ischemic encephalopathy	Effective	RCTs
Increased ICP	Effective	RCTs

settings of cardiac arrest (eg, arrest with pulseless electrical activity, asystole, in-hospital arrest[50]) are less compelling, but it is the practice of these authors to consider therapeutic hypothermia in most cases of successful initial resuscitation after cardiac arrest. Cooling can be initiated in this setting with rapid infusion of 1 to 2 L of intravenous cold saline while a decision about whether or not to undergo cardiac catheterization is made and central and arterial lines are placed. Cooling can be sustained with either active external cooling devices (Arctic Sun, Medivance, Louisville, KY, and others) or an intravascular cooling device inserted via the femoral vein (Thermogard XP, Zoll Medical, Minneapolis, MN). Current recommendations include cooling the patient to 32°C to 36°C for 24 hours with an 8-hour rewarming period, followed by another 48 to 72 hours of normothermia. Reaching the targeted temperature within 6 hours of the arrest has been associated with a favorable outcome. A large randomized trial demonstrated equivalent outcomes for targeted temperature of 34°C and 36°C.[51]

Therapeutic hypothermia has also been studied extensively in the setting of traumatic brain injury with elevated intracranial pressures (ICPs). A meta-analysis from 2012 highlights the effectiveness of decreasing ICP in this patient population.[52] In this meta-analysis, which included 18 studies and 1773 patients, there was a decrease in ICP with therapeutic hypothermia in all studies, with an average reported decrease in ICP of approximately 11 mm Hg. Unfortunately, although this intervention results in a significant decrease in ICP, a subsequent randomized multicenter trial failed to show improved outcomes using the Extended Glasgow Outcome Scale in patients treated with hypothermia.[53] A recent systematic review found no difference in mortality or poor outcome in patients with traumatic brain injury treated with hypothermia, echoing the variable outcomes of available literature.[54] In a multicenter randomized controlled trial, Hifumi et al[55] found that fever control with a moderate temperature maintenance at 35.5°C to 37°C, compared with hypothermia therapy, resulted in improved traumatic brain injury–related mortality in patients with Abbreviated Injury Scale 3 and 4 head injury. Although the effect on outcome remains unclear, these results support the importance of fever control and suggest that therapeutic hypothermia should only be considered in patients with refractory intracranial hypertension unresponsive to other therapy.

FROSTBITE

Frostbite occurs when tissues cool to the point of freezing for a sustained period. At about 24°C, ice crystals form in the intracellular or extracellular fluid, depending on the rate of cooling. The incidence of frostbite is increasing with a more mobile society partaking of a growing number of outdoor sports. The hands and feet account for 90% of reported injuries, and this injury occurs most commonly in adults between the ages of 30 and 49 years.[56] Frostbite is classified by grade based on severity at the time of exam[57] (Table 52-4).

TABLE 52-4: Classification of Frostbite Injury

Grade	Symptoms and findings
First degree	Numbness, erythema White or yellow raised plaque without blister
Second degree	Superficial skin vesiculation Clear or milky fluid in blisters Initial lesion on distal phalanx
Third degree	Deeper hemorrhagic blisters Initial lesion on proximal phalanx
Fourth degree	Extends into subcutaneous tissue Initial lesion on carpal/tarsal

Initial hospital management of frostbite should include rapid rewarming of the affected body part, most optimally in a 38°C to 40°C water bath to quickly restore blood flow to tissues as the metabolic rate increases. This is painful and will frequently require parenteral narcotics. Ibuprofen should be administered at a suggested dose of 12 mg/kg/d twice daily to a total daily dose of 2400 mg to provide inhibition of prostaglandins and thromboxanes. Blisters should not be debrided, although some authors suggest aspirating nonhemorrhagic blisters with a fine needle.

In patients with frostbite at risk for tissue loss (grade 3 or 4 injury), thrombolytic therapy and intravenous prostacyclin therapy may be considered. This therapy should be administered in a setting that includes intensive monitoring. A recent report of angiography and thrombolytic therapy included angiography in 69 patients over 14 years.[58] Angiography was performed within 24 hours of rewarming, and catheter-directed lytic therapy was used for intra-arterial thrombi (n = 472 digits). Of 198 digits with restored blood flow, 4 required amputation. In the digits with partial or no improvement, amputation rates were 37% and 69%, respectively. Another trial randomized 47 patients to aspirin plus either buflomedil (a vasoactive agent used to treat claudication), intravenous prostacyclin, or prostacyclin plus systemic lytic therapy (recombinant tissue plasminogen activator [r-tPA]).[59] The risk of amputation was 60% in the buflomedil group, 0% in the prostacyclin group, and 16% in the prostacyclin plus lytic therapy. Either intravenous iloprost or thrombolysis with r-tPA (or both) should be considered for use in patients with severe frostbite and high risk of tissue loss. These interventions should be administered within a 24-hour window of injury if possible and should be administered in a facility with appropriate monitoring.

Surgical debridement and amputation should be delayed until demarcation has occurred unless the patient develops wet gangrene, overwhelming infection, or spreading necrotizing infection. The majority of amputations can be performed 1.5 to 3 months after the initial injury. Long-term sequelae of frostbite include severe arthritis and joint pain secondary to loss of articular cartilage associated with prolonged severe cold sensitivity or even Raynaud phenomenon.

Cold Contact or Flash Freeze Injuries

Exposure to cold or pressurized gases (eg, carbon dioxide, oxygen, nitrogen, or propane) or contact with a cold object can produce an irreversible freeze injury.[60] Plantar injury occurs when walking on ice or snow with unprotected feet. Huge ice crystals form both extracellularly and intracellularly, immediately rupturing the affected cells. The injury may have the appearance of a thermal burn and can affect any body part because escaping gas can pass through layers of clothing. The wounds are treated with topical antimicrobials, and skin grafts are applied if the wounds granulate. Lytic agents have no benefit and are contraindicated in these patients.

Nonfreezing Cold Injuries

Rapid cooling of the exposed skin causes severe pain and pale skin color called frostnip, which has little clinical significance. Immediate rewarming prevents tissue freezing, but the tissue remains sensitive to changes in temperature. Repeated episodes of nearly freezing, especially in wet conditions, cause chilblains (also known as pernio), with intense vasospasm and damage to local nerves. Subsequent cold exposure triggers marked pain with features of Raynaud syndrome, which increases the risk of a secondary freezing injury. Treatment is symptomatic.[61]

SYSTEMIC HYPERTHERMIA

The normal human core body temperature is maintained at approximately 37°C by conduction, convection, evaporation, and radiation. Skin temperature is approximately 35°C, thus facilitating heat dissipation down this temperature gradient. Conduction and convection allow the body to gain or lose heat in response to the respective external climate. Radiation causes heat transfer to or from the body by electromagnetic waves.[62] Evaporation, the body's most effective cooling mechanism, causes a reduction in skin temperature of 0.58 kcal/mL of sweat.[63] Hyperthermia results when the internal core temperature is elevated above normal ranges and the body's compensatory methods are ineffective, impaired, or overwhelmed by intrinsic or extrinsic heat loads.

Primary Hyperthermia

Susceptibility to primary hyperthermia depends on both patient and environmental factors. Exercise increases heat production, which can exceed the cooling capacity of the body. Additionally, climate variability has been shown to impact the incidence of heat-related illness.[64] Increasing humidity decreases the body's most effective defense mechanism of sweating. Hyperthermia is common in military training or combat and strenuous contact or endurance sports. Patients with significant cardiovascular comorbidities, diabetes, dysfunctional compensatory mechanisms, or altered behavior are at higher risk of heat-related illness as well. External heat causing hyperthermia presents on a continuum

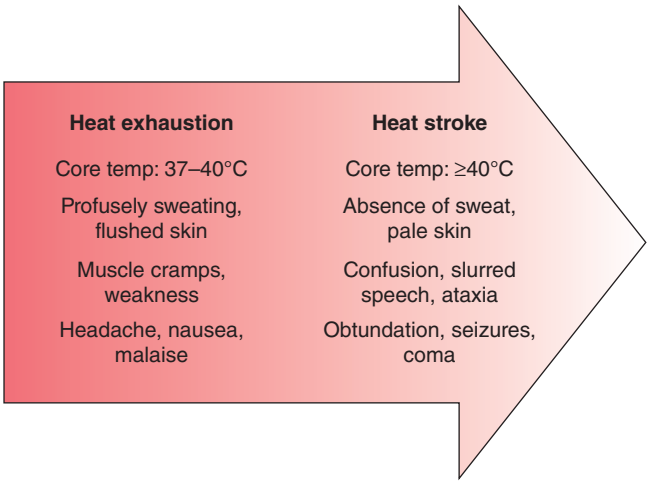

FIGURE 52-2 Continuum of severity of heat-related illness.

of severity (Fig. 52-2). Systemic hyperthermia begins as heat stress and progresses to heat exhaustion as fluid losses mount and core temperature increases. The patient is flushed, sweating profusely, and feels acutely ill. The patient may experience intense thirst, weakness, muscle cramps, nausea, and vomiting. Syncope may occur from functional orthostasis due to hypovolemia from sweating and peripheral shunting of intravascular fluid from vasodilation of skin vessels. Symptoms persist until the core temperature is lowered and fluids and electrolytes are replaced.[65]

As heat exhaustion progresses, the cutaneous blood vessels paradoxically vasoconstrict, and sweating stops in many, but not all, patients.[66] This more severe presentation of heat stroke is less commonly seen, albeit more deadly. An exact definition of heat stroke is difficult to pinpoint due to the range of severity and symptoms that may present; however, a generally accepted definition is a core temperature of at least 40°C and presence of central nervous system symptoms.[62,67] It is traditionally conceptualized as two distinct types. Exertional heat stroke is associated with generally healthy patients undergoing strenuous exercise. Classic heat stroke is typically a more passive process occurring in patients at extremes of age or in individuals with impaired mechanisms to escape or compensate to exposure to excess heat. The clinical picture can be mistaken for a cerebrovascular accident because the patient can be pale, cool to the touch, disoriented, paretic, or comatose. Prolonged, extreme elevation of core temperature may produce irreversible central nervous system injury.

Heat stroke accounts for 2% of sudden deaths among competitive athletes[68] and occurs in epidemic form during heat waves.[60] Two primary goals of treatment are cooling and cardiovascular support. Studies have shown that rapid cooling improves morbidity and mortality of patients.[70,71] Immersion in an ice bath is optimal, however, this may not be available or not be possible for patients with significant comorbidities requiring invasive monitoring. Additionally, patients may demonstrate variable levels of consciousness and combativeness and are prone to vomiting and diarrhea from

splanchnic hypoperfusion; therefore, immersion in water may prove difficult or dangerous to patient and staff in some cases. Removal of clothing (to facilitate sweat evaporation) and exposure to any cold object are essential, particularly near large vessels such as in the neck, groin, and axilla. Nearly all patients are hypovolemic from fluids lost through sweating; thus, this should be followed by fluid and electrolyte replacement. Resuscitation with normal saline is generally indicated due to hyponatremia from excessive sweating, which is often compounded by the patient's intake of large volumes of hypotonic solutions during early rehydration efforts. Laboratory workup may include assessment of electrolytes, liver and renal function, creatinine kinase, and/or coagulation factors. Further biochemical analysis or radiographic workup may be prudent in patients with significant comorbidities or suspicion for other concomitant causes of hyperthermia.

The downstream pathologic changes resulting from excess heat can have multiorgan system effects. Cellular changes, including protein denaturation, begin to take place at approximately 41.6°C to 42°C.[72] The brain and liver are thought to be the most vulnerable to hyperthermia; however, multisystem organ effects are seen due to hypoperfusion from centrally mediated shunting of blood to the skin for heat exchange, as well as the cellular effects of the excess heat.[62] Direct endothelial damage, cytokine release, and cell death contribute to the cytotoxicity and systemic inflammatory response that may be seen depending on the level of severity. At advanced stages of hyperthermia, activation of the coagulation cascade with progression to DIC has been seen. The mechanism is thought to be multifactorial, including direct heat damage to the endothelium, heat-mediated platelet aggregation, and fibrin deposition in arterioles.[72-74] Extremely high core temperature may additionally cause rhabdomyolysis and myoglobinuria, associated with compartment syndrome in affected muscles. Survival in such cases is rare.

Additionally, drugs such as cocaine, amphetamines, and 3,4-methylenedioxy-methamphetamine (MDMA or ecstasy) may cause or exacerbate hyperthermia. This is important in trauma treatment because hyperthermia has been shown to increase the risk of death after cocaine administration. The mechanism behind cocaine-induced hyperthermia is incompletely understood. This multifactorial process is likely a combination of a hypermetabolic state resulting in elevated heat production, disordered behavioral adjustment due to altered heat perception, and impaired mechanisms of heat dissipation through diminished sweating and cutaneous vasodilation.[75]

Iatrogenic Hyperthermia

Malignant hyperthermia (MH) is caused by exposure of susceptible individuals with a unique genetic composition to halogenated anesthetic agents. The unfettered release of calcium from the sarcoplasmic reticulum results in abnormal activation of skeletal muscle and increased metabolic rate. There is substantial variation in the reported prevalence of MH susceptibility. It has been estimated to be as high as 1 in 3000, although a recent epidemiologic study in New York state from 2001 to 2005 estimated a prevalence of 1:100,00[76] and even lower in subsequent years.[77] The heat released causes a precipitous spike in the core temperature that can be rapidly lethal. Patients present with increase in end-tidal carbon dioxide, increased oxygen consumption, tachycardia, muscle rigidity, and respiratory and metabolic acidosis.

The treatment follows several steps. The anesthetic agent must first be stopped, followed by ventilation with pure oxygen to drive off the anesthetic, treat acidosis, and reverse anaerobic metabolism. Occlusive drapes should be removed and active cooling initiated. Infusion of dantrolene, a hydantoid derivative muscle relaxant, is recommended to suppress the abnormal sarcoplasmic reticulum calcium release of MH, although the exact binding site of action is incompletely understood.[78] It may also be necessary to administer glucose to replace the depleted glycogen reserves. Patients with the genetic abnormality can safely receive general anesthesia with alternative anesthetic agents, nitrous oxide, and nondepolarizing muscle relaxants.[79]

Malignant neuroleptic syndrome (MNS) is a rare event in patients receiving antidepressant medications that block dopamine. It has been reported in trauma patients treated with haloperidol for agitation.[80] It is also caused by atypical antipsychotic agents or sudden withdrawal of dopamine agonists such as levodopa. The risk is increased with lithium administration, dehydration, or low serum iron levels. The patient presents with high fever and intense muscle rigidity; lesser features include depressed mentation or coma, tremors, autonomic dysfunction, or dysphagia. The illness is easily mistaken for meningitis, MH, or drug-induced delirium. Laboratory tests are not diagnostic, although creatinine kinase levels are elevated. The treatment is rapid cooling and rehydration, discontinuation of dopamine-blocking agents or restoring dopamine agonists, and supportive measures in the intensive care unit. The reported mortality is 10%.[81]

Serotonin syndrome is caused by an excess of intrasynaptic serotonin in different areas of the brain and can be caused by several mechanisms. Three features predominate in this condition, including altered mental status, hyperactivity of the autonomic nervous system, and abnormal neuromuscular excitation. Patients present with rapid onset of delirium, agitation, hyperthermia, diffuse sweating, flushing, tachycardia, hyperreflexia, tremor, shivering, and muscle rigidity.[82] Medications that may precipitate serotonin syndrome include serotonin reuptake inhibitors, tricyclic and atypical antidepressants, and monoamine oxidase (MAO) inhibitors.[83] The trauma surgeon encounters the syndrome in association with the use of cocaine, ecstasy, amphetamines, tramadol, or linezolid. Fentanyl has also been implicated in two case reports of serotonin toxicity, although controversy remains as to the risk associated with this drug interaction.[82] Nausea and diarrhea indicate a mild illness, but delirium, hyperthermia, and autonomic instability can be life threatening. These patients exhibit agitation rather than the stupor of MNS and require benzodiazepines for sedation, combined with cessation of the causative agent and supportive measures.

Modern Combat Casualty Care

Philbert Y. Van • Jennifer M. Gurney • Martin A. Schreiber

KEY POINTS

- The Joint Trauma System (JTS) has been identified by Congress in the National Defense Authorization Act for Fiscal Year 2017 as the reference body for trauma care in the Department of Defense.
- *Died of wounds* is the term used for mortality of casualties who arrive at a medical treatment facility alive and succumb to their injuries.
- The case fatality rate historically has trended with percent killed in action.
- The transition from gunshot wounds to blast injuries such as from the improvised explosive devices used in Iraq and Afghanistan has been in evolution since the US Civil War.
- Almost 90% of combat casualties who succumb to their wounds do so before they arrive at a medical treatment facility.
- Combat units that have trained all of their unit members, not just medics, in tactical combat casualty care have achieved the lowest incidence of preventable death on the battlefield in the history of modern warfare.
- In military roles of care, role 2 is the first level of care that has surgical capability, such as the forward surgical teams used by the US Army in the recent conflicts.
- A Critical Care Air Transport Team refers to the augmented aeromedical evacuation-type platform with specific capabilities for intensive care unit care.
- For transfusion of whole blood to military casualties, only group O whole blood donors with low titers of anti-A and anti-B antibodies are used.
- Kaolin-based dressings like Combat Gauze work by accelerating clotting pathways.

INTRODUCTION

He who wishes to be a surgeon must first go to war.
Hippocrates (460–377 BC)

How varied was our experience of the battlefield and how fertile the blood of warriors in rearing good surgeons.
Thomas Clifford Allbutt (1836–1925)

The military surgeon is faced with the challenge of preservation of life in an environment of destruction where loss of life is far too commonplace. Historically war comes at the cost of human life; battlefield medics deploy to this environment to alleviate pain and suffering, care for the wounded, preserve the fighting strength, and save lives. Medicine and surgery have seen great advances during times of large casualty volumes; the Mayo brothers are credited with the quote: "The only victor in war is medicine." The current conflicts in the Middle East have spanned over two decades and represent the longest conflicts in US history. During this period, there have been significant advances in prehospital care, hemostasis, resuscitation, evacuation, damage control surgery, and transfusion strategies. Vice Admiral Alasdair Walker, Surgeon General of the British Armed Forces, described a concept now referred to as the "Walker Dip" during the 2013 Military Health System Research Symposium. The Walker Dip describes the recurrent historical cycle where medical care improves during conflicts, the lessons are forgotten after, and then are relearned again during the next war. Unfortunately, the Walker Dip did not spare the current generation, and lessons from previous conflicts were relearned, such as the use of whole blood and providing blood far forward. It is the duty of our generation to learn from past experiences and build on the current knowledge so that the lessons learned (and relearned) are not forgotten but rather codified into future education and training in order to decrease preventable death from trauma.

Regardless of the nation, era, or location, combat casualty care has unique attributes that distinguish it from civilian trauma care. It tends to occur in austere, resource-limited

environments under hostile conditions. The structures, equipment, supplies, and personnel are often required to be both mobile and few. Patients frequently are moved by helicopter or plane to receive definitive care. Care on the battlefield may require tactical decisions to take precedence over clinical care depending on the nature of the hostilities. By nature, ongoing hostile gunfire may threaten treatment activities for patient and provider alike. In addition, the mechanisms of injury in combat trauma are mostly penetrating and blast associated.

Proximity to surgical care drives much of modern battlespace planning. Warfighters are often in remote locations in today's unconventional dispersed battlefield based on counterinsurgency operations. The Golden Hour mandate started in 2009 demonstrated that there was a decrease in mortality with decreased time to capability (hemorrhage control, transfusions, surgical intervention).[1] With the purpose of decreasing evacuation times and bringing capabilities closer to casualties, surgical care has been pushed further forward with a smaller footprint (facilities and personnel) to support remote tactical operations. Figure 53-1 is typical of this type of unit, in this case a forward surgical team (FST). In recent years, the FST is often divided into two teams in order to provide split operations at two different locations. The three service branches have also developed smaller and more mobile surgical teams for performing resuscitation and damage control surgery in even more remote and austere conditions. Damage control resuscitation and surgery is implemented with the goal of stabilization and transport to the next higher levels of care. A chain of medical treatment is established from the point of injury to the final medical treatment facility (MTF) in the United States. Currently this chain of treatment and transport evacuation is typically completed within 72 hours.

Over the course of this chapter, the current status of combat casualty care will be discussed. The battlefield is a dynamic environment, and clinical care evolves rapidly based on continuous performance improvement implemented by the Department of Defense (DoD) Joint Trauma System (JTS). The JTS has been identified by Congress in the National Defense Authorization Act (NDAA) for fiscal year 2017 section 707 as the reference body for trauma care in the DoD; the most updated battlefield clinical practice guidelines can be found on the JTS website (https://jts.amedd.army.mil). Unique aspects of military care will be emphasized as well as their translation to civilian trauma care. Special attention is devoted to recent discoveries and newly implemented practices. There continues to be a close bidirectional relationship between military and civilian care for the injured patient, each constantly informing the other with expertise and innovation.

Benchmarking and Progress

The ability to assess combat casualty care outcomes over time is necessary for continuous performance improvement and, when trended over time, provides a perspective and method

FIGURE 53-1 Medical evacuation (MEDEVAC) helicopter loading (top left), air drop of supplies (top right), the operating room tent (bottom left), and medical personnel of the 67th Forward Surgical Team (Airborne) (bottom right); FOB Todd/Bala Murghab, Afghanistan.

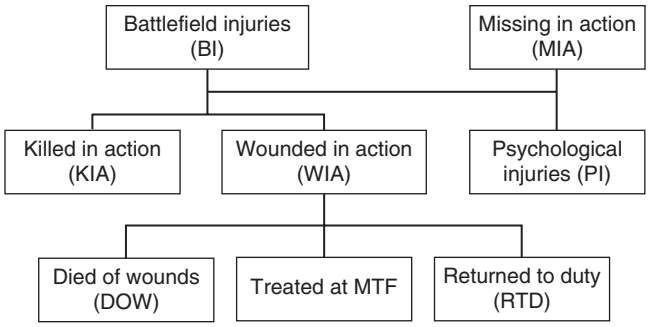

FIGURE 53-2 Classification of battlefield injuries. MTF, military treatment facility.

for comparison. Objective outcome assessment is foundational for evidenced-based care and requires standardization. The principal combat casualty care statistics that summarize the dynamic interplay between battlefield lethality and trauma care delivery are the case fatality rate (CFR), the percent died of wounds (DOW), and the percent killed in action (KIA) (Fig. 53-2).[2] Each summary statistic pivots on multiple dynamic factors such as prehospital care, transfusion capability, transport timing, protective gear and vehicles, surgical teams, and enemy tactics.

Killed in Action

Those with battlefield injuries who do not survive arrival to a military MTF are classified as KIA. Factors that directly influence the KIA rate are weapon lethality, prehospital care, and transport time to surgical capability. Devastating and sophisticated weaponry increases the KIA rate, while better prehospital care and shorter transport times decrease it. Efforts to decrease the KIA rate include body and vehicle armor, field care advances, and decreased evacuation times.

Died of Wounds

The DOW rate is a measure of mortality for casualties that arrive to the MTF alive and succumb to their injuries. It considers those wounded who die after reaching an MTF and has the potential to broadly, without unit or facility granularity, assess MTF effectiveness. Since the percent DOW (%DOW) formula relates those who succumb to their wounds to all the wounded, a surfeit of minimally injured patients decreases the %DOW. Key to its use as a comparative measure is the inclusion or exclusion of patients who are minimally wounded and return to duty. There is a reciprocity between the KIA rate and %DOW in regard to the quality and rapidity of prehospital care resulting in more patients with fatal injuries surviving to arrive at the MTF. Recent analysis of the %DOW demonstrates that it has not decreased since the Vietnam conflict, and unlike the other combat casualty care statistics, %DOW did not have a downward trend over the last decade in Iraq.

% Killed in Action (KIA)

$$\%\ \text{KIA} = \frac{\text{KIA} + \text{DOW}}{\text{KIA} + (\text{WIA} - \text{RTD})} \times 100$$

Died of Wounds (DOW)

$$\%\ \text{DOW} = \frac{\text{Died of wounds after reaching MTF}}{(\text{WIA} - \text{RTD})} \times 100$$

Case Fatality Rate (CFR)

$$\text{CFR} = \frac{\text{KIA} + \text{DOW}}{\text{KIA} + \text{WIA}} \times 100$$

FIGURE 53-3 Calculations for some of the common measures of combat casualty. MTF, military treatment facility; RTD, returned to duty; WIA, wounded in action.

Case Fatality Rate

The CFR is an overall summary statistic. The CFR provides a proportional measure of battlefield lethality and is the most comprehensive of the combat casualty statistics because it provides a summary measure of overall battlefield lethality as well as trauma care capability and delivery. Deaths from both KIA and DOW are included. The denominator includes all those injured on the battlefield—KIAs and wounded in action. It is expressed alongside the other equations in Fig. 53-3. When used to compare scenarios with similar battlefield characteristics, it can provide additional insights into the aggregate effectiveness of pre-MTF and post-MTF arrival casualty care.

The CFR historically has trended with the percent KIA (%KIA). CFR and %KIA, although valuable measures, are inherently limited in their capacity to provide accurate and granular assessment of MTF-level trauma care delivery. During the recent conflicts in the Middle East, the significant decrease in the CFR and %KIA likely reflect both clinical (point of injury care, en route care capabilities, and transport times) and tactical (improvised explosive device [IED] detection and defeat technology, body armor, safer vehicles such as mine-resistant ambush-protected [MRAPs] vehicles) improvements. Although the decreases in the CFR and %KIA have been attributed to improvements in battlefield medical care, this is certainly true for prehospital hemorrhage control but does endorse improved MTF or surgical battlefield care. Finally, although all statistic measures pivot based on the complex and multifactorial nature of the combat environment, the CFR is a composite statistic and can change significantly based on medical and many nonmedical factors.

Research comparing the current operations with prior conflicts has been limited due to variation in amount of data, how those data are recorded, and inconsistency of terminology. Recent comparisons of DOW rate to the DOW rate in Vietnam demonstrate that it has likely increased, especially when patients with minor injuries who return to duty are excluded from the calculations; additionally, the %DOW increased from 2003 to 2014.[3] It is not known exactly what this analysis means (shorter transport times bring sicker

patients to the MTFs vs changes in surgical care capability); further investigation and ultimately real-time unit performance improvement will help discern the discrepancies in the DOW rate. The civilian methods for benchmarking performance improvement and capturing data for analysis on a large scale are usually registry based and performed at local and regional levels (eg, the National Trauma Data Bank [NTDB] and the Trauma Quality Improvement Program). The DoD Trauma Registry (DoDTR) was created with these civilian models in mind. Since 2004, all comprehensive, standardized data are collected from the point of injury onward and maintained by the JTS.

PREVENTION AND PREPARATION

Injury Patterns and Injury Epidemiology

The IED has become the characteristic weapon of the recent conflicts in Iraq and Afghanistan. The IED and the countermeasures to mitigate its effects have shaped the distribution of injuries sustained. This transition from gunshot wounds to blast injuries has been in evolution since the US Civil War.[4] Other explosive devices, beside IEDs and gunshot wounds, still remain a significant source of morbidity and mortality.

IEDs are common in the recent and ongoing conflicts in the Middle East as well as in terrorist events in the United States and abroad. Increased adoption of their use has been driven by a combination of available materials, resources, and an understanding of how to maximize their destructive power. While their forms vary widely, they all share four essential components denoted by the acronym PIES: **p**ower source, **i**nitiator, **e**xplosive, and **s**witch (Table 53-1).[5] Adjuncts, such as formed charges or fragments, are often added. All items required for construction are readily available, making their creation easy and prevention problematic.

TABLE 53-1: Components of a Standard Improvised Explosive Device

Component	Examples
Power source	Battery, match
Initiator	Blasting cap, fuse
Explosive	Conventional artillery, "homemade" explosives, chemical
Switch	Cell phone, alarm clock, timers, circuits

A common utilization of IEDs has been in the form of roadside bombs. As the recent conflicts progressed, efforts were made to decrease the high number of injuries sustained in high-mobility multipurpose wheeled vehicles. This spurred the development of the MRAP vehicle with characteristic armor and a V-shaped hull to deflect blast energy (Fig. 53-4). Additionally, this protective vehicle has resulted in an epidemiologic shift of injury patterns, in that more closed fractures of the extremities and spine are seen in patients exposed to blasts who are in MRAP vehicles.

As coalition troops became less susceptible to roadside bombs with the advent of improved vehicle armor, the use of IEDs shifted. "Dismounted" IEDs became more common, targeting soldiers on foot patrols. IEDs have also been used via a variety of delivery devices, including vehicle-borne IEDs and suicide bombers. This interplay between development of weapons and the evolution of defensive mechanisms is observed in conflicts throughout history.

The torso is particularly vulnerable to penetrating projectiles such as IED-created fragments or firearm rounds. In response, modern body armor provides protection to this area (Fig. 53-5). The effectiveness of body armor used by the

FIGURE 53-4 Mine-resistant ambush-protected (MRAP) vehicles.

FIGURE 53-5 Example of improved outer tactical vest (IOTV) body armor.

US military has changed the distribution of combat injuries. Areas without protection, such as the extremities, are the more common sites of injury. The increased use of explosive devices by insurgent forces described earlier has also evolved in response to weaknesses in armor coverage. A recent review of 5 years of injuries in Iraq and Afghanistan revealed the presence of extremity injuries in 51.9% of combat casualties, and the vast majority of wounds (74.4%) were due to explosive devices.[6]

Education and Resources

CLINICAL PRACTICE GUIDELINES

As initial surgical interventions for combat casualties occur over a wide variety of dispersed locations, the challenge of standardization and education increases. As a response, JTS has created a series of clinical practice guidelines (CPGs). These guidelines are modeled after civilian guidelines published by several of the national trauma associations. As of this writing, there are over 40 evidence-based CPGs created by subject matter experts on a wide variety subjects (Table 53-2). The CPGs are updated routinely based on the available literature. The complete list can be easily found on the JTS website and is available as a portable device application.[7]

TABLE 53-2: List of Joint Trauma System Clinical Practice Guidelines Available in Multiple Formats from the US Army Institute of Surgical Research[7]

Acoustic trauma and hearing loss
Acute respiratory failure
Amputation
Battle/nonbattle injury documentation resuscitation record
Blunt abdominal trauma
Burn care
Catastrophic care
Cervical spine evaluation
Cervical and thoracolumbar spine injury
Clinical management of military working dogs
Compartment syndrome and fasciotomy
Damage control resuscitation
Concussion management algorithm cards
Department of Defense policy guidance for management of mild traumatic brain injury/concussion in the deployed setting
Emergent resuscitative thoracotomy
Fresh whole blood transfusion
Frozen blood
High bilateral amputations
Hypothermia prevention
Infection control
Inhalation injury and toxic industrial chemicals
Initial care of ocular and adnexal injuries
Intratheater transfer and transport
Invasive fungal infection in war wounds
Management of pain anxiety and delirium
Management of patients with severe head injury
Management of war wounds
Neurosurgical management
Nutrition
Pelvic fracture care
Postsplenectomy vaccination
Prehospital care
Prevention of deep venous thrombosis
Radiology
Resuscitative endovascular balloon occlusion of the aorta for hemorrhagic shock
Trauma airway management
Trauma anesthesia
Unexploded ordnance management
Urologic trauma management
Use of electronic documentation
Use of magnetic resonance imaging in management of mild traumatic brain injury in the deployed setting
Ventilator-associated pneumonia
Wartime vascular injury

INITIAL TREATMENT

Tactical Combat Casualty Care

When US military personnel are wounded on the battlefield, the prehospital phase of care is critical, in that almost 90% of combat casualties who succumb to their wounds do so before they arrive at an MTF with a surgical capability. This highlights the importance of the battlefield trauma care provided by combat medics, corpsmen, and pararescuemen (PJs). In addition, the care provided by other nonmedical unit members or the casualties themselves may be essential to survival.

FIGURE 53-6 Tactical combat casualty care logo. (Reproduced with permission of the Committee on Tactical Combat Casualty Care [CoTCCC]. Copyright © CoTCCC. All rights reserved.)

If the prehospital care provided to the casualty enables him or her to survive long enough to reach the care of a surgeon, the likelihood is very high that he or she will survive. Combat units that have trained all of their unit members, not just medics, in tactical combat casualty care (TCCC) have achieved the lowest incidence of preventable death on the battlefield in the history of modern warfare.[8]

TCCC was developed initially by a research project begun by the Naval Special Warfare Command in 1992 and continued by the US Special Operations Command. During this period, battlefield trauma care was comprehensively reviewed, and updated recommendations for care were subsequently published in *Military Medicine* in 1996.[9] The TCCC guidelines are continually reviewed and updated as needed by the Committee on TCCC (CoTCCC; Fig. 53-6). Trauma surgeons, emergency medicine physicians, combat medics, PJs, and corpsmen with combat deployment experience from all branches of the US military participate in the CoTCCC. The TCCC for Medical Personnel course is the only battlefield trauma care training course to have been endorsed by the US military, the American College of Surgeons Committee on Trauma, and the National Association of Emergency Medical Technicians. The CoTCCC is now one of the three trauma care committees in the JTS. The wide adoption of TCCC (including many international countries) has contributed to a remarkable decrease in prehospital mortality in recent combat operations.[8,10-12] TCCC makes battlefield trauma care recommendations in a tactical context, with basic management plans outlined for Care Under Fire, Tactical Field Care, and Tactical Evacuation Care, but caveated by noting that combat medical personnel may have to modify these recommendations as dictated by the tactical considerations of the specific casualty scenario.[9,13]

STAGES OF TACTICAL COMBAT CASUALTY CARE: CARE UNDER FIRE

In the Care Under Fire phase of care, TCCC recommends that the following actions be taken: (1) Return fire and take cover. (2) Direct or expect the casualty to remain engaged as a combatant if able. (3) Direct casualty to move to cover and apply self-aid if able. (4) Try to keep the casualty from sustaining additional wounds. (5) Casualties should be extricated from burning vehicles or buildings and moved to places of relative safety; do what is necessary to stop the burning process. (6) Stop life-threatening external hemorrhage if tactically feasible. Direct casualty to control hemorrhage by self-aid if able. Use a CoTCCC-recommended limb tourniquet for hemorrhage that is anatomically amenable. Apply the limb tourniquet over the uniform clearly proximal to the bleeding site(s). If the site of the life-threatening bleeding is not readily apparent, place the tourniquet "high and tight" (as proximal as possible) on the injured limb and move the casualty to cover. (7) Airway management is generally best deferred until the Tactical Field Care phase.

Stages of Tactical Combat Casualty Care: Tactical Field Care[8-12,14,15]

When the injured warfighter is no longer under effective hostile fire or has been moved to a location that provides cover, combat medical personnel can provide the additional interventions recommended for Tactical Field Care after a security perimeter has been established by the unit. These interventions include, in part:

- Disarming casualties with an altered state of consciousness
- Immediate control of massive external hemorrhage using limb tourniquets (Fig. 53-7), hemostatic dressings, junctional tourniquets, and/or XStat as required
- Allowing casualties who have direct maxillofacial trauma, but who are conscious and able to protect their airway by sitting up, leaning forward, and self-clearing the airway to do so

FIGURE 53-7 Combat application tourniquet.

- Protecting the airway in casualties who are unconscious but who have no direct airway trauma, through use of a nasopharyngeal or extraglottic airway
- Performing a surgical airway and inserting a CricKey in casualties when less invasive airway interventions are not sufficient to protect the airway
- The aggressive use of needle thoracostomy with a 10- or 14-gauge, 3.25-inch needle to treat suspected tension pneumothorax
- Applying vented chest seals for casualties with open pneumothoraces
- Reevaluation of external bleeding sites and the use of additional measures to control continued bleeding as needed
- Applying pelvic binders for casualties suspected of having sustained pelvic fractures
- Attempted conversion of limb tourniquets to other methods of hemorrhage control if the tourniquet has been in place for 2 hours
- Obtaining intravenous (IV) access only when that is required for medications or fluid resuscitation
- The use of intraosseous access when vascular access is needed but peripheral venous access is difficult to obtain
- Early administration of tranexamic acid (before fluid resuscitation) for casualties who are in, or judged to be at significant risk of, hemorrhagic shock
- Performing fluid resuscitation with whole blood or with red blood cells (RBCs) and plasma in a 1:1 ratio
- Faster, safer, and more effective relief of the pain of combat wounds through the use of the TCCC "Triple Option" analgesia plan than was achieved using the previous battlefield standard of intramuscular (IM) morphine; the Triple Option analgesia approach includes the use of ketamine for casualties in severe pain but with hemodynamic or pulmonary compromise and/or oral transmucosal fentanyl citrate lozenges for casualties who are in severe pain but who are otherwise stable
- IV or IM ondansetron in casualties with nausea and vomiting as a result of opioid use or the trauma itself
- Prevention of hypothermia with its attendant coagulopathy through use of the Hypothermia Prevention and Management Kit or other measures
- Administration of moxifloxacin or ertapenem to reduce morbidity from wound infections
- Bilateral needle decompression of both sides of the chest should the casualty suffer a traumatic cardiac arrest
- Documentation of care using the DoD Form 1380 (TCCC Casualty Card) and the electronic TCCC Medical After-Action Report[8]

Stages of Tactical Combat Casualty Care: Tactical Evacuation Care

Eventually, the casualty will be transported from the point of injury to a higher level of care using aeromedical, ground, or maritime mobility platforms. Evacuation should provide the opportunity to have additional and possibly more highly trained medical personnel as well as medical equipment such as electronic monitoring of vital signs, supplemental oxygen, and whole blood or 1:1 RBCs and plasma if these fluids were not available during Tactical Field Care.

ROLES OF CARE

Role 1

Initial care in the role 1 (prehospital) phase is TCCC provided by either the casualty him- or herself, nonmedical unit members, unit members with additional medical training (combat lifesavers), or combat medical personnel (medics, corpsmen, or PJs). The injured warfighter is then taken to a casualty collection point, battalion aid station (BAS), or shock trauma platoon for additional care prior to tactical evacuation.

The BAS is similar for the US Army and US Marine Corps. At the BAS, a physician, physician assistant, or medic/corpsman makes triage, treatment, and evacuation decisions. The goal of treatment is to return to duty or to stabilize and allow for the evacuation to the next role of care. There is no surgical or patient holding capacity at role 1.

The Shock Trauma Platoon is a small emergency medical unit that supports the Marine Expeditionary Force. Like the BAS, it has no surgical capacity; however, the Shock Trauma Platoon is staffed by two emergency medicine physicians and can hold patients for up to 48 hours, depending on the severity of their wounds.

Role 2

Role 2 care is the first level of care that has surgical capability. In the concept design for the battlefield, role 2 care was introduced in the 1990s when it was recognized that bridging the time and space gap from point of injury to definitive care would decrease death from hemorrhage on the battlefield. During recent conflicts, role 2 care has been heavily used and has the primary mission of damage control surgery and damage control resuscitation. Additionally, there is an introduction of basic primary care in some of the role 2 configurations in the Army and Air Force, which can include optometry, dental care, combat and operational stress control, behavioral health, laboratory services, and radiology services. This occurs when the role 2 is part of an area support medical company. Each branch of the Armed Forces has slightly different organization and capabilities.

For the US Army, the role 2 MTF is operated by the medical treatment platoon of medical companies. The medical company is assigned to support a brigade or division. Here, the warfighter is examined and evaluated. Those who can be treated and return to duty within 72 hours or who require immediate damage control surgery to preserve life, limb, or eyesight are held for treatment. The warfighter can receive blood transfusions, dental care, limited radiographic studies, clinical laboratory services, combat and operational stress control, and preventive medicine. The FST is a 20-person team with three general surgeons, one orthopedic surgeon,

two nurse anesthetists, critical care nurses, surgical scrub technicians, and combat medics. It is designed to provide life-saving resuscitative general and orthopedic surgery. An FST is deployed by ground, fixed or rotor wing aircraft, or airborne operations. A fully supplied FST can operate continuously for 72 hours on two operating tables for a maximum of 30 cases. However, an FST is not designed or equipped for stand-alone operation and thus must rely on the medical company for logistical support (electricity, water, and fuel) and security. In the last few years of Operation Iraqi Freedom and Operation Enduring Freedom, FSTs have been split to create two teams. The US Army is transitioning from the FST to a Forward Resuscitative Surgical Team. In this model, the 20-person team consists of two general surgeons, two orthopedic surgeons, two emergency medicine physicians, two nurse anesthetists, and additional nurses, medics, and operating room technicians. This staffing model provides for a symmetrical split of the team when necessary. For a smaller footprint team in support of Special Operations Command missions, the Golden Hour Offset Surgical Treatment Team (GHOST-T) was developed and implemented. The GHOST-T is tasked to support a Special Forces Group (Airborne) Operational Detachment Alpha Team and provide resuscitation and damage control surgery in a far-forward setting outside of the 60-minute medical evacuation (MEDEVAC) ring. Personnel in the GHOST-T include a surgeon, nurse anesthetist, operation room technician, medic, and nurse. The total number of team members on the GHOST-T can range from 5 to 10, depending on the length of mission and number of warfighters being supported.

In the US Air Force (USAF), the Mobile Field Surgical Team (MFST) is composed of five team members: a general surgeon, orthopedic surgeon, anesthetist, emergency medicine physician, and an operating room nurse or technician. Much like an FST, the MFST cannot participate in stand-alone operations and supports an aid station or flight line clinic. In order to accommodate the need for austere surgical support in ground combat operations, the Ground Surgical Team (GST) was established. The GST has six team members consisting of a general surgeon, anesthesiologist, emergency medicine physician, critical care nurse, operating room technician, and medic. Compared to the MFST, the GST sacrifices some surgical capability in exchange for patient holding capacity. To support special operations requirements, the Special Operations Surgical Team (SOST) was developed. This six-person team is composed of a general surgeon, emergency medicine physician, anesthesiologist, critical care nurse, cardiopulmonary technician, and operating room technician. The SOST is coupled with Special Operations Critical Care Evacuation Team (SOCCET) to provide resuscitation, damage control surgery, and critical care while aboard evacuation platforms. The 10-person Small Portable Expeditionary Aeromedical Rapid Response (SPEARR) team is an MFST with an additional three-person Critical Care Air Transportation Team (CCATT) and two-person preventive medicine team. A SPEARR team is stand-alone capable for 7 days and can perform up to 10 surgeries in 48 hours. The SPEARR team is designed to provide care during the early phase of deployment and is highly mobile. The Expeditionary Medical Support (EMEDS) Basic team builds on the SPEARR team, with an additional 15 personnel. In addition to resuscitative surgery, EMEDS Basic can provide 24-hour sick call, dental care, and limited radiology and clinical laboratory services. There are four holding beds, two operating room tables, and three climate-controlled tents. An EMEDS+10 facility has six additional holding beds for a total of 10 beds and 56 personnel but retains the same surgical capability as an EMEDS Basic.

For the US Navy (USN), role 2 care consists of a Casualty Receiving and Treatment Ship (CRTS) or aircraft carrier battle group. The CRTS is part of a three-ship Amphibious Ready Group (ARG). With 45 ward beds, 4 operating rooms, and 17 intensive care unit (ICU) beds, the CRTS has a 176-person Fleet Surgical Team with 1 surgeon, 1 nurse anesthetist, 1 ICU nurse, 1 operating room nurse, 1 general medical officer, and 12 support staff. The CRTS can be augmented with an additional two orthopedic surgeons and one oral maxillofacial surgeon. Support services include frozen RBC availability, radiology, and clinical laboratory capabilities. The CRTS can triage up to 50 patients and can only hold patients for 72 hours. The aircraft carrier battle group role 2 assets do not typically support ground forces and are not casualty receiving ships. The 52 ward beds, 3 ICU beds, and single operating room are staffed by one surgeon and five additional medical officers. For the delivery of trauma care afloat or ashore near the point of injury, the USN has the Expeditionary Resuscitative Surgical System (ERSS). The ERSS has three components: the Expeditionary Surgical Team (EST), Expeditionary Trauma Team (ETT), and the En Route Care Team (ERCT). In total, the ERSS has a general surgeon, anesthesia provider, critical care nurse, operating room technician, two emergency medicine physicians, and two independent duty corpsmen.

US Marine Corps role 2 care consists of a surgical company that provides surgical care for one infantry regiment of the Marine Expeditionary Force. The surgical company is composed of four Forward Resuscitative Surgical Systems (FRSS), four shock trauma platoons (role 1 providers), and four en route care teams. The FRSS is the basic surgical capability module that can doctrinally provide resuscitative surgery for 18 patients for 48 hours without resupply. Each FRSS has two surgeons, one anesthetist, one ICU nurse, two operating room technicians, and two corpsmen. Like the US Army FST, the FRSS is not a stand-alone unit and relies on the main unit for resupply and logistical support. The ERCT is composed of an ICU nurse and corpsman. They can transport and care for up to two critically injured warfighters (one requiring mechanical ventilation).

Although each service branch has its own form (or multiple forms) of role 2 care, the primary purpose is to control hemorrhage and implement damage control surgical and resuscitation techniques in order to stabilize life-threatening

injuries and move the patient along the continuum of care. Role 2 teams have adapted and been flexible with the mission sets. Many role 2 teams have provided definitive care for host national patients and participated in humanitarian surgical care when the battlefield medical rules of engagement allowed humanitarian care.

Role 3

Role 3 care comprises the highest level of care on the battlefield. The most common role 3 MTF is referred to as the Combat Support Hospital (CSH). The US Army is transitioning the CSH to the field hospital with the 2017 Force Design Update; the field hospital and CSH include the same capabilities. Role 3 care includes medical and surgical subspecialty care. The MTFs typically have neurosurgical, ophthalmology, vascular, and orthopedic capabilities. Although the size of the CSH varies depending on the operational need, doctrinally, a role 3 facility is resourced to care for up to 248 patients. Four ICUs and support staff can care for up to 48 critically ill patients, and 10 wards with intermediate nursing care for up to 200 patients. In terms of surgical capability, doctrinally, role 3s have six operating room tables, albeit in the current theaters of operations the capacity has been reduced. In addition to surgical expertise, radiology, clinical laboratory, blood banking, psychiatry, public health, pharmacy, and nutrition support are usually available at this role of care. Medical teams, medical detachments, or hospital augmentation teams can augment capabilities of the CSH. Augmented services can include hemodialysis, clinical pathology, infectious disease, and head and neck surgery teams (neurologic surgery, ophthalmology, and otolaryngology).

In the USAF, role 3 doctrinally, care consists of EMEDS+25 and the USAF theater hospital. With 84 support personnel, two operating room tables, and 25 patient beds, EMEDS+25 can provide up to 20 operations in 48 hours. Additional modules with subspecialty capabilities such as otolaryngology, neurologic surgery, ophthalmology, cardiothoracic, and vascular can be added to the EMEDS+25. Currently in Afghanistan, the Air Force theater hospital at Bagram Air Base provides the largest surgery capability and critical care support in theater.

Role 3 care for the USN consists of expeditionary medical facilities and the USNS *Mercy* and USNS *Comfort* hospital ships. Each hospital ship has 12 operating rooms and 999 beds with 68 ICU, 20 postanesthesia care unit, 11 respiratory isolation, 400 intermediate care, and 500 minimal care beds. These minimal care beds are usually upper bunk beds reserved for patients ready to return to full duty; 273 officers and 943 enlisted personnel staff the ship with full clinical laboratory, radiology (with computed tomography [CT] scanner), and blood banking services with frozen blood stores. The expeditionary medical facility has four operating rooms, 40 ICU beds, and 110 ward beds. Clinical support services and surgical specialties for the expeditionary medical facility are similar to the US Army CSH.

Role 4

There is currently only one role 4 OCONUS (outside the continental United States) role of care and multiple role 4 CONUS (within the continental United States) MTFs. Landstuhl Regional Medical Center (LRMC) in Germany is the only role 4 OCONUS MTF providing the first level of care outside the combat zone. All casualties (medical and surgical) pass through LRMC as part of the evacuation from the combat theater. Role 4 CONUS facilities are located throughout the United States and provide definitive, full-spectrum care for combat casualties.[16,17]

COMBAT CASUALTY EVACUATION

The en route care environment can be risky for severely injured casualties. There have been significant advances in the evacuation capabilities, and much work is ongoing in this arena. Patients are transferred intratheater usually by rotary wing aircraft (helicopters) and travel out of theater typically on fixed-wing aircraft (USAF C-17 or C-130). Evacuation and transport of combat casualties is a multiservice and occasionally a multinational endeavor. The current doctrine of US military evacuation from the point of injury is centered on the Golden Hour concept. All battlefield injuries doctrinally must be transported to a surgical capability (role 2 or role 3 MTF) within 60 minutes. Evacuation vehicles and surgical assets are geographically placed to meet these demands. Patients are transported from the point of injury serially to higher echelons of care. An arrangement of various transport platforms has been assembled, and a nonexhaustive list follows (Fig. 53-8).

Casualty evacuation (CASEVAC) refers to patient movement in a vehicle not specifically designated for medical care, essentially a vehicle or helicopter of opportunity. In CASEVAC transport, personnel may have little, if any, medical training. CASEVAC platforms are chosen when speed is more important than en route medical equipment or capabilities.

MEDEVAC pertains to vehicles that are in effect military ambulances—either by air or ground. The MEDEVAC platform most often used in recent operations is the Sikorsky HH-60M Black Hawk helicopter (Fig. 53-9). Nicknamed "DUSTOFF," a title coined during the Vietnam era, MEDEVAC helicopter crews are designed to expediently bring patients from the point of injury to the nearest surgical capability. Early in the conflicts, these vehicles were manned by basic medics, but they are now manned by advanced paramedics and en route critical care nurses. Resuscitation and stabilization of the patient continue while in the air. Hostile fire is often encountered in this process, and as a medical transport, minimal defense capabilities are available for protection.

Aeromedical evacuation (AE) is the term for USAF fixed-wing aircraft used to transport patients either within theater or out of theater. Examples would be from a role 2

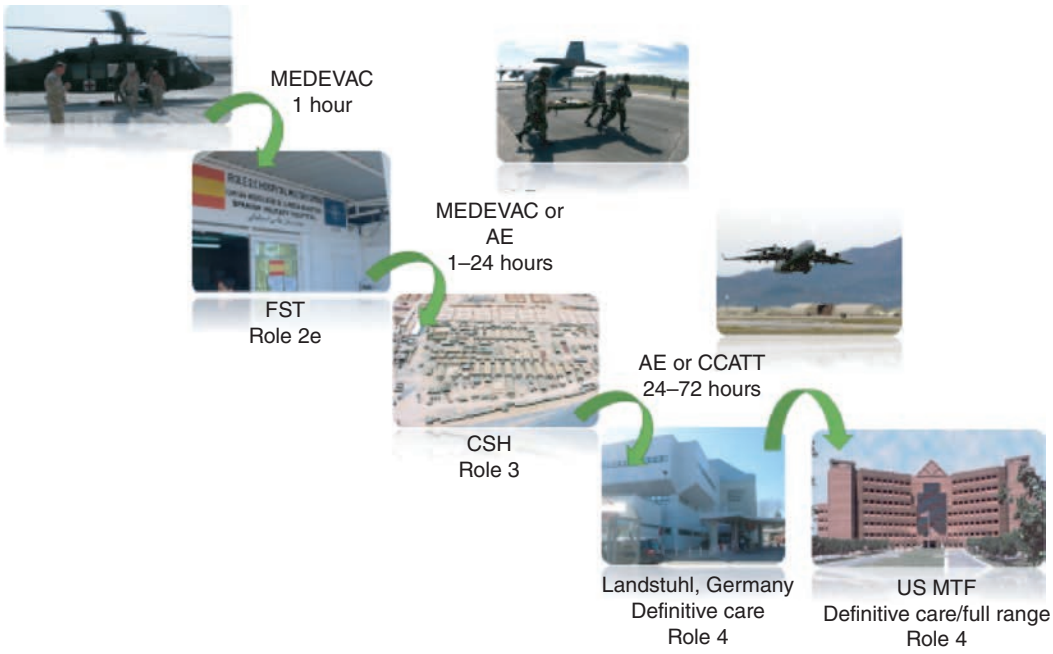

FIGURE 53-8 Schematic of roles of care and evacuation platforms. AE, aeromedical evacuation; CCATT, critical care air transport team; CSH, Combat Support Hospital; FST, forward surgical team; MEDEVAC, medical evacuation; MTF, military treatment facility.

facility to a role 3 (intratheater) or from Afghanistan to Germany. Physiologic capacity for flight and appropriate triage of patients via AE is determined by the flight surgeon, who is familiar with the demands and restrictions of care at altitude. The most common air frames used for AE include the C-130 and C-17 (Fig. 53-10). AE is used for patients who would generally meet criteria for ward or outpatient status within a hospital setting; they may be ambulatory or "litter patients" (named for the lightweight transport cot used).

Critical Care Air Transport Team (CCATT) refers to the augmented AE-type platform with specific capabilities for ICU care. Each team consists of an intensivist physician, a critical care nurse, and a cardiopulmonary technician (for ventilator and invasive monitor management). They are able to provide en route care for three to six critical patients for periods ranging from under an hour to over 16 hours. Specifically designed low-profile and air/altitude-worthy equipment, such as ventilators and monitors, is cleared for use prior to employment as part of the CCATT tool set. Despite the severity of injuries, long transport times, and additional constraints of providing care at altitude, the CCATT program has had an en route mortality of less than 0.02%.[17-20]

FIGURE 53-9 Approaching a medical evacuation Black Hawk helicopter with a casualty.

Medical Emergency Response Team–Enhanced

As the military continues to push high-level care further forward, the logical next step is physician presence on evacuation aircraft. The United Kingdom's Medical Emergency Response Team–Enhanced (MERT-E) represents this capability. It operates out of a CH-47 Chinook, a larger two-rotor helicopter. The team is designed to meet the needs of the most critically injured patients when evacuation times and distances may be long. A study evaluating the period from July to November 2008 recorded 324 missions for 429 patients. A physician was present for 90% of missions. A total of 64 physician interventions were performed including tube thoracostomy, death pronouncements, sedation, and blood product administration. In certain cases, the increased medical capability may be offset by the larger rotary wing platform that is unable to land in a "hot zone"; DUSTOFF MEDEVAC has less medical capability but will land in hot zones, which results in shorter transport times to role 2 or role 3 care. The benefit of physician presence overall is

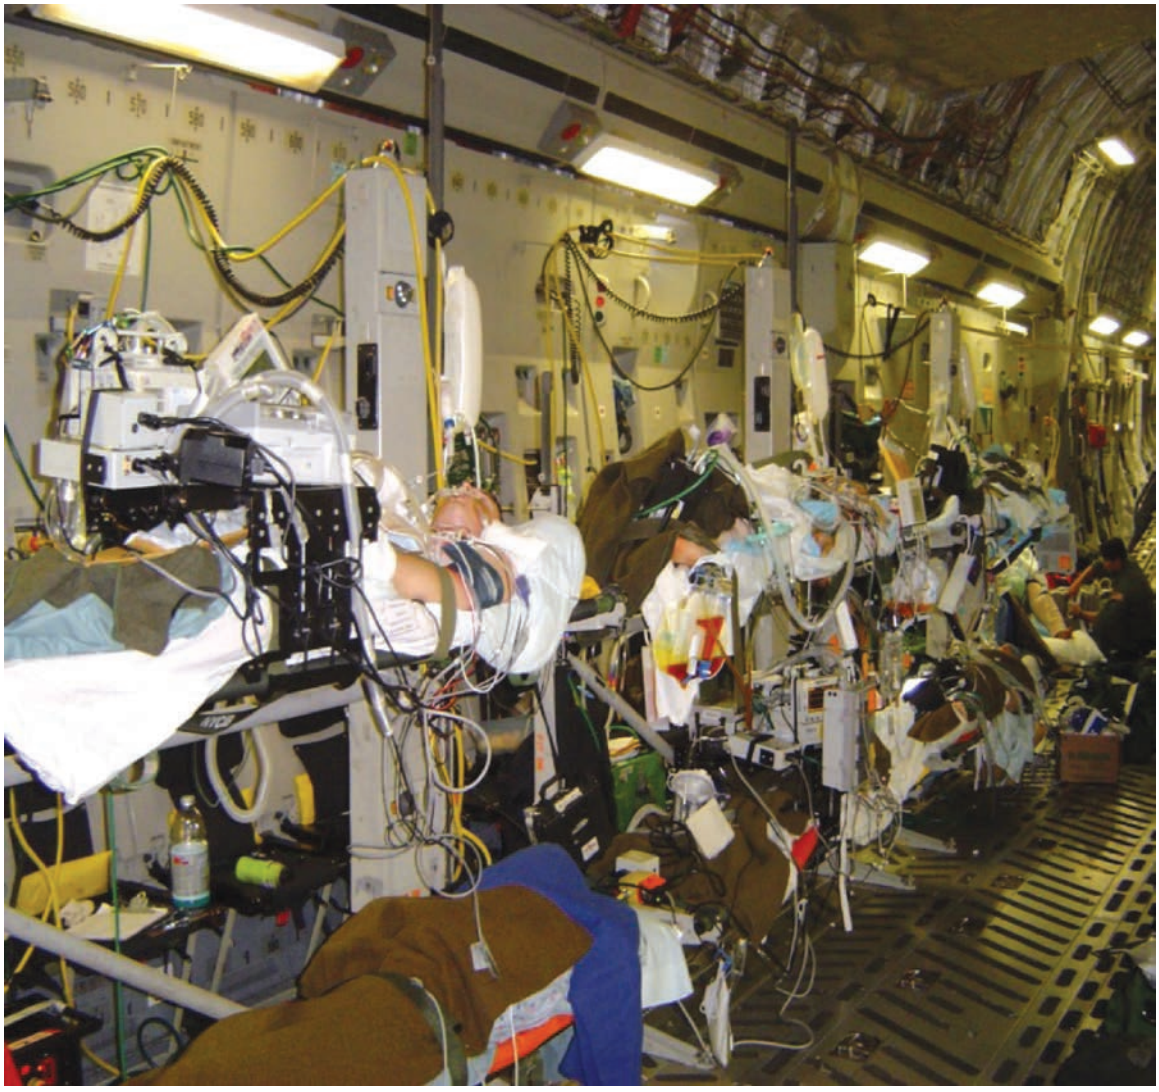

FIGURE 53-10 Critical care air transport team (CCATT) assembled in a US Air Force C-17 aircraft.

unclear as the decision not to perform advanced interventions can sometimes be important and is more difficult to measure. Additionally, the MERT-E model is equipment and personnel resource intensive in environments that often have minimal resources.[21] A comparative evaluation of forward AE platforms found lower mortality for all Injury Severity Score groups with the MERT-E platform.[22]

DAMAGE CONTROL RESUSCITATION

One of the greatest advances in the recent conflicts is the adoption of an overall damage control approach to battlefield care. The introduction of role 2 surgical capability is the battlefield planning aspect of damage control. Although the concept was introduced in 1983[23] in the description of an abbreviated laparotomy for a patient with a coagulopathy, the term *damage control* was introduced 10 years later in the landmark publication by Rotondo et al.[24] The refinement of damage control resuscitation (DCR) principles represents one of the major advances in trauma surgery during recent years, and the military has adopted the concept of damage control along the entire continuum of care. The high tempo and large volumes of casualties during combat operations lasting over a decade have provided a crucible for this change. Damage control starts with tourniquet use at the point of injury and also includes hemostatic resuscitation with blood component ratios that replicate whole blood, early whole blood use, prehospital transfusion, short transport times, minimal/no crystalloid use, and damage control surgical techniques. Patients with trauma necessitating a massive transfusion require vigilant attention throughout their treatment—from point of injury to the first MTF and definitive surgery, and throughout the continuum of care, including the en route care environment.[25]

Damage Control Criteria Recognition: The Lethal Triad

Acute coagulopathy of trauma (ACT) is caused by the combination of severe tissue injury and shock, and is mediated by activated protein C.[26] The infusion of high-chloride-containing crystalloid solutions exacerbates ACT by inducing the lethal triad, producing trauma-induced coagulopathy. The lethal triad is defined by the presence of acidosis, hypothermia, and coagulopathy in the setting of traumatic hemorrhage. It is a vicious cycle of clinical findings associated with increased mortality compared with noncoagulopathic patients.[27] Once this vicious cycle is induced, it is difficult to reverse as each component of the triad results in worsening of the others. There is tremendous interest in developing criteria to identify patients who require DCR early. Unfortunately, there is no single scoring system that will distinguish all traumatic coagulopathy patients requiring DCR.[28] Mechanism and clinical suspicion remain important factors for early recognition. Current predictors used by the US military as established by the CPG on DCR at forward facilities are included in Table 53-3 and are discussed in the following sections.[7]

ACIDOSIS

Acidosis, generally recognized as a pH less than 7.25, represents part of the lethal triad. A base deficit of greater than 6 has been demonstrated as an independent risk factor for coagulopathy and is associated with increased mortality.[29] Recognized via point-of-care testing, acidosis provides an early indication of metabolic derangements from profound hemorrhage. Acidosis impairs both platelet function and the coagulation cascade.[28]

COAGULOPATHY

Coagulopathy is concerning in the setting of trauma as both an indicator of increased mortality and a barrier to hemorrhage control. An international normalized ratio (INR) greater than 1.5 is an independent predictor of massive transfusion and is usually available in the resuscitation bay.[30] Impaired coagulation requires replacement of clotting factors and platelets rather than red cells alone.

TABLE 53-3: Clinical Predictors for Recognizing Patients Requiring Damage Control Resuscitation per the Most Recent US Military Clinical Practice Guidelines

Acidosis	pH <7.25
Coagulopathy	INR ≥1.5
Anemia	Hematocrit <32%
Hypotension	Systolic blood pressure <110 mm Hg
Tachycardia	Heart rate >105 bpm
Uncontrolled hemorrhage	

INR, international normalized ratio.

HEMOGLOBIN AND HEMATOCRIT

Anemia secondary to acute blood loss is another measure easily determined in the trauma bay. Traditional teaching dictates that the hemoglobin and hematocrit will not initially change immediately after hemorrhage as red cells and plasma are lost in equal proportions. Based on this premise, anemia would not be evident until after plasma levels equilibrate for the lost whole blood volume. However, when hemoglobin measures are obtained within the first 30 minutes of arrival to the emergency department, nearly 90% of trauma patients with major bleeding will be identified.[31] A hemoglobin less than 11 g/dL has been determined to be an independent predictor of massive transfusion.[30]

SYSTOLIC BLOOD PRESSURE

The presence and degree of hypotension provide measures for diagnosis, prognosis, and treatment in the bleeding trauma patient. Systolic blood pressure (SBP) less than 90 mm Hg is commonly used as the definition of shock. Advanced Trauma Life Support teaching also advocates for the use of blood pressure in its classification of hemorrhage. However, once a SBP below 90 mm Hg is reached, this already corresponds to a 40% loss of circulating volume—a late finding.[32] Earlier changes in blood pressure have been demonstrated to be indicative of changes in prognosis. A large study of NTDB patients found the prognostic cutoff to be 110 mm Hg, below which mortality increased by 5% for every decrement of 10 mm Hg.[33] An important note, however, is that prognostic criteria cutoffs do not necessarily translate into therapeutic goals. *Permissive hypotension* is an example of this. A goal of DCR is to keep the SBP at approximately 90 mm Hg prior to definitive surgical hemorrhage control. Previous experiences with SBP goals at normal levels translated into increased mortality.[34] Although an SBP of less than 110 mm Hg is useful to determine severity of hemorrhagic insult, it should not be used as an early resuscitation target.

Damage Control Intervention: Resuscitative Fluid Strategies

CRYSTALLOID MINIMIZATION AND SELECTION

Crystalloids have long been used in trauma as volume expanders to support blood pressure. However, select resuscitative fluids can propagate acidosis, and normotension may exacerbate hemorrhage. Rather than being resuscitative as intended, crystalloids can increase morbidity and mortality.

In far-forward prehospital settings, blood products are rarely available and crystalloids remain one of the options available for fluid resuscitation. In these situations, it is important to consider which type of crystalloid to use. The most common fluids used are normal saline (NS) and lactated Ringer's (LR). There are several key differences between the two, but the most notable is the fluid pH.

Saline infusions were developed in 1831 after observed "decreased fluidity" of blood among cholera patients. Despite the widespread use of NS, there is no available scientific basis

TABLE 53-4: Comparison of 0.9% Sodium Chloride (Normal Saline) Versus Lactated Ringer's Solution[30]

	Normal saline	Lactated Ringer's
pH	5.0	6.5
Osmolarity (mOsm/L)	308	272
Na (mEq)	154	130
Cl (mEq)	154	109
Potassium (mEq)	0	4
Calcium (mEq)	0	3
Lactate (mEq)	0	28
Coadminister with blood	Yes	No

for its initial use. The closest evidence is an in vitro study by a Dutch chemist, Jakob Hamburger, in 1888 noting a shared freezing point between human plasma and 0.9% NS of –0.52°C.[35] Ringer's solution was developed in the 1880s by Sydney Ringer with the purpose of maintaining activity of a frog myocardium using electrolyte constituents resembling plasma.[36] Later, lactate was added to Ringer's original solution (by Alexis Hartmann) to combat the effects of acidosis through conversion to bicarbonate in the liver.

Several animal studies over the past decade have supported improved outcomes with LR over NS.[37-39] Counterintuitively, hyperkalemia is increased with NS as opposed to LR. Hyperkalemia is attributed to extracellular shift of potassium due to the low pH of 5.0 found in NS (Table 53-4).[40] With both LR and NS, there is concern for dilution of clotting factors compounding coagulopathy. There are situations when judicious crystalloid resuscitation is appropriate. Part of this strategy includes the target blood pressure for resuscitative efforts.

BLOOD TRANSFUSION STRATEGIES

The primary tenant of the current concept of DCR is the use of blood—either whole blood or blood products in ratios replicating whole blood. This strategy comes directly from military experience after observing mortality trends associated with blood product ratios. Borgman et al[41] reviewed 246 patients at a US Army CSH in Iraq evaluating ratios of plasma to red cell units and association with mortality rates. This study revealed a significant decrease in mortality as the ratio approached 1:1. Results of the study by Borgman et al[41] provided confirmation for changes in the CPGs, which had already taken effect during 2004.

The move away from transfusion of low plasma to red cell ratios marked an important transition from previous practice. The use of individual blood product components had been dictated by laboratory parameters rather than the patient's clinical situation.[25] Patients would receive plasma for an elevated INR or partial thromboplastin time rather than the presence of severe hemorrhage. Similarly, platelet administration had been guided by measured thrombocytopenia. The transition to higher ratios was based on a paradigm shift toward matching the whole blood that was being lost. Despite changes in both military and civilian DCR guidelines, the ideal ratio is unknown.

The goal of the Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study was to provide further evidence regarding blood component ratios, particularly early transfusion of plasma and platelets. A total of 1245 patients from 10 US Level I trauma centers receiving at least 1 unit of RBCs within 6 hours of admission were in the original study group. Multiple separate subgroup analyses have been published from the data obtained. Among 905 patients from the main study group who also received greater than or equal to 3 component unit transfusions, increased plasma-to-RBC ratios were independently associated with decreased 6-hour mortality. Hemorrhagic deaths predominated in the first 6 hours. Patients with high ratios either tended to receive a 1:1:1 or 1:1:2 ratio of plasma to platelets to RBCs.[42,43]

The Pragmatic Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial further addressed the question of ideal transfusion ratios. A total of 680 patients were randomized to a 1:1:1 versus a 1:1:2 ratio during active resuscitation at 12 Level I trauma centers in the United States. There was no statistically significant difference in 24-hour or 30-day mortality. However, the 1:1:1 group achieved hemostasis more frequently and were less likely to die of hemorrhage in the first 24 hours.[44]

The use of an early balanced and hemostatic resuscitation strategy with blood products has been a significant paradigm shift that came directly from the experience, data analysis, and results from the wars in Iraq and Afghanistan and has been validated in civilian trauma. Hemostatic resuscitation is designed to replicate whole blood, and the military experience in treating combat casualties has demonstrated that whole blood is associated with superior outcomes when compared to component therapy. Anecdotally, fresh whole blood has been coined a *physiology changer* in the operating room.[45-48]

Prehospital Transfusion. Initiatives to bring blood far forward, as close as possible to the point of injury, have proven to be lifesaving. In 2012, a prehospital transfusion protocol initiated in Afghanistan placed RBCs and fresh frozen plasma (FFP) on MEDEVAC helicopters. Criteria for transfusion were signs of shock or mechanism of injury. Results from this protocol implementation demonstrated that prehospital blood product transfusion of combat casualties improved early and 30-day survival.[45,49] The retrospective analysis of US military casualties injured in Afghanistan and transported by en route care platforms with a transfusion capability demonstrated that transfusion within minutes of injury significantly reduced mortality. This study was unique compared to other prehospital transfusion studies in that all deaths in this military population were captured; this type of study design proved to be crucial when considering early hemorrhagic

deaths given they are the cohort of patients predicted to most benefit from prehospital transfusion. The study demonstrated that the median time to initiation of transfusion, 36 minutes after injury or 7 minutes after MEDEVAC, was associated with improved survival. This study supports sustainment of a system of care that reliably supports prehospital transfusion and implementation and investigation of similar systems in civilian trauma settings. Very recent results looking at prehospital plasma transfusion demonstrated decreased mortality, especially with longer transport times.[50]

Given that the vast majority of combat deaths occur in the prehospital environment prior to reaching a surgical capability, these are the combat casualties who will most benefit from blood far forward. Whole blood is the logical choice for a nearly perfect resuscitative fluid in the far-forward environment given that it has oxygen-carrying capacity, coagulation factors, and platelets in the same ratios that are lost during exsanguination. It is logistically easier to carry and transfuse 1 unit of whole blood compared to multiple units of components. In the current theaters of operation, blood transfusion capability continues to mature at both point of injury and in the en route care environment. In 2013, the Norwegian Special Operations Forces instituted a remote DCR protocol that includes far-forward collection and transfusion of whole blood. A similar protocol for tactical DCR in order to transfuse low-titer type O whole blood at point of injury was adopted by US Army Ranger Regiment: Ranger O-Low-Titer Type O (ROLO). Currently, US Special Operations Forces carry low-titer universal donor whole blood on select missions, and there is increasing availability of type O low-titer whole blood in the forward deployed environment.[45,51-53] Transfusion far forward is an essential capability that saves lives of combat casualties.

WHOLE BLOOD VERSUS COMPONENT THERAPY

Whole blood has a long history of use on the battlefield and was the primary resuscitation fluid for hemorrhage in World War I, World War II, the Korean War, and early in the Vietnam War. During the first two world wars, a combination of fresh whole blood (FWB) and stored whole blood (SWB) was used, with a peak of 2000 units per day in 1945.[54,55] The transformation to crystalloid therapy and component product resuscitation lacked clinical evidence of superior efficacy or improved outcomes; nevertheless, it was widely adopted until data from the wars in Iraq and Afghanistan resulted in the paradigm shift to a resuscitation strategy that replaces components in a manner mimicking the composition of whole blood. Despite this paucity of initial evidence, component therapy became the standard for blood banking.[56] Early in the recent wars, whole blood was used primarily by forward deployed teams that were equipped with limited units of packed RBCs (PRBCs); therefore, during this period, whole blood transfusion capability was a necessity driven by component therapy availability and was not necessarily clinically compelled. At the role 3 CSHs, whole blood was initially used because of the lack of platelet availability. Over time, through both focused empiricism and investigations of comparative efficacy that demonstrated improved survival with whole blood,[57] battlefield hospitals no longer use whole blood solely because of lack of component therapy availability, but also secondary to its clinical superiority. There continues to be enthusiasm for whole blood use in both military and civilian settings, and it is being considered, studied, and reestablished as the optimal therapy for hemorrhage. As of November 2018, over 10,550 units of whole blood have been transfused during the wars in Iraq and Afghanistan. These transfusions have almost exclusively occurred in the "hospital" setting: role 2 (FSTs) or role 3 (CSHs). Not only have complications been exceedingly low, but whole blood has repeatedly demonstrated improved outcomes in casualties with hemorrhagic shock.[58]

The reexamination of whole blood in the current era was also led by the military community. Logistical restraints are imposed on effective component therapy transfusion at forward operating bases owing to long supply chains and limited processing and storage of components. Platelets are stored at room temperature, require constant agitation, and have a shelf life of 5 days due to increasing risk of bacterial contamination. FFP and cryoprecipitate must be stored at –20°C and require at least 30 minutes to thaw. Additionally, the storage capacity for all components is limited.[59] Whole blood addresses many of these limitations as it eliminates the need for multiple products and storage conditions.

The theoretical clinical benefits of whole blood include avoidance of dilution, absence of anticoagulant additives, consistency with damage control surgery principles, and blood product age. Although a 1:1:1 transfusion ratio with component therapy attempts to approximate whole blood, it creates a dilute blood mixture with a hematocrit of 29% and platelet count of 90,000/μL, and 62% of coagulation factors found in fresh whole blood are achieved. As with component therapy, whole blood transfusion must have donor RBCs that are ABO compatible with the recipient in order to prevent acute hemolytic transfusion reactions. Group O whole blood donors have RBCs that are compatible with all recipients, but the plasma contains anti-A and anti-B antibodies that may cause hemolysis in a non–group O recipient. Therefore, only group O whole blood donors with low titers of anti-A and anti-B antibodies (<1:256 saline dilution method) are used. This whole blood can be considered universal and is known as low-titer O whole blood (LTOWB). Donors of LTOWB should be retested annually at minimum in order to ensure titers remain below 1:256. Additionally, LTOWB is collected from males and nulliparous women to lessen the risk of transfusion-associated lung injury in recipients.

FWB is whole blood collected from a walking blood bank (WBB) on an emergency basis. The WBB consists of volunteer donors (prescreened when possible) who are not needed immediately for warfighting activities or active resuscitation of the patient(s). FWB can be kept at room temperature up to 24 hours prior to use. Due to emergency conditions under which FWB is collected, it does not undergo transfusion-transmitted disease (TTD) testing prior to use. For this reason, FWB is not US Food and Drug Administration

(FDA) approved because it carries an increased risk of disease transmission.

SWB is whole blood that is collected, stored, and tested for TTD and is FDA approved. The Armed Services Blood Program provides SWB only as LTOWB to locations outside the continental United States (OCONUS). It can be stored for 21 days in CPD (citrate, phosphate, dextrose) at 1°C to 6°C and 35 days in CPDA-1 (citrate, phosphate, dextrose, adenine) at 1°C to 6°C. However, after 14 days, the hemostatic function of the platelets may be less effective and supplementation with fresher whole blood may be necessary. Of note, the use of LTOWB is now permitted by the American Association of Blood Banks (AABB), and it is used by several civilian trauma centers in the United States.

For DCR at the point of injury or in en route care, remote locations, or MTF, the order of priority of fluid administration should be as follows: (1) LTOWB, (2) component therapy at 1:1:1 ratio, (3) RBC and plasma at 1:1 ratio, (4) plasma and RBC at any ratio, and (5) RBC alone. Current US practice is guided by the US Army Institute of Surgical Research Clinical Practice Guideline for Massive Transfusions.[7]

ADJUNCTS AND ALTERNATIVES TO COMPONENT THERAPY: LYOPHILIZED PLASMA AND CRYOPRESERVED RED BLOOD CELLS

Storage conditions remain a limiting constraint on the availability of blood products during military operations. For the combat medic, weight is paramount because everything needs to be carried and refrigeration is rarely available. At the FST or CSH, the refrigerated shelf life of PRBCs can limit availability of this product.

The benefits of early plasma transfusions have been recognized with new information on component therapy ratios. The most common form of plasma, FFP, must be stored at –18°C and then undergo a thawing process in a warming bath for approximately 15 to 20 minutes.[60] These processes require specialized bulky equipment that is difficult to house or completely absent at far-forward facilities and for first responders. However, lyophilized (freeze dried) plasma represents a lightweight, easily carried option that can be stored at room temperature. Lyophilized plasma represents another rediscovery of previous military advances finding new uses again today. In World War II, lyophilized plasma was used due to the same concerns as today—transport and shelf life. Unfortunately, pooled plasma that was not screened for viral pathogens was used at that time—with associated increased viral infection risk. Thus, the practice was abandoned. With the ability to screen and test for disease more effectively, lyophilized plasma is being reinvented. Recent work evaluating the properties of lyophilized plasma has demonstrated 86% of prelyophilization coagulation factor activity[17] and decreased blood loss compared with FFP in a combat-relevant swine model.[61,62] European production of lyophilized plasma has continued in recent years with notable use by the French and Germans in overseas military activities at role 1, 2, and 3 facilities and MEDEVAC platforms.[63] In July 2018, the FDA issued an Emergency Use Authorization to allow for the use of pathogen-reduced leukocyte-depleted freeze-dried plasma (French FDP) to treat hemorrhage or coagulopathy during a medical emergency involving military combat when plasma is not available. This product is a lyophilized, pathogen-reduced, leukocyte-depleted pooled apheresis plasma product collected from volunteer donors. The packaged unit contains one flask of freeze-dried plasma, one flask of 200 mL of sterile water, one transfer set, a sterile tubing set with an in-line 200-µm filter, and a needle for product infusion. French FDP can be stored between 36°F and 77°F for 2 years. At the time of use, the FDP and sterile water should be brought to room temperature. The sterile water flask is spiked first, followed by the FDP flask. If the FDP is spiked first, the vacuum is lost and subsequent water transfer becomes more difficult. Once the water has filled the FDP flask, gentle mixing without generating foam is completed over the span of 3 to 5 minutes.

Deglycerolized RBCs (DRBCs) were first used on a large scale by the US military during the Vietnam War after large volumes of standard PRBC preparations were being discarded due to age. The technique currently approved for use by the FDA involves the use of a glycerol buffer to prevent crystal formation–associated membrane disruption and cellular damage due to large temperature changes. The red cells are stored at –80°C with 40% glycerol weight/volume within 6 days of collection. They can be stored for up to 10 years before they are thawed and deglycerolized for patient use.[64,65] The storage lesion is minimized while also allowing for larger inventories of blood in settings with sporadic or unpredictable use. Despite these benefits, including FDA approval, DRBCs are only being employed in rare specific situations today. This is likely attributed to the increased time (~90 minutes) and cost associated with the thawing and deglycerolizing process. They have been used increasingly in current military operations with hundreds of units provided and are used in an equivalent manner to PRBCs. They are also part of the response plan for potential large-scale natural or manmade disasters domestically.

Damage Control Interventions: Temporary and Definitive Direct Hemorrhage Control

The general principle of damage control in the combat environment is to provide only the interventions required to safely get the patient to the next echelon/role of care. This approach begins at the point of injury with the teachings of TCCC, including tourniquets and topical hemostatic agents. It continues through the FST with a variety of vascular control and repair techniques. The goal is to salvage potentially survivable injuries, over 90% of which are associated with hemorrhage.[12]

TOPICAL HEMOSTATIC AGENTS

Research and development of novel topical hemostatic agents has seen much interest during the current era of combat casualty care. The agents primarily used in theater are either chitosan (a positively charged compound derived from shrimp shells) or

kaolin (aluminum silicate mineral) based. Chitosan-based dressings, such as Celox, work as mucoadhesive agents that stick to open wounds, sealing bleeding. Kaolin-based dressings, such as Combat Gauze, work by accelerating clotting pathways. When used as a straight powder or impregnated gauze, these agents can provide hemorrhage control alone or as an adjunct to tourniquet use. As addressed in the earlier section on tactical field care, Combat Gauze is used as the primary hemostatic by first responders based on CoTCCC guidelines. The gauze has been selected over powder formulations for ease of use and ability to provide compression in cavitary wounds. Hemostatic gauze products continue to be useful in the operating room as well and have become common in civilian settings. There has been an explosion of improvements and options for topical hemostatic agents in recent years with several new agents being investigated currently.

Self-expanding foam represents a promising new technique to provide hemostasis for otherwise noncompressible intra-abdominal hemorrhage. A polyurethane expanding foam that is introduced into the abdomen as two liquids that combine and polymerize providing pressure on bleeding sites has recently been FDA approved for early clinical trials to assess for efficacy and safety. This intracavitary foam is designed to temporize hemorrhage until definitive surgical control can be achieved.[66]

Expandable sponges under the label XStat (RevMededx, Wilsonville, OR) have also been developed through military research, with FDA approval for use in 2014 (Fig. 53-11). The device consists of a large syringe that can deliver many pill-sized, nonabsorbable, radiopaque sponges, which expand within 20 seconds of contact with moisture. The volume of material delivered and the size of the delivery device provide tamponade control of junctional wounds in the groin and axilla.

TRANEXAMIC ACID

The Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH-2) study, an international prospective randomized trial of over 20,000 trauma patients, demonstrated a mortality benefit with tranexamic acid.[67] When studied in a military role 3 hospital, the Military Application of Tranexamic Acid in Trauma Emergency Resuscitation (MATTERs) study also revealed a mortality advantage.[68] In both studies, the benefit was seen only if treatment occurred early after injury (<3 hours). As such, tranexamic acid is currently endorsed in the TCCC guidelines as well as the DCR CPG.[7]

FIGURE 53-11 XStat expandable sponge delivery device.

TRAUMATIC ARREST AND PROFOUND SHOCK

Combat casualties have a high frequency of penetrating injury from mechanisms designed to be lethal. Traumatic arrest and profound shock en route to the first surgical facility are realities that must be anticipated. Aortic occlusion represents a means to limit hemorrhage and maintain perfusion to neurologic and central structures. However, this remains a very aggressive maneuver, and patient selection is paramount.

RESUSCITATIVE THORACOTOMY

The indication for resuscitative thoracotomy is usually loss, or impending loss, of vital signs in the initial resuscitation setting after penetrating trauma. The specific indications for this extreme measure vary between institutions and remain an area of contentious debate. It is promoted as the "last opportunity" to save a life. However, the nature of the procedure poses risk to medical personnel in terms of infectious disease exposure from sharp rib fractures or instruments. A large series of emergency thoracotomies during a 4-year period in Iraq revealed an overall survival rate of 11%.[69] The current US military indication for emergency thoracotomy is limited to penetrating trauma, without isolated head injury and not if vital signs have been lost for over 10 minutes.[7]

RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA

The use of intra-arterial balloon occlusion of the aorta was first reported in 1954 by Colonel Carl Hughes.[70] However, it has only recently gained popularity in the current era of expanded endovascular technologies. Resuscitative endovascular balloon occlusion of the aorta (REBOA) has several potential advantages over emergent thoracotomy. In terms of risk to providers, this catheter-based technique reduces the opportunities for direct exposure to biohazardous materials through puncture by broken ribs. As the balloon can be inflated at different locations, selective occlusion—either in the chest or inferior to the renal arteries—can be performed. Particularly for the patient with exsanguinating isolated pelvic trauma, obtaining the benefits of aortic occlusion while maintaining renal and visceral blood flow is possible. REBOA does require a specialized skill set and equipment that may not be available in all circumstances. Recent promising experiences with REBOA have prompted the creation of military-specific indications for its use (CPG).

OPERATIVE RESUSCITATION

Operative intervention in the setting of DCR is an extension of prehospital and initial MTF intervention goals of

hemorrhage and coagulopathy management. Unlike most civilian settings, *both* tactical and physiologic considerations mush be considered. A prime example is the FST, which often operates in a split-based configuration (two general surgeons or one general surgeon and one orthopedic surgeon) with one operating room and only 6 hours of holding capacity after surgery. The focus includes rapidly assessing the patient, controlling hemorrhage, minimizing contamination, and facilitating evacuation to the next higher level (role/echelon) of care. Because time and resources are limited, only those interventions that are required to stabilize the patient for transport to the next level of care are performed.

Damage control laparotomy is a familiar component of DCR in the setting of intra-abdominal or lower extremity junctional hemorrhage. Hemorrhage is controlled by ligation, repair, compression, or shunting. Injured bowel requiring resection is left in discontinuity. The abdomen is packed and left open in a nearly universal manner. This allows for an abbreviated operative time, facilitating expedient return to the ICU for further resuscitation. Additionally, the operating room is made available more rapidly for the next patient(s)—who regularly arrive in multiples. The chaos inherent in a war zone can adversely affect communication concerning the patient's injuries. An open abdomen allows the next-higher receiving MTF to directly visualize the injuries sustained when communication is impaired. The abdominal pack dressing is routinely labeled with indelible ink as an additional means to ensure the full extent of injuries is recognized and can be appropriately treated (Fig. 53-12).

Major arterial injury presents conflicting priorities of control to prevent exsanguination and preservation of flow to maintain viability of tissues distant to the injury. The primacy of life over limb remains. When the limb can be salvaged while preserving the patient's life, the intervention used is contingent upon the resources available. Extra time spent on a formal repair may place other casualties needing operative intervention at unacceptable risk. Generally speaking, at role 2 facilities, the employment of temporary vascular shunts is encouraged over formal repair, which is best left to the role 3 or higher. Exploration, proximal and distal control, thrombectomy, and local heparinization are still used for shunting (CPG for vascular injuries). Not all vessels can or should be shunted; a list of major vessel considerations for shunting is provided in Table 53-5.[18] When an extremity's vascular inflow is maintained through shunting or repair, a fasciotomy is currently recommended. The amount of soft tissue compartment swelling after injury in young, muscular patients is often profound.

FIGURE 53-12 Open abdomen labeled for transport.

SPECIAL MISSIONS

Acute Lung Rescue Team/Extracorporeal Membrane Oxygenation in Transport

Combat trauma-associated acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) are present in 26% to 33% of critically ill casualties.[71,72] ALI and ARDS among combat-wounded patients are attributed to sources including blast injury, pulmonary contusion, transfusion complications, fat/marrow emboli, pneumonia, inhalation injuries, sepsis, near-drowning, and large overall injury burden. CCATT had been established for the transport needs of critical patients out of the theater of operations. Most patients with ALI/ARDS are responsive to standard low-volume ventilation lung-protective strategies based on

TABLE 53-5: List of Vessel Considerations for Temporary Vascular Shunts

Consider for shunting	Poor candidates for shunting
Subclavian artery (difficult)	Radial and ulnar arteries
Axillary artery	Profunda femoris artery
Brachial artery	Tibial arteries
Common femoral artery	Vertebral arteries
Superficial femoral artery	Portal vein
Popliteal artery	Mesenteric vessels
Large extremity veins	Jugular vein
Aorta	
Iliac arteries	

ARDS Network guidelines.[73] However, there remains a subset of patients with such severe pulmonary injury that they either have to wait for improvement to meet CCATT criteria or die prior to evacuation. In 2005, the Acute Lung Rescue Team (ALRT), a joint service endeavor, was implemented to meet the needs of these patients. The ALRT involves an intensivist-led team available for consults from the combat zone and capable of activating a team to meet and transport severely lung-injured patients. Composed of two critical care physicians, two critical care nurses, and two respiratory therapists with specialized experience, the ALRT team is able to provide over 24 hours of continuous care. Adjuncts to standard mechanical ventilator support employed include prone positioning, buffer therapy, inhaled prostacyclin, and use of the Volumetric Diffusive Respiratory (VDR-4) (Percussionaire Corporation, Sandpoint, ID).[74]

Eventually, pump-driven venovenous extracorporeal membrane oxygenation (ECMO) has been employed with cannulations being performed at the role 3 hospitals in Iraq and Afghanistan. The most recent ECMO transfer was from Baghdad, Iraq, to San Antonio, Texas, in November 2017 (Fig. 53-13). The miniaturization of the ECMO filter and circuit combined with improvement in the electrical/computer interface have made these advances and transcontinental transports possible.[71,75,76]

Care of the Military Working Dog

Military working dogs (MWDs) are regularly employed for detection of explosives and illicit materials. They are an integral component of special operations and military police activities and often involved in far-forward activities. In the setting of injury or illness, the ideal responders are military veterinary personnel. However, other health care providers may be the only available resource for preservation of life, limb, or eyesight. The scope of this chapter does not allow for an exhaustive description of battlefield canine care, but there are some cogent considerations below.[77] Upon stabilization, the MWD should be evacuated to a military veterinarian at the earliest convenience.

- Demographics and clinical information should be confidential, similar to MWDs' human counterparts.
- The MWD's handler should be present during care for the protection of the animal and the treating staff (Fig. 53-14). Muzzles should be used during examination and treatment.
- Direct communication with a military veterinarian should occur prior to any surgical procedure to provide guidance.
- A thin or fenestrated mediastinum is present in dogs, requiring *bilateral* chest tubes in the setting of a unilateral pneumothorax.

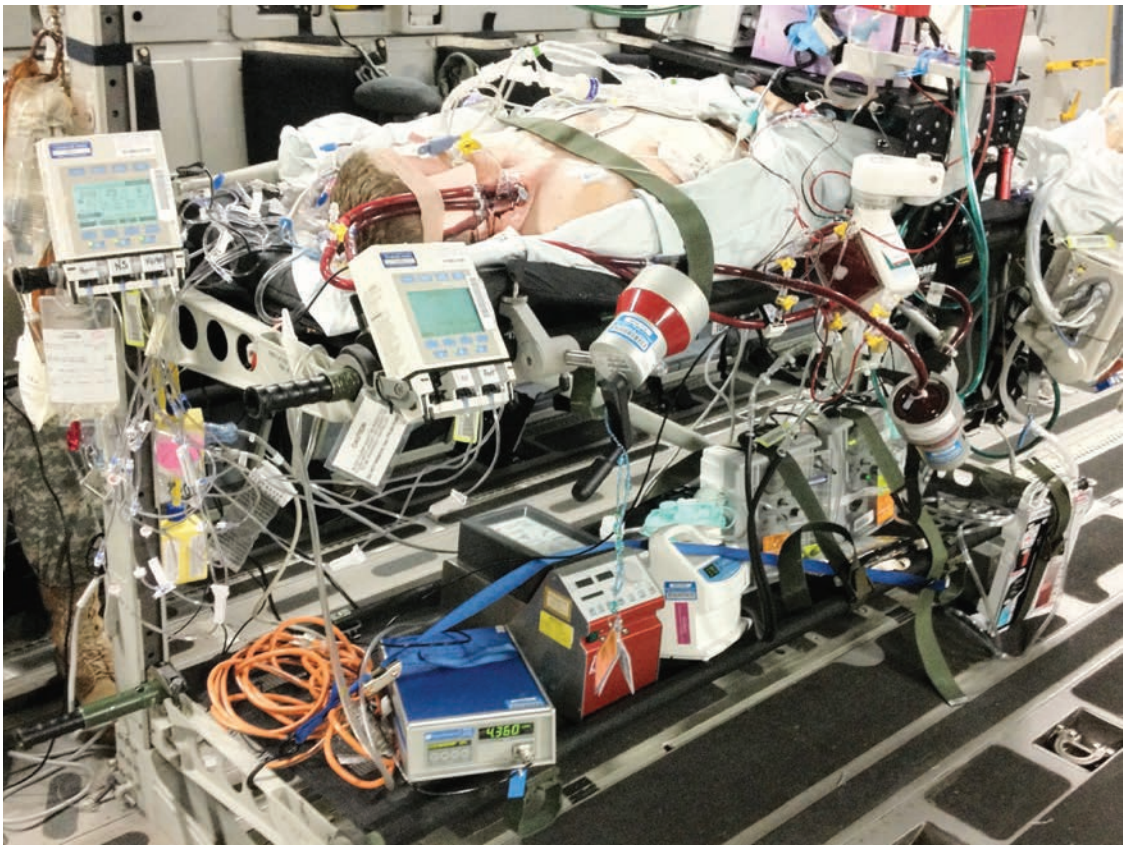

FIGURE 53-13 Extracorporeal membrane oxygenation (ECMO) patient being transported via critical care air transport team.

FIGURE 53-14 Military working dog receiving medical care attended by their handler.

- Pulse oximetry can be placed on the tongue in a sedated dog.
- Gastric dilatation-volvulus syndrome is a common canine surgical emergency. Prophylactic gastropexy is performed in most MWDs, but not all, and is still subject to failure. Clinical presentation includes abdominal distention, ineffective vomiting, and signs of shock (due to decreased venous return). Lateral thoracic radiography aids in the diagnosis. Treatment consists of immediate decompression by a percutaneous gastric trocar (14- to 18-gauge IV) decompression. Definitive therapy requires exploratory laparotomy, detorsion, gastropexy, and resection of ischemic tissue, preferably performed by a veterinarian if urgent evacuation is possible after decompression.[78]
- Acetaminophen and ibuprofen can cause liver toxicity in MWDs—DO NOT USE.
- MWDs are subject to canine posttraumatic stress disorder–like syndrome; listen to the handler for changes in behavior after significant events.
- MWDs may be euthanized in the case of catastrophic wounding with poor prognosis for recovery and in order to relieve the MWD from undue suffering.

Recent evidence confirms that MWDs can be adequately resuscitated and/or treated by nonveterinarians. A study of gunshot wounds sustained by MWDs in Iraq and Afghanistan revealed 29 such injuries. Half of the wounds were thoracic but otherwise had a similar distribution to humans. The died of injury rate was 38%, and 17 of the 18 MWDs killed died prior to evacuation or treatment. Of the 11 survivors, all were returned to duty.[79]

Joint Trauma System and Department of Defense Trauma Registry

One of the biggest advances of the recent conflicts was the development of the military trauma system. When the United States entered into the conflicts in the Middle East in 2002, the military did not have a codified trauma system that unified the levels of care and set the standards for battlefield trauma care delivery. While trauma care has advanced through the exchange of innovation and experience between civilian and military medicine going back to antiquity, statutory changes that have occurred in 2017 should stand the test of time helping to ensure that the lessons learned from these conflicts will not be forgotten. Examples of the reciprocity between the development of military and civilian trauma systems were seen during the Vietnam War when prehospital interventions and decreased evacuation times due to aeromedical platforms influenced civilian trauma care. During the same era, the American College of Surgeons shaped civilian trauma management through the publications *Early Care of the Injured Patient* followed by *Optimal Resources for Care of the Injured Patient.*[80,81] These resources became the guide for the development of civilian trauma centers that have been associated with improved outcomes. The trauma system is defined as "an organized effort in a geographic region to deliver a full range of trauma care."[82] Organization within an area of operations or activity allows for increased oversight and information availability across the spectrum from the prehospital setting through definitive care. Areas covered by an integrated trauma system have shown a decrease mortality of 15% to 20%.[82]

Shortly after the military conflicts began in the Middle East, medical and military leaders looked toward the successes of civilian trauma systems and began to build a military system that emulated the successes seen in the civilian system.[83] The military's trauma system, the JTS, was established in 2004 and grew out of efforts in the US Army Institute of Surgical Research. Military surgeon leaders such as Colonel (Ret) John Holcomb, Colonel (Ret) Brian Eastridge, and Colonel (Ret) Don Jenkins set the stage for building on a trauma system that was informed by performance improvement with the patient at the epicenter. Given that casualties would travel 5000 to 8000 miles to reach the stateside hospital where they would undergo the majority of their care, one of the pillars of the military's trauma system was a weekly performance improvement video teleconference to discuss casualties among all the providers involved in the surgical, medical, and critical care air transport of the patients. This effort evolved over time, and CPGs were developed using the clinical casualty data. The stated mission of the JTS is "to provide evidence-based process improvement of trauma and combat casualty care, to drive morbidity and mortality to the lowest possible levels, and to provide evidence-based recommendations on trauma care and trauma systems across the Department of Defense (DoD)."

The three pillars of the JTS are described in the following sections.[84,85]

Analysis of Clinical Data from the DoDTR

Previously known as the Joint Theater Trauma Registry (JTTR), after the US Army Institute of Surgical Research program was adopted by all military services, it became the DoDTR. The registry was initially launched the same year as the JTS (2004), and it was modeled after a civilian trauma registry that was modified to capture military-relevant clinical data. Some of the strengths of civilian programs were the ability to compare outcomes to each other and over time in order to make incremental improvements and, when necessary, abandon nonbeneficial practices. The DoDTR electronically captures data in the following categories: demographics, mechanism/circumstances of injury, diagnosis, treatment, and outcomes. The patients included are comprehensive—regardless of US citizenship, military/civilian status, or presence of a wartime environment. This store of information is used for official activities, for monitoring of continuous metrics, and as a source for queries and research similar to the NTDB. Over 250 peer-reviewed publications, most relating to performance improvement, have used data from the DoDTR. As of 2018, the DoDTR has over 75,000 patient entries.

Trauma Care Delivery

The delivery of battlefield trauma care and en route combat casualty care occurs throughout the continuum of care and ideally with clinical data that get captured in the DoDTR. Standards for trauma care delivery are set by the JTS CPGs. Trauma care delivery has seen changes throughout the recent conflicts, as described earlier, in regard to the full-spectrum implementation of the principles of damage control to include early transfusion of blood products and whole blood. The refinement of battlefield trauma care is through process improvement and analysis of DoDTR data. Efforts are constantly underway to obtain increased granularity of the data with a specific interest in gathering detailed prehospital and en route care data.

Performance Improvement

Inherent in all of the JTS activities is the aspect of performance improvement (PI). Whereas this is a general motivation behind the comprehensive data acquisition and management activities of the DoDTR, specific activities and positions within the JTS are organized around PI. The development and monitored implementation of the CPG is one of the more visible PI initiatives. The effect of CPG use has been measured with reassuring results, including decrease in mortality from 32% before implementation to 21% after CPG implementation for the DCR guidelines addressed earlier.[70] A form of ongoing PI has been the use of the weekly video teleconference. This conference connects providers from every aspect of care including prehospital, the FST, CSH, Landstuhl, and military hospitals in the United States to discuss current critically ill patients to assess the quality of care and provide 360° follow-up. Also under the umbrella of PI are the constant education and readiness efforts of the JTS, including predeployment training to continuing medical education.

THE FUTURE OF THE JOINT TRAUMA SYSTEM AND THE BATTLEFIELD HEALTH CARE SYSTEM

The amount of clinical research, PI, and guideline development generated by the recent conflicts has been voluminous. The system of care that evolved and the JTS came to be without any mandate, law, or requirement. It was not until 2016 that a DoD Instruction (DoDI) required that a military trauma system (ie, the JTS) exist. This was codified in the NDAA of 2017 that established the JTS by law. From a historical perspective, it is a credit to the military leaders who had experience with the civilian trauma system that such a complex system of care grew into existence without any requirement to function. The JTS is now well established and known for establishing battlefield standards of care through the CPGs throughout the military, civilian, and international trauma communities.

Valuable lessons have been learned from prior conflicts, but the records of those lessons are too often incomplete; with the establishment of the JTS, it is hoped that this will be mitigated during future conflicts. Ultimately, preservation of the many costly lessons learned is contingent upon continuation of the systems and ideals instituted through the JTS and DoDTR. Future challenges faced by military surgeons include maintenance of trauma surgery skills in a period when the military tempo decreases and when the majority of cases done during peacetime do not support the needed trauma skill set. Elements of the new JTS are poised to address these issues by advocating (and requiring) military–civilian collaborations for trauma skill sustainment. As the military and civilian trauma systems continue to grow and collaborate with a focus on the preservation of valuable wartime lessons learned, both civilian and military members benefit; additionally, this focus on trauma readiness helps to ensure that in future conflicts the surgical force will be well poised to care for severely injured combat casualties.

Organ Donation from Trauma Patients

Naeem Goussous • Joseph R. Scalea

KEY POINTS

- Solid organ transplantation is the treatment of choice for end-organ dysfunction in many organs and provides advantages in survival and improved quality of life.
- The use of organs from HIV- and hepatitis C virus–infected donors along with advancements in organ preservation will help to narrow the gap between organ supply and demand.
- The Organ Procurement and Transplantation Network is the organization that oversees these activities.
- Trauma and acute care surgeons play a pivotal role in early management of potential organ donors.
- The transplant team does not manage the donor in donation after cardiac death until the patient dies.
- Brain death is associated with a series of events that affect every organ system, but especially the cardiovascular and respiratory systems.
- The early adoption of aggressive donor management protocols will allow maximization of organ utilization and expansion of the donor pool.
- Unmanned aircraft systems are a promising modality for more efficient and safe organ transportation.

INTRODUCTION

Advances in the field of immunosuppression, organ preservation, surgical techniques, and critical care have resulted in significant improvements in the outcomes of transplant recipients (Fig. 54-1). Indeed, in most cases, solid organ transplantation provides a survival advantage and improved quality of life when compared with standard medical therapies. It has become the treatment of choice for end-stage kidney, liver, islet, intestine, heart, and lung failure. With improved medical treatments and improved transplant outcomes, increased demand for transplantation has resulted, yielding longer waitlists. As such, there is a woeful disparity between the number of patients who require transplants and the number of available donor organs. According to the Organ Procurement and Transplantation Network (OPTN) official website (http://optn.transplant.hrsa.gov), a new patient is being added to the transplant waiting list every 10 minutes, and on average, 20 people die on the waiting list every day. Currently in the United Sates, there are 124,370 patients on the transplant waiting list (Fig. 54-2).

Major innovations in organ replacement sciences have occurred in the past decade. Living and deceased donor allogenic transplants, however, remain the favored approach for patients with organ failure. Indeed, innovative approaches such as bioengineering and organ regeneration are still in experimental stages.[1] Xenotransplantation has seen a resurgence of interest, perhaps as a result of clustered regularly interspaced short palindromic repeats (CRISPR) technology, which allows investigators to manipulate multiple animal genetic loci simultaneously. In this way, several large public–private partnerships have suggested that the first pig-to-human transplants may occur in the next 5 years.

Recent innovations in infectious disease management have changed the field of transplantation as well. In 2013, the senate passed the HIV Organ Policy Equity (HOPE) act, which allowed organs from HIV infected donors to be transplanted into patients with HIV infection.[2] Several transplant centers have initiated HIV-positive to HIV-positive transplants under research protocols. The use of organs from HIV infected donors will have the potential to expand the donor pool with 500 to 600 extra donors annually. Further, transplant centers are also routinely transplanting hepatitis C virus (HCV)–positive donor organs into HCV-negative recipients. Although counterintuitive, the development of the new direct-acting antiviral medications for the treatment of HCV infection has resulted in transformation in the management of HCV with successful eradication of the virus in greater than 98%

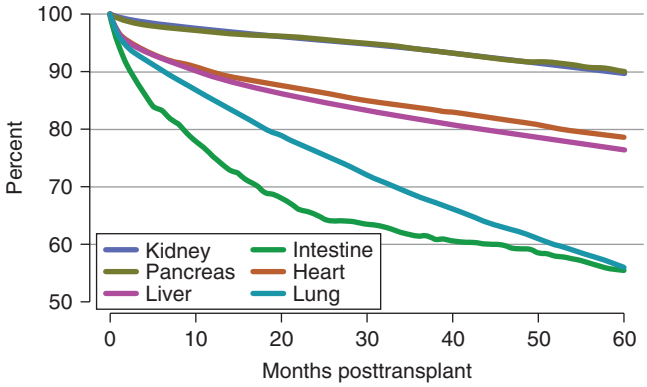

FIGURE 54-1 Patient survival among all transplant recipients, 2008 to 2012, by organ. (Reproduced from Organ Procurement and Transplantation Network. OPTN/SRTR annual report 2017. https://optn.transplant.hrsa.gov. Accessed June 2019.)

of patients. With the introduction of these highly effective anti-HCV medications, many centers are adopting policies to transplant organs from HCV-infected donors to HCV-negative recipients and treat HCV infection afterward. With this approach, the donor pool is expanded with good-quality organs.[3] The opioid epidemic has changed organ donation, as well. With the increasing number of narcotic overdoses, more and more organ donors are considered at increased risk for the transmission of viral infections (including HCV) by the US Public Health Service.

Exciting innovations in biotechnology have also advanced transplantation in recent years. Promising results with utilization of normothermic machine perfusion devices will allow more liberal use of marginal liver allografts (livers from older donors, fatty livers, and livers recovered from donors after circulatory arrest), thereby increasing the pool for all forms of organ transplantation.[4] Beyond devices for prolonging the time between explant and implant, recent exciting data suggest that organs may be able to move unmanned using remotely piloted or unmanned vehicles (ie, drones). This is of

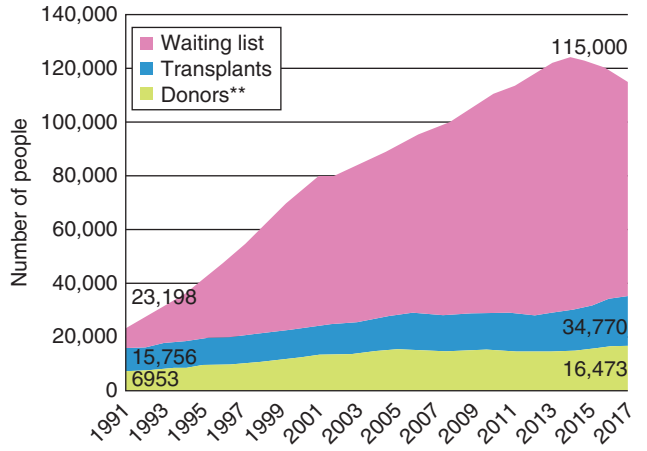

FIGURE 54-2 Total number of patients on the waiting list in the United States and the number of donors and transplants from 1991 to 2017. **Includes both living and deceased donors. (Reproduced from Organ Procurement and Transplantation Network. https://optn.transplant.hrsa.gov. Accessed June 2019.)

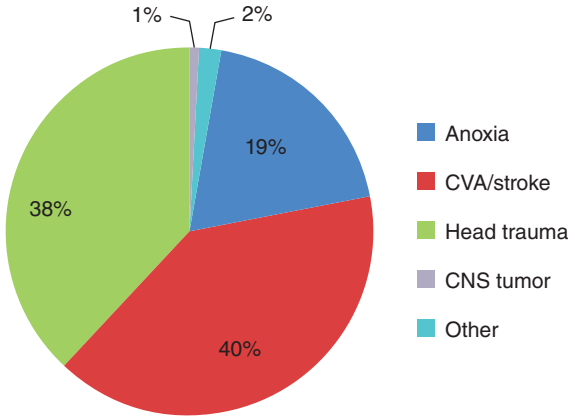

FIGURE 54-3 Pie chart demonstrating categories of deceased organ donors by cause of death in the United States from 1994 to 2014 (total number of donors = 142,822; donors with unreported cause of death are excluded). CNS, central nervous system; CVA, cerebrovascular accident. (Reproduced from Organ Procurement and Transplantation Network. http://optn.transplant.hrsa.gov. Accessed February 4, 2020.)

substantial potential benefit to the field because current shipment practices are expensive, time insensitive, and potentially unsafe for transplant recovery teams. Taken together, recent innovations are improving the delivery of transplant care.

INJURY AND DONATION

Traumatic brain injury is the second most common cause of death leading to cadaveric solid organ donation, closely following cerebrovascular accidents/stroke (Fig. 54-3). Clinicians caring for severely injured patients play a key role in the initiation and implementation of the organ donation process. Early recognition of potential organ donors is critical to maximizing the available pool of donor organs and the number of transplantable organs per donor. It is essential for those caring for potential organ donors to be knowledgeable about the criteria and process for declaring brain death and the physiologic effects of brain death. Familiarity with local organ procurement organizations (OPOs) is important because of the vital role they play in counseling the families of potential organ donors and coordinating the transplant process. Lastly, following the declaration of brain death, treatment priorities aimed at minimizing brain injury require adjustment. Afterward the priority shifts to providing physiologic support to maintain perfusion of potentially transplantable organs, and timely initiation of this support is crucial to increasing the probability of successful transplantation.

THE INFRASTRUCTURE AND ORGANIZATIONS INVOLVED IN ORGAN DONATION

Under the National Organ Transplant Act, the US Congress established the OPTN.[5] The OPTN is a unique public–private partnership linking professionals involved in the organ

donation and transplantation system. The OPTN is governed by the United Network for Organ Sharing (UNOS). UNOS is a private nonprofit charitable organization contracted by the Health Resources and Services Administration of the US Department of Health and Human Services to develop organ transplantation policy. UNOS facilitates organ transplantation by organizing the medical, scientific, public policy, and technologic resources required to maintain an efficient national transplantation system. UNOS is responsible for developing recipient priority policies and for managing the national transplant waiting lists. UNOS maintains the national transplant database, plays a very important role in raising public awareness of the importance of organ donation, and helps to keep patients informed about transplant issues and policy.

To alleviate the shortage of organs available for transplantation, the Revised Uniform Anatomical Gift Act requires OPOs and donor hospitals to have the necessary policies and procedures in place to preserve the option of donation for all patients and their families.[6] In an effort to maximize donation opportunities, the American College of Surgeons (ACS) qualitatively evaluates each hospital's organ donation practices during the trauma center verification process.[7] Specifically, the ACS requires verified trauma centers to establish a relationship with an OPO, develop policies and clinical triggers for notification of the OPO about patients with the potential for neurologic death, have a formal process to review organ donation rates, and implement protocols for the declaration of neurologic death. Organ donation, allocation, and procurement require a closely coordinated and complex series of efforts. In the United States, this process is coordinated by independent local OPOs. The United States is split into 11 UNOS regions and is covered by 58 OPOs. OPOs are responsible for two main functions within their designated service area as follows: (1) increasing the number of registered donors; and (2) coordinating the donation process when actual donors become available. OPOs employ specially trained professionals who assist with the following: (1) evaluation of potential organ donors; (2) the declaration of brain death; (3) counseling of donor family members; (4) management of the donor; (5) organ allocation; and (6) the procurement process. When an organ donor is identified, the local OPO serves to ensure that brain death has been established and assists in obtaining consent for organ donation. Thereafter, coordination of organ placement and the procurement of the organs are facilitated by the OPO. For organ allocation, UNOS maintains a centralized computer network, UNet, which links all OPOs and transplant centers in a secure, real-time environment using the Internet. Each organ waiting list incorporates specific criteria to establish individual patient ranking on the list. In general, waiting lists incorporate factors such as geography, patient's blood type, waiting time, severity of illness, and human lymphocyte antigen matching in cases of kidney allocation.

Trauma surgeons play an important role in organ donation. It has been shown that hospitals with trauma surgeons on their organ donor councils had a significantly higher number of donors per trauma admissions as well as significantly more donors per admissions.[8]

UNOS CRITICAL PATHWAY FOR ORGAN DONORS

UNOS has developed the Critical Pathway for management of organ donors, which is available through local OPOs and UNOS.[9] Preliminary data from a pilot study using this pathway showed an increase in the number of organs procured per donor. The Critical Pathway has five distinct but partially overlapping phases as follows:

Phase I (referral): When a patient with a severe brain injury is identified as a potential organ donor, critical care staff should initiate the Critical Pathway. This step establishes contact between the hospital and the local OPO and initiates referral before the potential organ donor becomes brain dead.

Phase II (declaration of brain death and acquisition of consent): Once the potential donor is confirmed brain dead, the patient's choice about organ donation is evaluated through the donor registry (usually through the motor vehicle registry) and the family is provided with this information. If no first-person consent is found, the family is approached about the option of organ donation. First-person consent supersedes a family declining the option of donation in many states and OPOs in the United States.

Phase III (donor evaluation): After consent for organ donation is obtained or confirmed through a donor registry, donor evaluation and management protocols are initiated.

Phase IV (donor management): As the donor is being evaluated, optimal management needs to be started simultaneously to achieve adequate perfusion and oxygenation of organs.

Phase V (organ recovery): Organ procurement takes place after potential recipients are identified. Various procurement teams work together to maximize organ recovery.

IDENTIFYING A POTENTIAL ORGAN DONOR

Federal law requires that every death in a hospital be called in to their respective OPO, and the OPO coordinators evaluate every call to assess suitability for donation. All patients who have suffered severe brain injuries and are either brain dead or likely to progress to brain death should be considered for organ donation regardless of their age, underlying cause of illness, and overall social history.

According to the Centers for Medicare and Medicaid Services (CMS), hospitals and respective OPOs must agree upon "triggers" to identify potential brain dead donors, although CMS does not specify these triggers. For instance, some OPOs consider an intubated patient with a Glasgow Coma Scale score of 5 or less a potential organ donor. If a patient meets initial criteria, the donation case moves on

TABLE 54-1: Absolute Contraindications to Organ Donation

- Active malignancy with evidence of spread outside affected organ
- Primary intracerebral lymphoma and secondary intracerebral tumors
- Melanoma
- Active hematologic malignancy
- Tuberculosis: active and untreated
- West Nile virus infection
- Coroner exclusion

to the next step in the process, which is referral to the local OPO. Although perceived contraindications to donation may exist, they should be discussed with a representative of the local OPO before concluding that a given patient is not a candidate for organ donation (Table 54-1). Bacteremia, fungemia, and high-risk social history are not absolute contraindications. For increased-risk donors, a nucleic acid test is performed to detect recently acquired HIV, HCV, or hepatitis B virus (HBV) infections when routine serology tests are negative. Sometimes, donors with HCV, HBV, and HIV are considered suitable for organ donation. For instance, an otherwise normal liver or a kidney from a donor with HCV infection can be transplanted into an HCV-infected recipient as previously noted. Trauma to the chest and/or abdomen is not uncommon in potential organ donors. Appropriate surgical management is required to control bleeding and prevent complications such as a pneumothorax. Typical interventions include insertion of a thoracostomy tube, laparotomy, or splenectomy. A retroperitoneal hematoma, hepatic and splenic lacerations, and an open abdomen are not contraindications to utilization of an abdominal organ; however, such circumstances demand careful evaluation of organs at the time of procurement. A computed tomography (CT) scan using intravenous contrast is important in the assessment of severity of injury and vascular integrity.

The physician caring for a potential organ donor is responsible for notifying the local OPO of such patients. All OPOs employ personnel who are responsible for advising health care providers on the suitability of an individual patient for organ donation. Communication with local forensic authorities is extremely important. The OPO will contact the medical examiner or coroner in order to obtain permission to proceed with organ donation. Once a donor is identified, the OPO is responsible for obtaining family consent for organ donation. Organ procurement specialists are trained in counseling families about the importance and process of organ donation, and it is advisable to refer families to these specialists when potential organ donation is discussed. Also, these individuals perform a careful review of the potential donor's social and past medical history. The circumstances leading to brain death are very important, as is any history of the occurrence and duration of cardiopulmonary arrest. Screening also includes an extensive laboratory and serologic evaluation to exclude chronic diseases and transmissible infections. A donor profile is then generated and includes current hemodynamics as well as an assessment of current organ function. The assessment of organ function is individualized to the donor based on the donor profile, the specific organs under consideration, and the level of medical support required to maintain the donor. The overall profile that is generated is crucial for transplant physicians who must evaluate the suitability of a given organ donor for the individual recipient.

DECLARATION OF BRAIN DEATH

Brain death occurs when a person has an irreversible, catastrophic injury which causes total cessation of brain function. Some causes of brain death include (but are not limited to) the following: (1) trauma to the brain (eg, severe head injury caused by a motor vehicle crash, gunshot wound, fall, or blow to the head); (2) cerebrovascular accident (eg, stroke or rupture of an aneurysm); (3) anoxia (eg, respiratory arrest, drowning); and (4) brain tumor. Ethical standards in the United States mandate that all organ donors must be declared dead before organ donation can proceed. Brain death must therefore constitute a sufficient basis on which to declare a person legally dead. The vast majority of cadaveric organs are procured from donors whose deaths are declared on the basis of brain death. Consequently, cadaveric organ donation is dependent on the ability to reliably determine that a patient is brain dead. Unfortunately, many clinicians remain poorly informed about brain death and how it is defined. The current concept of brain death used in the United States is based on guidelines published in 1981 by the President's Commission for the Study of Ethical Problems and adopted under the Uniform Determination of Death Act (Table 54-2).[10] This act states that death has occurred when there is irreversible cessation of all functions of the brain including the brainstem. Each state government has adopted these guidelines in legislating local criteria for the determination of brain death. The qualifications and number of physicians who must agree on the diagnosis of brain death in order to legally declare a patient brain dead vary considerably among different states.

TABLE 54-2: Defining Brain Death

Preconditions

Coma with known cause

Documentation of irreversible structural brain injury

Exclusions (preclude diagnosis of coma)

- Hypotension
- Hypothermia
- Hypoxemia
- Drug intoxication
- Metabolic derangements

Tests

Absence of brainstem function; pupillary, corneal, oculovestibular, gag, and cough reflexes absent

Apnea (strict definition)

Electroencephalogram not indicated

Some states require two separate declaration procedures with a defined time interval between the two examinations. Some states require that two separate physicians make the declaration. In other states, a single physician may declare a patient brain dead on the basis of one examination. In no case can the declaring physician take part in the recovery or transplantation of organs from the donor. Most hospitals have established policies within state guidelines for physician qualifications required to make the diagnosis of brain death. Physicians caring for these patients should be aware of local requirements and hospital guidelines in order to facilitate the declaration process and allow termination of care for brain dead patients who will not be organ donors.

Symptoms that support the diagnosis of brain death are the absence of brainstem reflexes, absence of cortical activity, and demonstration of the irreversibility of this state.[11] Therefore, in order to declare brain death, there must be a proof of the cause of the brain injury; otherwise, the irreversibility requirement cannot be met. Secondly, all reversible causes of coma must be excluded. Causes of reversible coma include hypothermia, hypoxia, hypoglycemia, hyperglycemia, uremia, hepatic failure, Reye syndrome, hyponatremia, hypercalcemia, myxedema, adrenal failure, and central nervous system (CNS) depressants. The presence of CNS-depressing agents such as narcotics, sedatives, anticonvulsants, anesthetics, and alcohol must be assessed. If any of these agents are present, confirmatory testing is usually required to declare brain death.[12] In the brain dead patient, all cranial nerve functions will be absent. The absence of brainstem reflexes must be confirmed by careful neurologic examination. Neuromuscular conduction must be intact in order to allow adequate examination; consequently, the presence of neuromuscular blocking agents must be excluded.

The most definitive finding supporting the diagnosis of brain death is the presence of apnea. The apnea test remains one of the most important parts of the neurologic evaluation of potential organ donors.[13] To perform a reliable apnea test, the $Paco_2$ is normalized to 40 mm Hg. The patient is preoxygenated with 100% oxygen for at least 5 minutes. The patient is then disconnected from the ventilator and placed on 100% oxygen delivered passively to the endotracheal tube via a T-piece at 8 to 12 L/min. The $Paco_2$ is allowed to rise to 60 mm Hg, confirmed by a blood gas drawn after approximately 10 minutes. If hemodynamic instability occurs, the patient should be immediately returned to mechanical ventilation and a blood gas should be drawn to assess the $Paco_2$. If there is any evidence of respiratory activity, the patient is not brain dead and should be immediately returned to the ventilator. If there is no evidence of spontaneous respiratory activity, the $Paco_2$ has reached 60 mm Hg, and the pH is acidotic, apnea is established and is strongly supportive of brain death.

In many cases, confirmatory testing must be performed in addition to a careful neurologic examination in order to firmly establish the diagnosis of brain death. Patients with cervical fractures above the level of C4 may not have intact diaphragmatic function, precluding a reliable apnea test. Apnea testing is also unreliable in patients with overdoses of substances that depress respiratory drive such as alcohol, antiseizure medications, and sedatives. Hemodynamic instability during apnea testing will also preclude the establishment of the diagnosis of brain death on the basis of apnea. In other cases, local requirements and/or hospital policy may dictate the use of additional confirmatory testing. Confirmatory tests may also be useful in demonstrating a clear etiology for brain death or severe anatomic damage and can decrease the observation period required to establish the diagnosis of brain death.[12]

Confirmatory tests of brain death include an electroencephalogram (EEG) and methods of demonstrating the absence of cerebral blood flow. EEGs are not entirely reliable and are now rarely used for this purpose with the exception of brain death determination in young infants. Demonstration of the absence of cerebral blood flow is the most common confirmatory test currently in use. Methods used to make this determination include cerebral angiography, Doppler ultrasound scanning, and radionuclide cerebral blood flow scanning. The latter two methods are noninvasive, low risk, relatively inexpensive, and more readily available than cerebral angiography. These tests are highly accurate in verifying the absence of cerebral blood flow and are useful in reducing the time required to establish the diagnosis of brain death. Conversely, an examination that indicates continued cerebral blood flow does not necessarily exclude the diagnosis of brain death. Uncommonly, cerebral blood flow may persist despite brain death due to testing before increasing intracranial pressure completely shuts down flow, skull pliability in infancy or in the presence of decompressing fractures, ventricular shunts, ineffective deep brain flow, reperfusion, brain herniation, jugular reflux, the presence of emissary veins, and pressure injection artifacts.[14]

Appropriate documentation of brain death is very important in facilitating organ donation for a brain dead patient. The diagnosis of brain death must be documented in writing, and it must be unequivocal. The circumstances leading to brain injury, the specific findings of the neurologic examination, and the results of any confirmatory tests should be clearly recorded. Lastly, the date and time of the declaration of brain death must be noted before OPO personnel may obtain the permission of local authorities and the consent of the potential donor's family. Despite the presence of evidence indicating a person's desire to be an organ donor, family consent for donation must be obtained. Family refusal is the most common reason that otherwise suitable donors do not become organ donors. If consent for donation is declined, appropriate testing and documentation of brain death are necessary in order to initiate the withdrawal of care.

The most common form of deceased donation is donation after brain death (DBD). For DBD, donors are brought to the operating room intubated and frequently on vasoactive medications. Surgical recovery teams confirm brain death testing, brain death documentation, laboratory values, and blood group. Thereafter, the recovery teams work in concert with recipient teams and hospitals to confirm the logistics of presumed aortic cross-clamp and organ recovery times. This

is important because organs need to be transplanted expediently to reduce cold ischemia time. In some patients with catastrophic brain injuries, the intracranial pressure (ICP) is maintained and brain death does not occur; however, in these patients, the severity of neurologic injury is such that no meaningful neurologic recovery is anticipated. As such, regardless of the disease process, families may elect to withdraw life support because of a hopeless prognosis. In these cases, patients can still donate under a practice known as donation after cardiac death (DCD).

DCD can be controlled or uncontrolled. Controlled DCD involves planned withdrawal of ventilatory and organ perfusion support in the face of catastrophic illness, usually in the operating room. Uncontrolled (currently not practiced in the United States) DCD involves unexpected cardiopulmonary arrest and/or unsuccessful resuscitation (Maastricht classification I, II, or IV).[15] Controlled DCD offers the patient and the family the opportunity to donate organs when criteria for brain death are not met prior to cardiac death. The procurement/transplant team plays no role in whether or when support will be withdrawn.

PHYSIOLOGIC CONSEQUENCES OF BRAIN DEATH

Brain death is usually associated with increased ICP, causing physiologic responses, mainly in the cardiovascular and respiratory systems.[16] Disruption of normal autonomic regulation may lead to profound vasodilation and hypotension. In turn, decreased organ perfusion is injurious to potentially transplantable organs.

Cardiovascular

Increased ICP is associated with marked sympathetic stimulation (catecholamine storm), resulting in arterial hypertension, intense vasoconstriction, raised systemic vascular resistance, tachycardia, and direct myocardial depression.[16] Echocardiographic evidence of myocardial dysfunction is seen in 40% of brain dead donors being considered for heart donation.[17] After the catecholamine storm, there is a loss of sympathetic tone causing peripheral vasodilatation and hypotension, resulting in hypoperfusion of all organs and leading to significant injury that may preclude organ donation if not corrected in a timely fashion.

Respiratory

Respiratory dysfunction associated with brain death will have profound effects on all other organ systems due to hypoxia. Impaired gas exchange is common in brain dead patients who have required mechanical ventilation for any length of time. Pulmonary infection and/or aspiration injury frequently occur in potential organ donors. Neurogenic pulmonary edema is another cause of impaired gas exchange that may accompany brain death.[18] Myocardial dysfunction may also contribute to lung dysfunction due to increases in left atrial pressure, thereby potentiating pulmonary edema. Hypoxemia will further impair myocardial function, leading to a precarious hemodynamic state.

Endocrine

A number of hormonal changes occur after brain death and reflect anterior and posterior pituitary failure. There is early depletion of antidiuretic hormone and development of diabetes insipidus in almost 80% of brain dead organ donors. This is characterized by inappropriate diuresis, severe hypovolemia, hyperosmolality, and hypernatremia. These changes may exacerbate neurogenic pulmonary edema and lead to tissue hypoperfusion. If not managed appropriately, diabetes insipidus will have a profound effect on fluid and electrolyte balance. A rapid decline in free triiodothyronine (T_3) is seen after brainstem death. Insulin levels fall after brain death, leading to a decrease in intracellular glucose concentration, the development of an energy deficit, and a shift toward anaerobic metabolism and acidosis. Significant decreases in cortisol levels occur after brain death as a result of a decreased release of the stimulating factor adrenocorticotropic hormone (ACTH) from the anterior pituitary. The administration of exogenous corticosteroids has been associated with stabilization of organ function.

Other interrelated effects of brain death include endothelial activation, systemic release of proinflammatory cytokines, complement activation, and consumptive coagulopathy. Without appropriate intervention, brain death is followed by severe injury to all other organs, and circulatory collapse will usually occur within 48 hours.

MANAGEMENT OF THE DONOR

Prior to the declaration of brain death, the treatment of patients with severe brain injury is directed at controlling ICP and preserving cerebral perfusion pressure in order to limit secondary brain injury. Once the diagnosis of brain death is established and a patient is recognized as a potential organ donor, treatment priorities must shift in favor of preserving the function of potentially transplantable organs. Preservation of organ function requires maintenance of adequate organ perfusion. The most common derangements requiring interventions are the previously mentioned hypothermia, hypotension, and diabetes insipidus. Because of the profound effects on the cardiovascular system, invasive hemodynamic monitoring is essential to guide the appropriate resuscitation of brain dead patients. Central venous access should be obtained to allow measurement of volume status and to provide a reliable means of administering vasoactive drugs. Arterial access is required to facilitate continuous monitoring of blood pressure and frequent measurement of acid–base status, gas exchange, and serum biochemical parameters.

One of the strategies with proven success in increasing organ donation is utilization of an aggressive donor management (ADM) protocol, by decreasing the number of donors

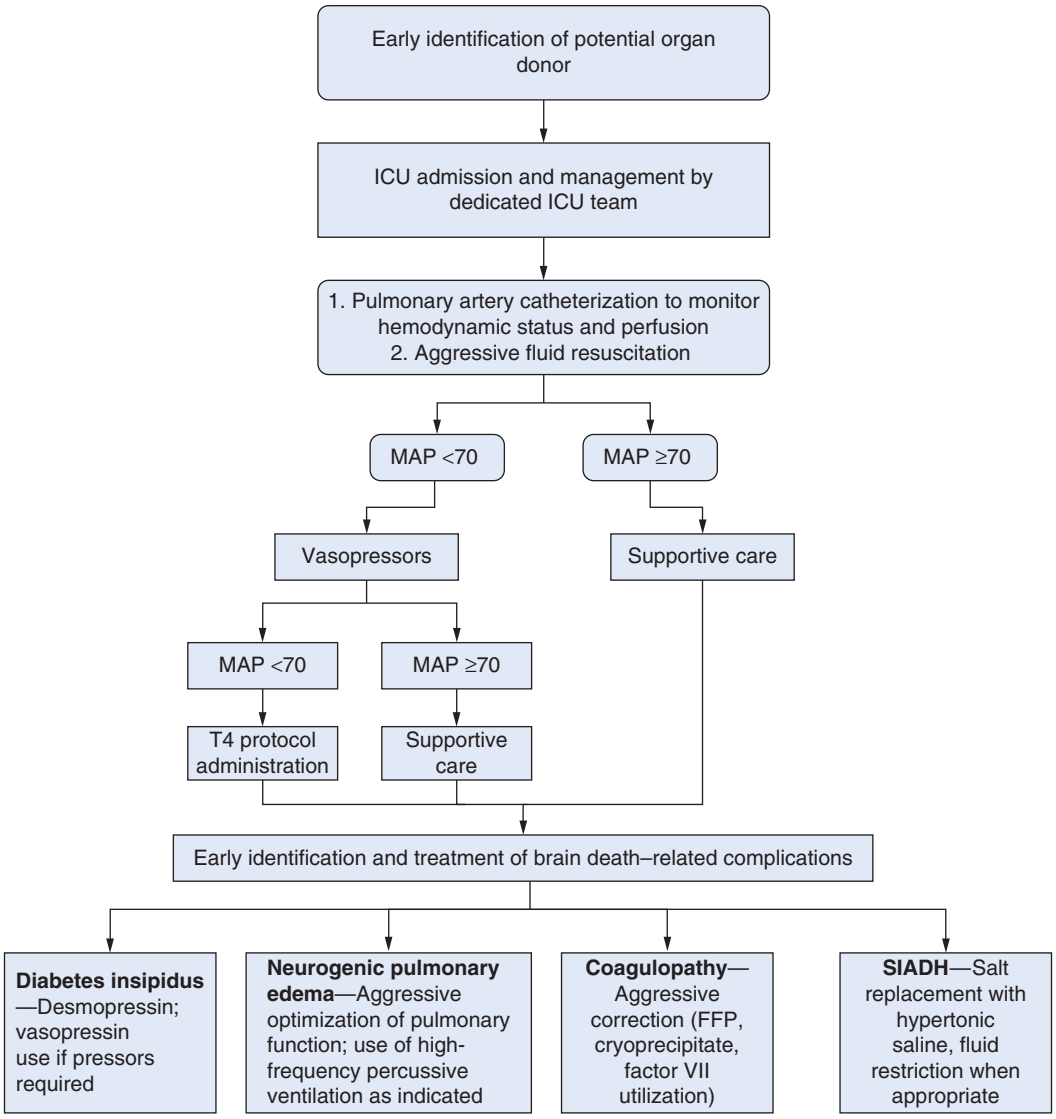

FIGURE 54-4 Protocol for aggressive donor management. FFP, fresh frozen plasma; ICU, intensive care unit; MAP, mean arterial pressure; SIADH, syndrome of inappropriate antidiuretic hormone; T4, thyroxine. (Reproduced with permission from DuBose J, Salim A. Aggressive organ donor management protocol. *J Intensive Care Med*. 2008;23(6):367-375.)

lost as a result of cardiovascular collapse.[19] The components of ADM include the following (Fig. 54-4): (1) early identification of potential donors; (2) admissions and management by a dedicated team; and (3) early and aggressive resuscitation with fluids, vasopressors, and hormone therapy.

Hypovolemia is common in brain dead patients due to vasodilation and, in some cases, blood loss as a result of trauma or fluid loss due to diabetes insipidus. In general, patients should be resuscitated with crystalloid solutions and appropriate blood products based on measurements of hematocrit and coagulation status. Resuscitation should be guided by frequent monitoring of central venous pressure or pulmonary capillary wedge pressure. Avoiding excessive fluid loading in donor management is associated with increased numbers of transplantable lungs and pancreas.[20] Body temperature must be monitored and should be maintained above 36°C using passive warming as needed. Urine output should be maintained at 2 mL/kg/h. Renal dose dopamine (3–5 mcg/kg/min) is recommended for nearly all donors unless higher doses are required to maintain perfusion. Vasopressin should be infused to treat diabetes insipidus when present, and fluids should be adjusted on the basis of electrolyte measurements. Serum sodium and osmolarity should be kept as normal as possible. Replacement fluids should be based on measurements of serum electrolytes and urine output. Frequent serum glucose measurements are required to facilitate treatment of hyperglycemia.

Inotropic support should be introduced to support blood pressure if initial volume resuscitation fails to restore adequate perfusion pressure.[21] Dopamine is usually the first agent of choice, as noted earlier. Pure vasoconstrictors such as norepinephrine should be avoided whenever possible due to

deleterious effects on myocardial and splanchnic perfusion. Dobutamine is frequently added to increase cardiac output. If these agents are not effective at restoring hemodynamic stability, an epinephrine infusion should be initiated and titrated to the lowest dose required to achieve adequate support. The use of high doses of norepinephrine in donors is associated with increased cardiac graft dysfunction, particularly right ventricular performance, and higher early and late mortality in the recipients. Thyroxine (T_4) or T_3 infusions are commonly used due to their inotropic effects and potentiation of myocardial catecholamine sensitivity.[22-24]

Ventilator management in potential organ donors is guided by the respiratory function of the donor. Pulmonary injury is common in brain dead patients, and all attempts should be made to preserve the possibility of lung donation. As mentioned previously, fluid overload must be avoided and infusions should be guided by measurements of central venous pressure. Chest x-rays should be obtained to assess pulmonary expansion, guide appropriate intervention to counteract atelectasis, and assess the suitability for transplantation. A nasogastric tube should be placed and kept on suction in order to minimize gastric distension and the risk of aspiration. An endotracheal tube with an internal diameter of 7.5 mm or larger should be inserted whenever possible in order to accommodate a therapeutic size fiberoptic bronchoscope. This will assist in the evaluation of potential lung donation and will facilitate clearing secretions to optimize lung expansion. Excessive mean airway pressures should be avoided. Tidal volumes and physiologic levels of positive end-expiratory pressures (PEEP) should be maintained to provide adequate lung expansion and minimize atelectasis. High concentrations of inspired oxygen are injurious to the lungs and should be avoided. The inspired oxygen concentration should be titrated to maintain an oxygen saturation of 95%. In patients with significant pulmonary injury, lung donation is unlikely; therefore, increased levels of PEEP and higher inspired oxygen concentrations may be required (Table 54-3).

TABLE 54-3: Donor Management Goals

- Mean arterial pressure: 60–100 mm Hg
- Central venous pressure: 4–10 mm Hg
- Ejection fraction: 50%
- Vasopressors: ≤1 and low dose[a]
- Arterial blood gas pH: 7.3–7.45
- Pao_2:Fio_2: >300
- Serum sodium: 135–155 mEq/L
- Blood glucose: <150 mg/dL
- Urine output: 0.5–3 mL/kg/h over 4 h

[a]Low dose of vasopressor was defined as dopamine ≤10 mcg/kg/min, neosynephrine ≤60 mcg/kg/min, and norepinephrine ≤10 mcg/kg/min.

The impact of meeting donor management goals on the number of organs transplanted per donor: results from the United Network for Organ Sharing Region 5 prospective donor management goals study. *Crit Care Med.* 2012;40:2773-2780.

ORGAN PROCUREMENT

The actual process of multiorgan procurement occurs in the operating room environment under the usual sterile conditions. Representatives of the local OPO will coordinate the use of the operating room with various transplant procurement teams involved with a particular donor. Frequently, this procedure may involve several teams whose members are operating together for the first time. In addition, the initial phases of the recipient operations for heart and lung recipients are commonly carried out simultaneously with the donor procurement procedure in order to minimize graft ischemia time.

The logistics of organizing the donor operating room fall to the OPO. Frequently, the timing of the organ procurement is dependent on the wishes of the donor family. Donor operating room timing is also informed by the availability of the recovering surgeons as well as the needs of the transplant recipients. For example, a heart recipient with a ventricular assist device may have operative challenges that limit the timing of both the donor and the recipient operating room procedures. Operating room timing may also be affected by the availability of rooms and staffing, particularly at smaller hospitals.

Procurement procedures may be as short as 30 minutes for a DCD in which kidneys alone are recovered or as long as 4 to 5 hours when both abdominal and thoracic organs are recovered. Unexpected delays at the donor facility or any extra tests or procedures needed (eg, liver biopsy, bronchoscopy, and/or blood gas results for lung transplantation) may affect the length of the donor procedure as well. Beyond medical and technical delays, potential intraoperative organ declines by a procuring team and the need to reallocate the organ to different teams may also occur, adding time to recovery and transport.

Before the start of the recovery procedure, the donor history, labs, and imaging are reviewed and the death note is reviewed by procuring teams, as previously noted. The instruments needed for a procurement include a major abdominal tray with a large sharp Balfour retractor, an electrical sternal saw or a Lebsche knife, and a Finochietto retractor. An anesthesiologist is required to provide physiologic support to the donor during the procurement procedure. The donor patient is prepped and draped to allow an incision from the sternal notch to the pubis. In this manner, the thoracic and abdominal organs can be evaluated and procured simultaneously. In all cases, the final determination of organ suitability for transplantation is made after visual inspection and manual palpation of the organ and other viscera to rule out any malignancy. Biopsy of any suspicious lesions should be performed, and pathologic evaluation of frozen sections must be confirmed before the recipient transplant operation is initiated. Similarly, biopsies of liver and kidneys may be required to evaluate the quality of organs in some donors.

In the case of brain dead donors, the intended organs are prepared for rapid removal after exsanguination of the patient. For this purpose, the important vascular structures of the

respective organs are identified and the organs are mobilized. The patient is systemically anticoagulated with a large dose of heparin. Appropriate vascular cannulas are inserted in the abdominal and thoracic vessels to allow rapid flushing of the organs being procured. There are a number of preservation solutions in use, and these vary according to the organ being procured and the preference of the procuring institution. All preservation solutions are kept at approximately 4°C because hypothermia is a key element of organ preservation. When all members of the procuring teams are prepared, the superior vena cava, ascending aorta, and supraceliac aorta are clamped. The inferior vena cava is transected at the cavoatrial junction, and blood is suctioned from the open inferior vena cava, exsanguinating the patient. The left atrium is vented in order to prevent left ventricular distension and back pressure on the pulmonary vascular bed. Preservation fluids are infused through the previously placed cannulas, flushing the procured organs of blood and rapidly lowering their temperature. Topical ice is applied, augmenting rapid cooling. Thereafter, the heart and lungs are usually removed first. Donor hepatectomy is then carried out, followed by removal of the kidneys. Variations in this sequence are required when the pancreas and/or small bowel are also procured. The iliac vessels and occasionally segments of the descending thoracic aorta are then removed to provide additional vascular conduits that are sometimes necessary for complex vascular reconstructions at the time of organ implantation. All organs are inspected on the back table to ensure that no surgical damage has occurred. Finally, the organs are placed in sterile containers containing cold preservation solution. The containers are then packed in ice in preparation for transport to the location where transplantation will occur. Once all solid organs are removed, any additional tissues approved for donation are removed.

In case of procurement from DCD, hospitals have their own protocols for withdrawal of life support and declaration of cardiac death. In principle, the withdrawal of life support occurs in the operating room. Heparin is administered prior to withdrawal of support, except in the rare case when it might be expected to hasten death and/or is prohibited per local procurement protocol. Morphine and/or other analgesics may be given at the discretion of the patient's treating care team if the purpose is to minimize discomfort according to accepted end-of-life protocols. The initial required instruments are set up on a Mayo stand to expedite the first steps of the procurement, which involves entry into the abdominal and thoracic cavities and gaining access to the abdominal aorta. Procurement team members do not participate in decisions regarding the use of such agents and/or declaration of death. Members of the procurement team are not present in the operating room at the time of withdrawal of support and until the declaration of death. During this period, the OPO coordinators document hemodynamic measurements every minute. After cessation of cardiorespiratory function, the patient's treating physician declares death. Subsequently, a waiting period, typically 2 to 5 minutes, is observed prior to initiation of procurement to ensure that cardiac activity does not resume. After this waiting period, the procuring teams rapidly enter the abdominal and thoracic cavities and cannulate the respective blood vessels for flushing the organs with preservation fluid. Following this, the procurement proceeds similar to that in brain dead donors. When performed, premortem cannulation of the femoral artery and femoral vein prior to withdrawal of support decreases the rush inherent with the rapid recovery technique and may decrease warm ischemia time. If the patient has not been declared dead within the time frame stipulated by the local procurement protocol (usually 60 minutes), then the donation is aborted and the patient is returned to the intensive care unit for comfort care.[25]

Some centers use premortem cannulation in conjunction with postmortem extracorporeal membrane oxygenation (ECMO) to restore the flow of warm oxygenated blood to the intra-abdominal organs during the interval between death and organ procurement, possibly improving graft function. This is done by cannulation of the femoral artery and vein on one side for the ECMO circuit and the contralateral groin is cannulated with an intra-aortic balloon occluder that is placed in the descending thoracic aorta above the diaphragm to prevent cardiac reanimation. The cannulation and confirmation of intra-aortic balloon placement are done in the intensive care unit premortem. After withdrawal of life support and after the mandatory waiting period is observed, the balloon occluder is inflated and the ECMO circuit is initiated. The donor is then transferred to the operating room where a standard organ procurement is performed and the organs are flushed in a retrograde fashion with cold preservation solution via the arterial cannula.[26]

ORGAN PRESERVATION AND SHIPMENT

Organ shipment in the United States is arranged by OPOs. Organs are shipped by ground transport, helicopter, and airplane, depending on the time the organ needs to arrive at the transplant center. Culturally, hepatic and thoracic surgeons recover their recipient's organs and subsequently perform the transplant procedure as well. As a result of redistricting processes, however, this cultural norm may be changing because of the increased frequency with which organs are traveling further distances.

Historically, organs have been preserved using "cold storage," wherein organs are placed in preservation solution and packed in ice. This process has the effect of reducing the tissue metabolic rate of the organ and prolonging the organ's "shelf life." With normothermic perfusion, organs are placed on special pumps that perfuse the organ with warmed, oxygenated blood after recovery and prior to transplantation. This practice mimics posttransplant physiology and may prolong the allowable time between explant and implant. There are several devices in use that have shown promise in hepatic and kidney transplantation.[4] Hypothermic perfusion is performed as well. In this scenario, kidneys are perfused with a hypothermic solution rather than being placed in static cold

storage. Of interest, these organs have lower rates of delayed graft function after transplantation.[27]

With changing organ allocation systems, solid organs are moving further distances and experiencing longer cold ischemia times in many cases. This has led to several problems, including the challenge of finding on-demand small aircraft. To this end, investigators have recently begun testing organ shipment using unmanned aircraft systems (UAS). The benefits of UAS organ shipment would be reduction of cold ischemia time, improved safety for the organ recovery team (only the organ travels, not the team), decreased cost, improved outcome, and better access to organ location and estimated time of arrival. While experimental, these technologies have shown great promise.[28]

CONCLUSION

Organ transplantation benefits thousands of people every year in the United States. There is, however, a critical shortage of organs available for lifesaving transplantation with no increase in the numbers of deceased donors in recent years. A significant number of deceased donors in the United States are victims of trauma. Therefore, health care providers who care for injured patients will continue to play an important role in the identification and critical care management of potential organ donors. It is imperative that trauma surgeons and personnel be aware of the critical steps involved in organ donation and advanced protocols in the management of potential organ donors.

Rehabilitation

Paul F. Pasquina • Caitlin L. McAuliffe-Gray • Ingrid A. Parrington

KEY POINTS

- The fundamental principles of rehabilitation are founded on mitigating and preventing (when possible) the effects of immobility.
- Daily range-of-motion, flexibility, and muscle strengthening exercises help maintain the appropriate balance of muscle activity across joints and can be used to both prevent and treat muscle atrophy, disuse osteoporosis, and contracture formation.
- Immobilized patients have a reduction in blood volume, venous return, and stroke volume.
- Decreased gastric transit time in immobilized patients may cause symptoms of gastroesophageal reflux, regurgitation, and heartburn.
- To determine pain level, most health care organizations use a visual analog scale typically ranging from 0 (no pain) to 10 (worst imaginable pain).
- Approximately 12,000 spinal cord injuries occur nationally each year, and approximately 259,000 trauma survivors are living with spinal cord injuries in the United States.
- Spinal cord injuries are classified by their severity and level of injury, using the American Spinal Injury Association Standard Neurological Classification Worksheet.
- Between 25% and 80% of patients with a spinal cord injury eventually develop a decubitus ulcer.
- It is estimated that 19% to 23% of military service members who deploy overseas sustain a concussion or mild traumatic brain injury.
- Vascular occlusive diseases cause over 80% of amputations and account for nearly 30,000 new cases annually.

INTRODUCTION

The goal of rehabilitation is to optimize an individual's physical, cognitive, and psychological recovery from a disease, injury, or traumatic event to maximize the patient's functional independence. This is achieved through an interdisciplinary team of professionals who use therapeutic exercise, assistive technology, patient and family education, and fundamental rehabilitation principles to prevent secondary injury, optimize pain control, and achieve established patient goals. Although the first priority in treating trauma casualties is to preserve life, early initiation of rehabilitation can have a significant positive impact on recovery, length of stay, community reintegration, and quality of life.[1]

Trauma patients, especially those who sustain spinal cord injury (SCI), traumatic brain injury (TBI), burns, and/or amputation, often experience polytrauma and are particularly vulnerable to secondary complications, which are best addressed by early preventative strategies. Rehabilitation professionals are especially skilled at mitigating the risks in developing secondary complications frequently associated with trauma; therefore, consultation to rehabilitation specialists should be initiated upon early hospitalization. In fact, evidence demonstrates that early mobilization in the intensive care setting results in fewer ventilator days, fewer intensive care unit and hospital days, less hospital complications, less sedation and delirium days, improved overall functional outcomes, reduced overall hospital cost and mortality, and increased likelihood of being discharged home.[2] The rehabilitation team can also be very helpful regarding other critical decisions during the acute management of trauma patients, including pain control strategies, bowel and bladder management, selection of definitive amputation levels, facilitating patient and family education, and disposition considerations, including the timing of transfer to a rehabilitation center.

As in other areas of medicine, subspecialty designation within the field of rehabilitation is common. Many physicians, therapists, nurses, and counselors receive subspecialized

training and board certification in areas such as spinal cord medicine, neurologic rehabilitation, amputee care, and TBI. Rehabilitation facilities themselves receive special accreditation by the Commission on Accreditation of Rehabilitation Facilities (CARF), which helps to ensure quality.[3] The National Institute on Disabilities and Rehabilitation Research (NIDRR) also recognizes excellence in rehabilitation institutions with their Models Systems Programs for Burns, SCI, and TBI.[4]

Trauma providers should not wait until the resolution of all medical and surgical issues before engaging in rehabilitation interventions; rather, they should be initiated early during hospitalization and remain an integral part of every trauma patient's care. Furthermore, health care professionals should recognize that the quality of the medical, surgical, and rehabilitative interventions provided during the acute phase of trauma casualty care will likely have longlasting implications for the patient's overall recovery, functional independence, and quality of life.

EFFECTS OF IMMOBILITY

The fundamental principles of rehabilitation are founded on mitigating and preventing (when possible) the effects of immobility. The physiologic and psychological effects of immobility lead to adverse organ system changes that may complicate healing and recovery. A thorough understanding of these potential consequences will help optimize any treatment plan.

Musculoskeletal Effects

MUSCLE ATROPHY AND WEAKNESS

Muscle responds to alterations in loading conditions. Whereas increased activity leads to muscle fiber hypertrophy, less activity may result in disuse atrophy. The muscles most affected by such disuse atrophy during immobilization are the antigravity muscles of the lower limbs and trunk. Thus, muscles with different functional roles atrophy at different rates during unloading.[3] In addition, during immobilization, the rate of protein synthesis declines while proteolysis increases. The resulting loss in total body protein is accompanied by a significant remodeling of muscle architecture, including loss of sarcomeres both in series and in parallel, leading to reduced muscle thickness and length.[5] As a result, it is estimated that immobilization leads to a loss of strength at a rate of 10% to 15% per week.[6] It is also recognized that muscle strength decreases at a faster rate than muscle size, indicating that, in addition to atrophy, other factors contribute to muscle weakness,[7] such as a decrease in mitochondrial volume density. This can result in reduced muscle oxidative capacity and loss of endurance.[8,9]

DISUSE OSTEOPOROSIS

Bone, like muscle, is sensitive to loading stresses. Bone mass increases under mechanical stress and decreases in the absence of muscle activity or gravitational forces. During bedrest, an unloaded skeleton leads to a decrease in bone formation with little to no impact on the rate of bone reabsorption, resulting in disuse osteoporosis because of a mismatch between bone growth and bone loss. It is estimated that bone mineral density reduces at a rate of 1% to 2% each month during immobilization.[10,11] Patients with preexisting osteopenia or osteoporosis are especially susceptible to bone mineral turnover during immobilization, resulting in a greater risk of osteoporotic-related fractures. Individuals with major limb loss are also susceptible to significant bone mineral loss, particularly when the amputation is performed at the proximal transfemoral level.[12] This is further complicated with any delay in weight bearing from poor soft tissue healing, infection, fracture, or difficulty with prosthetic fitting.[13] Finally, because of the high rate of bone reabsorption, trauma casualties are also at risk for hypercalcemia; therefore, calcium levels should be monitored closely.[14]

CONTRACTURES

A contracture is defined as a shortening of a muscle or connective tissue, which prevents movement through the normal range of motion. Joint contractures are classified according to etiology as either myogenic or arthrogenic. *Myogenic* contractures are caused by changes in muscle, tendon, or fascia. Although reduction in muscle length clearly contributes to the formation of a myogenic contracture, remodeling of intramuscular connective tissue during immobilization also plays a significant role. Such changes have only been observed when the muscle is immobilized in a shortened position, suggesting that limb positioning plays a direct role in connective tissue properties.[15] *Arthrogenic* contractures are caused by changes in bone, cartilage, synovium/subsynovium, capsule, or ligaments. Proliferation of intra-articular connective tissue, adaptive shortening of the capsule, and increases in cross-linking of collagen fibrils promote this type of contracture formation.[16]

PREVENTION AND TREATMENT

The best way to prevent the deleterious effects of immobility on the musculoskeletal system is to keep immobilization to a minimum. Strength, endurance, and flexibility programs are integral to both the prevention and treatment of musculoskeletal damage. Physical therapists, occupational therapists, and the nursing staff should promote activity as soon as it is determined to be safe by the medical and surgical teams. Resistance exercise has been shown to both maintain muscle protein synthesis and increase bone mass, reducing the incidence of muscle atrophy and disuse osteoporosis during immobilization.[7] Electrical stimulation may also be helpful by passively contracting skeletal muscle and maintaining muscle oxidative capacity.[17] Daily stretching has been shown to prevent serial sarcomere loss and reorganization of tissue components, leading to a reduced risk of muscle atrophy and contracture formation. Daily range-of-motion, flexibility, and muscle strengthening exercises help maintain the appropriate

balance of muscle activity across joints and can be used to both prevent and treat muscle atrophy, disuse osteoporosis, and contracture formation.[18]

Cardiovascular Effects

SHIFT OF BODY FLUIDS

Lying in a supine position eliminates the gravitational gradient normally present during standing, leading to a fluid shift of approximately 1 L from the legs to the thorax. The resultant increase in pressure within the heart's ventricles causes an increase in diastolic filling and stroke volume. As a consequence, the regulatory mechanisms within the heart react to this increase in intrathoracic volume, triggering urinary excretion, reduced thirst, resetting of the cardiopulmonary baroreflex, and overall reduction in plasma volume.[19]

CARDIAC EFFECTS

The circulatory system is also negatively affected by immobility, as skeletal muscles play an important role in compressing veins, forcing blood return to the heart. Therefore, loss of skeletal muscle due to injury or during bed rest impairs venous return, decreasing diastolic pressure and stroke volume. In response, heart rate typically increases and may lead to tachycardia. In fact, after 4 weeks of bed rest, the resting heart rate may increase by approximately 10 bpm.[20] Similar to skeletal muscle, cardiac muscle is also plastic in response to stress; therefore, as stroke volume decreases, myocytes begin to atrophy. The resulting reduction in cardiac mass and myocardial thinning lead to an overall decreased cardiac pump effectiveness.[21]

ORTHOSTATIC HYPOTENSION

Immobilized patients have a reduction in blood volume, venous return, and stroke volume. These factors in conjunction with cardiac deconditioning and myocardial thinning lead to the development of orthostatic hypotension.[20] Orthostatic hypotension is characterized by an excessive fall in stroke volume on assuming an upright position and has been reported after as little as 20 hours of bed rest.[22,23] Orthostasis is magnified in patients with SCI because a loss of sympathetically mediated vasoconstriction compounds venous pooling in the abdomen and lower limbs. This results in dizziness, lightheadedness, or loss of consciousness when assuming an upright position. Symptoms of orthostatic hypotension may significantly interfere with a patient's ability to participate in therapy or perform activities of daily living (ADLs) and may persist even after a protracted period of time, particularly for elderly patients.

AEROBIC CAPACITY

Maximal oxygen consumption (VO_{2max}) is a measure of cardiovascular fitness and has been shown to decrease in proportion to the duration of immobilization.[24] Individuals with preexisting cardiovascular disease present a higher risk for cardiac complications when recovering from a traumatic event and require explicit cardiovascular guidelines for participation in therapy. Typical guidelines for initiating therapeutic exercise include not exceeding a greater than 10 to 15 mm Hg rise in systolic blood pressure or greater than 60% to 65% maximal heart rate. Perceived exertion scales are often used to help monitor effort, and when needed, supplemental oxygen and monitoring with pulse oximetry should be used during therapy. Prior to initiating an appropriate exercise program, additional considerations should be made regarding the patient's preinjury conditioning, other cardiovascular risk factors, and medication use.[25]

VENOUS THROMBOSIS AND PULMONARY EMBOLUS

The incidence of deep venous thrombosis (DVT) after major trauma has been reported to be as high as 58%.[26,27] Without prophylaxis, its incidence after a motor complete SCI may be as high as 72%.[28] Typical features of DVT include swelling, erythema, and pain in the affected extremity. A pulmonary embolism (PE) is a potentially fatal consequence of a DVT, caused by part of the clot breaking away from the vein wall and lodging in a pulmonary artery. Typical symptoms include tachycardia, dyspnea, and chest pain. Unfortunately, both DVT and PE may manifest silently without producing any traditional symptoms, especially in patients with paralysis, sensory loss, or impaired consciousness.[29] Computed tomography (CT) pulmonary angiography has emerged as the preferential test in diagnosing a PE due to its high accuracy, ease of use, and ability to provide alternate diagnoses.[30] Other tests for assessing the presence of DVT or PE include ultrasound, lung ventilation/perfusion scans, and blood tests including D-dimer, but these are not as accurate in trauma patients.

PREVENTION AND TREATMENT

Minimizing the effects of cardiovascular deconditioning is achieved by reintroducing activities as soon as possible during the initial care of an injured patient. Management of orthostatic hypotension begins with preventing venous pooling in the abdomen and lower limbs by using abdominal binders and lower limb compression stockings. If necessary, the use of medications such as midodrine or fludrocortisone may also be helpful in treating or preventing episodes of orthostatic hypotension.[31] The incidence of DVT can be reduced to 7% to 10% with appropriate prophylaxis.[28] The current recommendation for the prevention of DVT and PE following trauma is to initiate pharmacologic anticoagulation as soon as possible after injury, provided no contraindications exist (eg, bleeding, ongoing surgical procedures, or progressive changes in the brain on CT). Anticoagulation may be accomplished with low-molecular-weight heparin or adjusted-dose unfractionated heparin in patients with impaired renal function. In addition to pharmacologic prophylaxis, use of mechanical prophylaxis such as compression hose or intermittent compression boots should be initiated as soon as possible and continued for at least 2 weeks. If contraindications to

pharmacologic prophylaxis exist, a vena cava filter may be inserted to minimize PE. Duration of pharmacologic prophylaxis is dependent on the extent of trauma and continued risk of thrombus formation. Guidelines for the management of individuals with SCI suggest the following indications to continue prophylaxis: (1) until hospital discharge for those with uncomplicated motor incomplete SCI; (2) 8 weeks for those with uncomplicated motor complete SCI; and (3) 12 weeks for those with complicated SCI (eg, lower limb fracture, age >70 years, or history of thrombosis, cancer, heart failure, or obesity).[32] Lifestyle modifications such as avoiding immobility and dehydration, tobacco cessation, and maintaining normal blood pressure can also help prevent DVT and PE.

Pulmonary Effects

LUNG VOLUME AND STRUCTURAL CHANGES

Patients take fewer deep breaths when lying down due to decreased respiratory muscle strength during immobilization. This decreased tidal volume (amount of air inhaled or exhaled during normal respiration) contributes to a 25% to 50% decrease in total respiratory capacity.[33] A similar reduction in the diameter of the airways leads to a decrease in functional residual capacity (the amount of air left in lungs after expiration), which can restrict airways and decrease gas exchange.[34] Further complicating respiratory function, bedridden patients have difficulty clearing secretions, leading to accumulation of mucus in the air passages and secondary atelectasis and pneumonia.[35]

PREVENTION AND TREATMENT

Promoting deep inspiration with an incentive spirometer is important for all trauma patients. Chest physiotherapy, vibration, and postural drainage techniques may be administered by a respiratory therapist and should be considered for any patient with acquired pneumonia while on bed rest. Clearing secretions is especially challenging for patients with SCI. Respiratory therapy, postural drainage, tracheal suction, manual cough support, and mechanical insufflation–exsufflation should be considered.[36] Special coughing techniques, such as the "quad cough," where after maximal inspiration the patient initiates a cough, while simultaneously receiving assistance from an attendant, who gently pushes inward and upward on their abdomen, should also be taught to the patient and family to help better manage respiratory secretions.[35,37]

Urinary System Effects

URINARY RETENTION, STONES, AND URINARY TRACT INFECTION

The urge to urinate is often lessened when supine, even when the bladder is full, and this contributes to urinary retention. An overdistended bladder may cause the stretch receptors to lose sensitivity, further reducing the urge to urinate. The aforementioned bone loss due to immobilization results in hypercalciuria, increasing the risk of forming bladder and renal stones. Urinary retention also encourages the growth of bacteria that raise the pH of urine and increase the risk of infection as well as precipitation of calcium that exacerbates stone formation.[38,39]

PREVENTION AND TREATMENT

For most trauma patients, an indwelling catheter is placed to ensure adequate emptying of the bladder, prevent fluid stasis and subsequent infection, and prevent a high-pressure system that may lead to hydronephrosis and renal damage. An indwelling catheter allows the trauma team to monitor fluid output and assess fluid status but should be removed as soon as medically possible to prevent urethral or bladder damage and to avoid reducing bladder compliance and storage capacity. After removing an indwelling catheter, it is important to monitor initial postvoid residual (PVR) bladder volumes to ensure adequate emptying. A PVR greater than 50 to 100 cm^3 should raise concern and consideration of replacement of the indwelling catheter.[40] Patients with a neurogenic bladder, whether from an injury to the central or peripheral nervous system, can develop either bladder contraction or distension; therefore, an appropriate bladder training program should be initiated as soon as the indwelling catheter is removed (see the later section "Spinal Cord Injury").

Gastrointestinal Effects

APPETITE AND GASTRIC TRANSIT TIME

Bed rest negatively impacts taste acuity, leading to a reduction in food intake.[41] In addition, immobilization results in structural and functional changes of the gastrointestinal tract, including atrophy of the mucosal lining and reduced glandular capacity.[42] Gastric transit time is prolonged during bed rest. The resultant decreased rate of evacuation from the stomach may cause symptoms of gastroesophageal reflux, regurgitation, and heartburn. The rate of intestinal peristalsis is also slowed during bed rest, further delaying intestinal motility and increasing water absorption, and may lead to constipation and fecal impaction.[39,43] These effects are likely to be magnified with the use of opioids or other pharmacologic agents that may also slow intestinal motility.

PREVENTION AND TREATMENT

Minimizing immobility, promoting activity, and ensuring adequate hydration are essential components of proper bowel management. The use of a bedside commode or bathroom toilet rather than a bedpan is encouraged. Bowel management should be targeted to the specific dysfunction that is present. Effective bowel programs include dietary modifications, timing evacuation about 30 minutes after a meal to take advantage of the gastrocolic reflex, and manual disimpaction, especially for individuals with neurogenic bowel dysfunction from an SCI. If further treatment is required, medications such as bulk-forming agents (eg, Metamucil), enemas, colonic irritants (eg, Dulcolax), and intestinal motility agents (eg, Senna) may be used. The ability of the patient

to independently perform manual disimpaction or self-administer enemas or suppositories will depend on his or her level of impairment. A surgical colostomy may be necessary to provide continence in certain patients, and appropriate colostomy care should be taught to the patient or caregiver.

Integumentary System Effects

DECUBITUS ULCERS

Immobilization is strongly associated with the formation of decubitus ulcers. Bony prominences such as the occiput, shoulder blades, sacrum, and heels are at greatest risk in supine patients.[44] Ulcerations that occur over the ischial tuberosities are generally attributable to increased seating pressure. Because immobilized patients are unable to make natural postural changes that alleviate pressure on susceptible body parts, blood flow to tissues may become obstructed, leading to necrosis of soft tissue and skin.[45] Patients with impaired cognition or sensation are particularly susceptible to the formation of pressure ulcers, and between 25% and 80% of patients with an SCI eventually develop pressure ulcers, with up to 8% developing fatal complications.[35] In addition, urinary and fecal incontinence may lead to excessive skin maceration and subsequent breakdown.[46] When present, pressure ulcers may have a significantly negative impact on rehabilitation, recovery, and quality of life.[47]

PREVENTION AND TREATMENT

Frequent skin inspection, appropriate hygiene, achieving urinary and fecal continence, proper fitting of orthotics, and avoiding excessive pressure through a regular turning schedule are all critical aspects of caring for the skin of a trauma patient. Providers should remain particularly attentive to the pressure-sensitive areas such as the sacrum, occiput, and heels/ankles. The utilization of specialty beds, padded orthotics, and seating cushions is encouraged but should not replace vigilant medical and nursing care. Many trauma centers have a dedicated skin and wound care team. These professionals should be consulted at the earliest signs of skin breakdown and should be involved in continuous education of the medical, nursing, and therapy staff. The primary treatment of pressure ulcers should focus on prevention through frequent position changes by a caregiver or the patient. This requires early patient and caregiver education, as well as the use of specialized equipment, including wheelchairs with adjustable tilting features.

Unique Complications of Trauma Patients

HETEROTOPIC OSSIFICATION

Heterotopic ossification (HO) is the formation of mature lamellar bone in tissue that is not normally ossified.[48] It commonly develops in patients with TBI, SCI, burn injury, or blast-related amputations.[49-51] The most common site of HO following SCI is the hip, but it may also occur in the elbow, shoulder, and knee.[52] For patients with burns, 92% of cases occur in the elbow,[53,54] and up to 80% of patients who sustain an amputation from a blast injury may develop HO.[55] The clinical presentation of HO may include a decrease in range of motion and erythema and swelling about the involved joint. Radiographs, bone scans, and monitoring of serum alkaline phosphatase levels may aid in the diagnosis. Prophylaxis with bisphosphonates, nonsteroidal anti-inflammatory drugs (NSAIDs), and local irradiation may prevent HO.[56] Treatment of HO involves active and passive range of motion to prevent worsening; however, in severe cases, surgical excision may be required to improve functional outcomes.[52,57] Even when treated aggressively, HO may still result in significant restrictions in range of motion and subsequent disability.

SPASTICITY

Spasticity is defined as a velocity-dependent increase in muscle tone that occurs following injury to upper motor neurons and is associated with increased deep tendon reflexes and other signs of upper motor neuron disease. Spasticity occurs frequently in patients with TBI and SCI and may significantly impede successful rehabilitation if not treated appropriately. During the acute stage, however, a patient with SCI may have diffusely diminished reflexes below the level of injury. This period of hypotonicity and hyporeflexia is referred to as spinal shock. In the weeks following SCI, reflexes return and gradually increase while spasticity develops. The incidence of spasticity following SCI at 1 year is estimated to be 65% to 78%.[58] Spasticity may result in significant pain, impaired mobility, difficulty with dressing and hygiene, and an increased risk of skin breakdown. In certain circumstances, however, spasticity may be of benefit to the patient, particularly when lower limb tone is used to aid in transfers. Therefore, the decision to treat spasticity must be based on improving patient function, hygiene, and/or care.

Conservative treatment of spasticity begins with positioning, stretching, splinting, and range-of-motion exercises. Medications used for spasticity include γ-aminobutyric acid (GABA) agonists (eg, baclofen), centrally acting α_2-agonists (eg, tizanidine), and medications that inhibit skeletal muscle contraction (eg, dantrolene). Botulinum toxin or phenol injections may also be helpful in the management of spasticity. Implanted pumps may be used to deliver highly concentrated doses of medications directly to the spinal cord through an intrathecal catheter, which minimizes systemic side effects, and surgical treatment of spasticity may be required to correct fixed deformities.[58] The appropriate choice of medication, however, should be based on the patient's response as well as the presence of adverse side effects.

PAIN MANAGEMENT

Background

Inadequate pain control is associated with delayed healing, increased complications, prolonged hospitalization, poor sleep, and diminished quality of life.[59] It has also been shown

to be a significant cause for hospital readmission.[60] Therefore, attentive pain management should be a priority for any trauma team. Unfortunately, many patients are undertreated for their pain.[61] Multiple professional organizations, including the American Pain Society (APS) and the Agency for Healthcare Research and Quality (AHRQ), have developed and disseminated clinical practice guidelines to address the insufficient treatment of pain in America's health care delivery system.[62] In addition, The Joint Commission introduced new standards for pain assessment and management, advocating pain management as a patient right and requiring health care organizations to employ effective pain management policies.[63] Despite these initiatives, significant challenges still remain in changing clinical practice.[64] Postoperative pain is a significant problem for most patients and demands special attention from the trauma team.[65] Although a multitude of pain interventions currently exist, numerous barriers prevent patients from receiving optimal care.[66] Patients may underreport their level of pain, particularly if they expect it as part of their disease process or treatment. Pain medications prescribed on an "as-needed" basis can cause a lag in treatment and a "peak and trough" pain pattern of analgesia. Such poor pain management may lead to significant anxiety, poor sleep, and loss of appetite. In addition, undertreating pain may impair the patient's ability to participate in rehabilitation. Once severe pain has been established, it is more difficult to treat. Therefore, aggressively treating perioperative pain early with the use of multimodal and scheduled analgesia can be very helpful in avoiding the development of more complex pain syndromes. Furthermore, uncontrolled or protracted acute pain may lead to chronic pain conditions, which may have long-term negative implications on function, return to work, and quality of life.[67,68]

Providers traditionally underestimate a patient's level of discomfort. Therefore, it is important to establish a standardized method of communication between the patient and provider. To determine pain levels, most health care organizations use a visual analog scale typically ranging from 0 (no pain) to 10 (worst imaginable pain). In addition to communicating pain levels, this tool may also be used to assess the effectiveness of pain interventions and establish therapeutic goals for each patient. Determining pain levels for children or individuals with cognitive impairment may be challenging. In such cases, providers may use the FACES Scale, in which images of faces ranging from smiling to grimacing reflect pain scores.[69] A speech-language pathologist may be of great assistance to the patient and treatment team by developing an effective communication system for more challenging communication barriers. Family members should also be engaged with the treatment team to help provide feedback on the patient's nonverbal expression of pain and response to therapeutic interventions.

Phantom Limb Pain

Although pain affects all patients with traumatic injury, phantom limb pain (PLP) is unique to individuals with acquired amputation. PLP is the experience of a painful sensation (eg, cramping, burning, aching) within a missing (phantom) limb. The phenomenon occurs in up to 90% of patients following amputation of a major limb and is thought to be the result of central nervous system reorganization or hypersensitivity. PLP symptoms may occur immediately after limb loss or may be delayed by several weeks. Although most individuals experience a gradual decrease in PLP over time, many individuals will report persistent symptoms. Most common treatments include medications that are typically used for neuropathic pain. In addition, mirror therapy has also been shown to be an effective treatment. This involves the patient placing a mirror in front of them in a way that the reflection of their intact limb appears to represent their phantom (missing) limb, which they are then able to voluntary move and, through visual feedback, trick their brain that the phantom limb is moving, which helps decrease their pain.[70]

Terminology and Pathophysiology

Although a detailed discussion is beyond the scope of this chapter, the proper treatment of pain requires a basic understanding of common pain terminology and a familiarity with nervous system physiology (Table 55-1).

Treatment

Pain management strategies should target the suspected source of nociception (Fig. 55-1). Issues such as positioning, poor sleep, anxiety, and depression may augment the perception of pain. In addition, chronic underlying conditions such as migraine headaches, diabetic neuropathy, osteoarthritis, or other musculoskeletal injuries may be exacerbated by trauma, adding to a patient's discomfort. Therefore, a thorough history and physical examination are critical in evaluating every trauma patient. It is possible that other injuries may have been overlooked during the initial trauma screen due to a distracting injury; therefore, a tertiary survey is necessary for all trauma patients. Pain management strategies should be readily discussed among the trauma team, and a pain specialist should be consulted for patients with complex pain problems. Treatment strategies are often multimodal and include pharmacologic and nonpharmacologic approaches.

PHARMACOLOGIC

With the current opioid crisis, clinicians are encouraged to use a multimodal pain regimen to minimize the use of opioids while still providing adequate pain control.

- *Opioids* are the most common analgesic medications used during acute care of the trauma patient and may be administered orally, intramuscularly, or intravenously. Morphine remains the most frequently used opioid because it is inexpensive, is readily available, and has clear analgesic, amnestic, and sedative effects. Although fentanyl is more expensive and not as readily available, it offers a shorter half-life and less sedation than morphine, which may be

TABLE 55-1: Common Pain Terminology

Term	Definition
Nociception	The neural process of encoding and processing noxious stimuli
Hyperalgesia	An increased sensitivity or response to a painful stimulus
Allodynia	A painful response to a normally nonpainful stimulus
Dysesthesia	An unpleasant or painful sensation that occurs spontaneously
Paresthesia	A sensation of a tingling or numbness of the skin or region of the body that occurs spontaneously
Epicritic sensations	Nonpainful sensations such as light touch, vibration, and position sense, transmitted through low-threshold, large-diameter myelinated nerve fibers
Protopathic sensations	Painful sensations transmitted through high-threshold, small-diameter unmyelinated nerve fibers
Visceral pain	Pain generated through internal nociceptors as a result of internal organ damage
Somatic pain	Pain generated from peripheral nociceptors within the skin, muscle, soft tissue, and bone
Acute pain	Pain associated with an acute event, generally lasting <30 d
Chronic pain	A pain syndrome lasting beyond 3–6 mo or pain that extends beyond the expected period of healing

better in some trauma casualties.[71] Patients on chronic opioids may be safely treated with intravenous opioid bolus dosages up to 20% of their total daily use; however, as when using any opioid, caution should be observed because of the risk of addiction and respiratory depression. The coadministration of opioids and benzodiazepines may have a synergistic effect on increasing respiratory depression and delirium.[72] Evidence suggests that short-acting opioids may be favorable to long-acting opioids, especially during acute care hospitalization. Reliance on long-acting opioids at time of hospital discharge has a 27.3% probability of continued use after 1 year, whereas short-acting oxycodone demonstrated only a 4.7% probability.[73]

- *Continuous infusion analgesia and anesthesia* may be achieved with intravenous patient-controlled analgesia (PCA) or with regional anesthesia through a peripherally placed catheter. Intravenous opioid administration through PCA helps to avoid the "peak and trough" phenomenon of inadequate pain management. Continuous infusion of an anesthetic agent through a catheter in the region of a peripheral nerve or plexus offers outstanding pain control for limb injuries and avoids the secondary cognitive effects of systemic opioids. Regional anesthesia catheters should be monitored for effectiveness as well as signs of infection and have been reported to be safe for up to 34 days in combat-related injuries.[74]

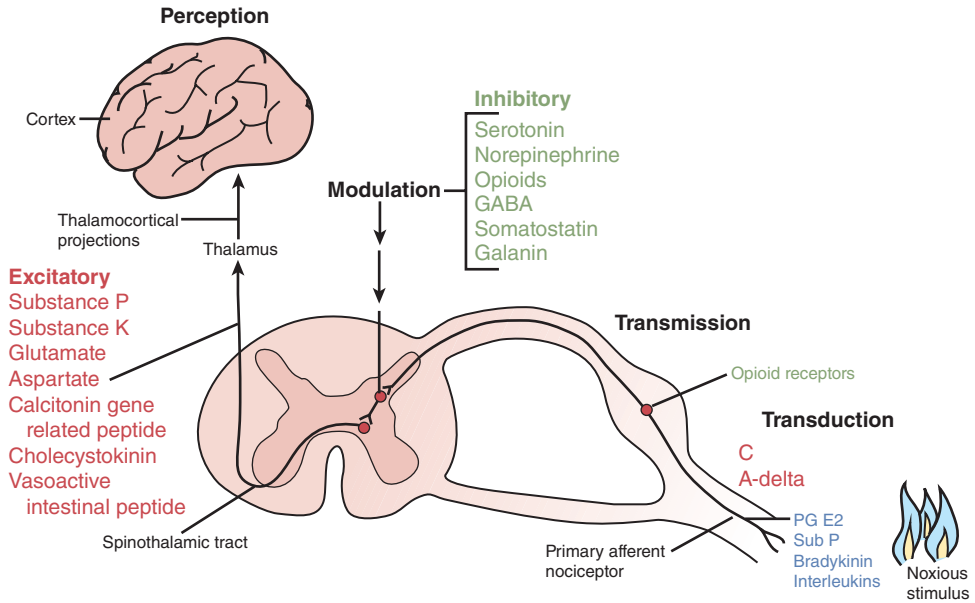

FIGURE 55-1 Afferent nociception pathway: demonstrates pain signals originating from a peripheral noxious stimulus, traveling along sensory afferents through the dorsal root ganglion and into the spinal cord, where both excitatory (red) and inhibitory (green) neurotransmitters modulate impulses before the signal is perceived within the brain. GABA, γ-aminobutyric acid; PG E2, prostaglandin E2; Sub P, substance P.

- *NSAIDs* can be very helpful in relieving peripherally generated pain by blocking cyclooxygenase and the subsequent formation of prostaglandins, which promote pain and inflammation. There are two isomers of cyclooxygenase (COX-1 and COX-2), each involved in a range of physiologic functions. The prostaglandins produced by COX-1 protect the stomach and support platelet aggregation. Therefore, nonselective COX inhibitors should be used with caution in the injured patient to avoid the possible side effects of peptic ulceration and dyspepsia. Ketorolac (Toradol) is the only NSAID in the United States available in an injectable form. Its administration, either intravenously or intramuscularly, has analgesic effects similar to morphine. All NSAIDs should be used with caution in the presence of complex fractures, particularly those with high propensity for nonunion, although data are conflicting.[75]
- *Acetaminophen* is a nonopioid analgesic without the antiplatelet and anti-inflammatory properties of NSAIDs. When used in combination with opioids, it has been shown to lower opioid requirements by up to 20%.[76]
- *Muscle relaxants* such as tizanidine and baclofen are often used in the trauma setting, particularly for painful spasms and spasticity due to upper motor neuron injury.[72] α_2*-Adrenergic agonists* such as clonidine can also help to reduce spasticity and also help decrease anxiety and opioid withdrawal symptoms. However, care should be taken to avoid hypotension and bradycardia.[76]
- *N-Methyl-*D*-aspartate (NMDA) receptor antagonists* such as ketamine are thought to inhibit nociopathic pathways within the central and peripheral nervous system, with evidence suggesting similar analgesic effects to morphine and reducing the overall need for opioids.[72] Administration is intravenous and requires continuous monitoring for potential tachycardia, hypertension, agitation, and hallucinations.[77]
- *Antiepileptic medications* such as gabapentin, pregabalin, carbamazepine, valproic acid, and oxcarbazepine are often used to help treat neuropathic pain and may also provide relief from PLP. These medications act as membrane stabilizers to the axons in the central and peripheral nervous systems through modulation at the sodium and calcium channels.[76]
- *Antidepressant medications* have long been used to help augment pain management, particularly for neuropathic pain. Tricyclic antidepressants (TCAs) are effective but have sedative effects. They also have anticholinergic properties, which may lead to secondary problems such as confusion and urinary retention, especially in the elderly. Therefore, side effects should be monitored and the dose of medication adjusted accordingly. Duloxetine is an antidepressant medication with fewer side effects than TCAs and is approved for the treatment of diabetic nerve pain. Although the effect of selective serotonin reuptake inhibitors on acute or chronic pain is unclear, these medications should be considered to treat depression or anxiety, which may be a contributing factor to the patient's pain.[72,76]
- *Sympathetic blockade* may be helpful in patients with a sympathetically mediated complex regional pain syndrome (CRPS). CRPS should be suspected if the pain in an extremity persists long after what would be normally expected in patients with similar injuries. Symptoms typically include regional pain, allodynia, hyperalgesia, swelling, and local dysautonomia (sweating, discoloration, or temperature changes). Because prolonged immobility may be a precursor to CRPS, early rehabilitation may prevent its occurrence. When CRPS is suspected, a pain specialist consultation is recommended.

NONPHARMACOLOGIC

- Modalities such as heat or ice may provide effective pain relief for injured patients and should be made available as needed. Caution should be observed when using these modalities for patients with injuries to the central or peripheral nervous system or those with cognitive impairment. Lack of protective sensation or awareness my lead to a skin injury and/or burn.
- Interventions such as acupuncture, desensitization techniques, self-hypnosis, biofeedback, and music therapy may also provide some pain relief for injured patients. Such therapies are generally well received and can be administered without fear of side effects or adverse interaction with other medications.

FUNCTIONAL IMPROVEMENT THROUGH INTERDISCIPLINARY TEAM CARE

The early application of rehabilitation principles helps prevent secondary injury and facilitates patient recovery. Consultation with rehabilitation specialists should be considered for every trauma patient. An interdisciplinary rehabilitation team employs a variety of specialists from physiatry, physical therapy, occupational therapy, mental health, and speech-language pathology. For patients with cognitive impairment, a neuropsychologist may also offer invaluable assistance in identifying cognitive deficits and formulating management decisions. In addition to providing holistic care, rehabilitation providers spend additional time with patients and family members to perform a comprehensive functional assessment to determine preinjury functional capacity as well as current functionality. Rehabilitation professionals will assess any potential barriers that might prevent timely hospital discharge (eg, cognition, mobility, safety, architectural barriers) or independent living with or without assistance. Once these barriers are identified, therapeutic interventions may be initiated, and appropriate assistive equipment can be ordered in a manner to fit with establishing short- and long-term rehabilitation goals.

Physical Medicine and Rehabilitation Specialists (Physiatrists)

Physiatrists are board-certified physicians who specialize in neuromusculoskeletal disorders and rehabilitation. These

health care providers are skilled at integrating medical and surgical treatment plans with the rehabilitation team. Physiatrists are also helpful in establishing safety precautions for the patient, managing pain and bowel/bladder issues, and aiding in appropriate discharge planning and disposition. Subspecialty certifications currently exist in brain injury, neuromuscular, pain, SCI, sports, and pediatric rehabilitation medicines.

Physical Therapists

Physical therapists evaluate motor function and mobility. This includes assessing range of motion of joints and motor strength as well as a patient's balance and ability to sit, stand, transfer, or walk independently or with an assistive device. Treatment should begin early during the acute care hospitalization and continue until goals are met. Physical therapy assessments are very helpful in guiding appropriate discharge planning. It is important for the trauma physician to provide the therapist with guidance on appropriate weight bearing, range of motion, or activity precautions.

Occupational Therapists

Occupational therapists assess a patient's ADLs and instrumental ADLs (IADLs). ADLs include feeding, toileting, dressing, and hygiene. IADLs refer to activities beyond basic personal care, typically requiring devices such as a telephone, kitchen utensils, or appliances. Examples of IADLs include managing finances, preparing meals, and doing laundry. A patient's independence in ADLs and IADLs will help determine appropriate discharge planning. Occupational therapists are also skilled at helping those with extremity trauma or nervous system injury regain both gross and fine motor hand function.

Speech-Language Pathologists

Speech-language pathologists assess, diagnose, and treat patients with difficulties related to speech, language, swallowing, or cognitive–communication deficits. Because adequate nutrition is necessary for tissue healing and recovery, evaluating a patient's ability to swallow safely may help guide appropriate interventions to ensure appropriate caloric intake.

Additionally, the speech-language pathologists may develop ways to improve the necessary communication between the treatment team and the patient.

Orthotists and Prosthetists

Orthotists and prosthetists are certified in evaluating, fabricating, and custom fitting orthopedic braces (orthotics) and artificial limbs (prostheses). Orthotics are devices used to align, support, protect, or improve the function of a body part. Examples of orthotics used in trauma casualties include halo cervical traction splints, ankle-foot orthotics for ambulation and pressure relief,[78] and thoracolumbosacral orthotics. Orthotics may be either static (rigid) or dynamic (assist with desired motion). Prostheses may be used for upper or lower limb amputations and are composed of a socket, suspension, joint(s), shank, and terminal device (hook, hand, or foot). Early prosthetic fitting may enhance acceptance and functional recovery.

Mental Health Professionals

Mental health professionals should be a part of any interdisciplinary team. Traumatic events have a significant psychological impact on the patient, family members, and caregivers. Nearly all survivors of major traumatic events will exhibit stress-related symptoms, and up to 40% may have a psychiatric disorder at 1 year following trauma.[79] For combat casualties, rates of comorbid posttraumatic stress disorder (PTSD) have been reported to be 16.7%,[80] but may be as high as 30% to 45% in those sustaining amputation or SCI.[81] Fear of isolation, lack of wholeness, and concerns about the future are common but can be eased by supportive family members and caregivers. A preventative medicine approach to psychiatry helps to decrease the stigma that is often associated with seeing a behavioral health specialist. Fostering appropriate mental health care acutely likely helps to prevent the development of disabling psychiatric disorders often associated with trauma.[82] Special considerations should also be made to the children and other family members of those who suffer trauma, particularly those with disfiguring injuries.

Rehabilitation Engineers and Assistive Technology Specialists

Rehabilitation engineers specialize in the fabrication, fitting, and training of assistive technology devices. Assistive technology devices provide essential support for individuals with disabilities, allowing them to perform ADLs and return to work, sports, and recreational activities. They include manual and powered wheelchairs, seating/standing systems, adaptive vehicles, augmentative communication systems, electronic aids, and assistive robotics. As technology becomes more sophisticated, expertise is needed in these areas. The Rehabilitation Engineering and Assistive Technology Society of North America (RESNA) currently provides credentialing to suppliers, health care providers, and engineers to ensure quality in products and service delivery.

Peer Support Visitors

Peer support visitors are trauma survivors who receive training to support other patients and their families. Peer visitors generally have suffered a similar life-changing injury as the patient and demonstrate a successful recovery by adapting and returning to community participation. Peer support visitors are especially beneficial for individuals with paralysis, vision loss, disfiguring scars, or limb loss. Not-for-profit organizations, such as the Amputee Coalition, offer specialized peer support training programs, which may be helpful

for individuals or institutions interested in initiating such a program.

Vocational Rehabilitation Specialists

Vocational rehabilitation specialists help match career goals with functional capacity, assistive technology, and professional talents. Community reintegration and return to vocation should be in the long-term goals of all trauma patients. Although controversy exists as to the optimal timing of intervention, discussing vocation during early hospitalization may facilitate engagement in rehabilitation and hasten recovery.

Case Managers and Social Work Services

Case managers are essential to adequately address discharge planning and transfer to the next level of care, coordinate equipment needs, and provide patient and family education. Therefore, these professionals should be an integral part of the trauma treatment team.

SPINAL CORD INJURY (SEE CHAPTER 26)

Introduction

Injury to the spinal cord results in impaired motor strength and sensation below the level of injury. SCI is often associated with bowel and bladder dysfunction and may cause sexual impairment as well as dysfunction of the autonomic nervous system. Approximately 12,000 SCIs occur nationally each year, and approximately 259,000 trauma survivors are living with SCI in the United States. Males account for approximately 80% of those with SCI, and motor vehicle accidents represent the largest proportion of injuries, followed by falls, violence, and sports injuries. The societal impact of SCI is staggering, resulting in total lifetime costs of between $1 million and $4.6 million per patient.[83]

Classification

SCIs are classified by their severity and level of injury, using the American Spinal Injury Association (ASIA) Standard Neurological Classification Worksheet.[84] This classification system provides guidelines for measuring key motor levels and sensory examination points that represent function at a given spinal level. According to this method of classification, patients are given two scores, with one based on level and the other on the degree of impairment. The neurologic level of injury is defined as the lowest level of normal functioning. The impairment is rated as *A*, *B*, *C*, *D*, or *E*. An *A* is assigned to a patient with a complete injury, with no motor or sensory function in the S4 or S5 levels. *B* represents an incomplete injury with sensory sparing but no motor activity below the level of injury. A patient with some motor (nonfunctional) strength below the level of injury is assigned a *C*, whereas a *D* classifies a patient with more motor sparing below the level of the lesion, as indicated by antigravity strength in greater than 50% of those muscles spared. A classification of *E* represents normal strength and sensation.

Acute Management

Treatment of acute SCI in a trauma center has a significant positive impact on survival and long-term functional recovery.[85] Immediate spinal stabilization is essential to prevent further neurologic compromise. Although not all patients require surgery after SCI, current literature suggests that surgical treatment relieving spinal cord compression can prevent further neurologic deterioration.[86]

The routine use of corticosteroids for the treatment of acute SCI is no longer recommended. In 1990, the National Acute Spinal Cord Injury Study recommended that high-dose methylprednisolone be administered for 24 to 48 hours. Although prior recommendations endorsed the use of high-dose methylprednisolone following acute SCI,[87] increasing concerns about infection, gastrointestinal bleeding, and steroid myopathy led some trauma centers to question the safety and efficacy of this protocol. As result, the 2013 guidelines of the American Association of Neurological Surgeons and Congress of Neurological Surgeons recommended against the routine use of methylprednisolone following acute SCI.[88] In addition, a meta-analysis in 2015 failed to demonstrate a benefit in functional outcome in those receiving methylprednisolone versus a placebo at both the 6-month and 1-year follow-ups.[89] Currently there is no international consensus for the application of high-dose methylprednisolone in acute traumatic SCI, and recent recommendations consider steroids at best as an option rather than standard of care.[90,91]

Regenerative Medicine

When an SCI occurs, the axons of the spinal cord nerves are destroyed and the surrounding oligodendrocytes die. Because the body cannot replace these cells, a functional defect results. Stem cells have become a source of research as a potential way to repair the nerve cells of the spinal cord and surrounding structures. They not only have the theoretical ability to rebuild the physical defect in structure, but they also have anti-inflammatory and immunomodulatory effects that are postulated to have a positive effect following SCI.[92-94]

In preclinical studies, embryonic stem cells transplanted into rodent models of SCI have demonstrated some recovery of function; however, concerns about the use of embryonic stem cells are both logistical (the plausibility of translating rodent models to humans) and ethical (the use of embryonic tissue). Mesenchymal stem cells are found in the bone marrow and may also exist in adipose and muscle tissue. They are not only easier to isolate, but their usage has fewer ethical concerns than embryonic stem cells; however, a major concern is the potential for spontaneous malignant transformation.[95] Preclinical studies thus far have had mixed success in improvements

in functional outcome following the implantation of mesenchymal stem cells into rodent models.[96] The potential of stem cells to provide a cure for SCI has resulted in many clinical trials over the past decade. Thus far, the question as to their efficacy is still unanswered, and there is no consensus about which type of stem cell will be the most effective therapeutically.[97]

Functional Outcomes After Spinal Cord Injury

The expected level of independence and functional capacity after an SCI depends largely on the level of injury and the impairment rating. Although lifelong mechanical ventilation is typically required for patients with complete injuries at the level of C3 or above, it is often not necessary for those with injuries at C4 or below. An injury at the C5 level is expected to result in independent mobility in an electrically powered wheelchair and driving in a van with appropriate modifications. C7 level injuries allow independence with transfers, weight-shifting maneuvers, and bowel and bladder management. Although individuals with thoracic level injuries have full function of the upper limbs, they typically require the use of a manual wheelchair with varying degrees of truncal support. Patients with an L1 or L2 injury generally also require a manual wheelchair but have independent truncal control. Patients with L3 or L4 injuries may be able to ambulate with assistive devices, and those with injuries at L5 or below should be able to independently ambulate.[85]

New technologies are emerging to facilitate rehabilitation and assist those with SCI to achieve better functional outcomes. Multiple motorized exoskeletal systems are currently available to augment mobility. Evidence suggests that these systems may also offer improvement in cardiovascular, gastrointestinal, and bladder function, as well as improved bone health and psychological well-being.[98,99] Brain–machine interfaces have also been investigated as a technology to achieve functional restoration of limb movement for those with an SCI. These devices allow the patient to have control of assistive devices by analyzing brain signals.[100] In addition, spinal cord stimulation has been investigated as a way of activating networks to induce locomotor-like movements in the legs, with promising results in preliminary animal models.[101]

Complications After Spinal Cord Injury

The management of patients with SCI is focused on the prevention of complications that may interfere with successful rehabilitation. The recognition of and attention to these complications are critical components of a successful rehabilitation program.

AUTONOMIC DYSREFLEXIA

Autonomic dysreflexia (AD) is a severe and life-threatening complication of SCI that occurs in patients with lesions at or above T6. AD typically occurs as a result of a noxious stimulus below the level of the injury, which triggers a sympathetic reflex that goes "unchecked" or uncorrected because of injury to the descending inhibitory tracts within the spinal cord. This results in elevated blood pressure, bradycardia or tachycardia, headache, and sweating or piloerection above the level of the injury. If not recognized and treated properly, stroke or death may occur. Once AD is recognized, the patient's head should be elevated and the noxious stimulus (eg, tight or constricted clothing, pressure on the skin, bladder distension, or bowel impaction) should be identified. If an indwelling catheter is in place, it should be thoroughly examined for constriction or kinks that may cause distension. If replacement is needed, it should be inserted with the use of lidocaine gel to decrease the amount of noxious stimuli. A rectal exam should be performed to assess for fecal impaction, and if present, manual disimpaction may be required. If blood pressure remains elevated, pharmacologic management may be necessary. Typical first-line medications include nitroglycerin paste (which can be easily removed to prevent rebound hypotension) or chewable calcium channel blockers. During the management of AD, blood pressure should be continually monitored, and the patient should be continually reexamined for sources of noxious stimulation.[31,102,103]

HYPERCALCEMIA

Hypercalcemia as a result of upregulation in osteoclast activity may occur in individuals with SCI, especially adolescents and young adult males. This may result in lethargy, abdominal pain, nausea, vomiting, psychological changes, polydipsia, and polyuria. If hypercalcemia is suspected, serum calcium levels should be monitored and treated appropriately.[104]

BLADDER DYSFUNCTION

Bladder dysfunction following SCI may lead to incontinence and urinary retention. In a typical upper motor neuron lesion, the bladder will become spastic and inadequately store urine, resulting in frequent episodes of small-volume incontinence. In lower motor neuron lesions, the bladder may become flaccid, resulting in failure to empty and overflow incontinence. Many patients with SCI develop detrusor–sphincter dyssynergia, characterized by a detrusor contraction against an unrelaxed sphincter, leading to failure to empty and a high-pressure urinary system. Management of bladder dysfunction aims to prevent incontinence and urinary reflux and infection, while ensuring adequate voiding at socially acceptable times. Options for bladder voiding include indwelling catheters (eg, Foley catheter or suprapubic catheter) or clean intermittent catheterization. Crede maneuver is also helpful, in which the patient or a caregiver provides manual pressure to the suprapubic region to facilitate emptying of the bladder. Pharmacologic management of a hyperactive bladder consists primarily of anticholinergic medications to relax the detrusor muscle. Intravesical administration of botulinum toxin may also be considered to treat detrusor spasticity. Surgical options include augmentation cystoplasty, cutaneous conduits, and urinary diversions.[105]

BOWEL DYSFUNCTION

Bowel dysfunction is common after SCI due to a loss of bowel control from the central nervous system, resulting in constipation, delayed gastric emptying, and poor colonic motility.[106] Both incontinence and failure to empty may result (see the earlier section "Effects of Immobility").

SPASTICITY, ORTHOSTATIC HYPOTENSION, SKIN BREAKDOWN, AND HETEROTOPIC OSSIFICATION

These are also significant problems for patients with SCI. The reader should refer to the previous discussion of these topics.

TRAUMATIC BRAIN INJURY (SEE CHAPTER 22)

Introduction

TBI is the leading cause of death and disability in young adults in the United States, with over 1.4 million individuals presenting to emergency and other acute medical settings each year. Of these, 275,000 require hospitalization and 52,000 cases are fatal.[107] In addition, it is estimated that 19% to 23% of service members who deploy overseas sustain a concussion or mild TBI.[108] Reports estimate that there were approximately 313,816 service members diagnosed with TBI between 2000 and 2014 from the wars in Iraq and Afghanistan.[109] TBI may occur from multiple mechanisms including blunt, penetrating, or blast trauma. The presence and severity of TBI may be difficult to diagnose, particularly if the injury was not witnessed. Additionally, secondary effects of trauma, such as hypovolemia, anoxia, and metabolic changes, may lead to significant brain injury. TBI may occur in discrete lesions or more diffusely such as in diffuse axonal injury. Neuroimaging, including CT, magnetic resonance imaging (MRI), functional MRI, and diffusion tensor imaging, is used to confirm the presence of a mechanical lesion that may require surgical evacuation.[110]

Classification

Much debate surrounds the optimal way to classify TBI. Most trauma centers rely on the Glasgow Coma Scale (GCS) or length of posttraumatic amnesia (PTA) to determine severity of the TBI (Table 55-2). PTA is the time between injury and the development of new memories, demonstrated by the patient's ability to recall daily events. It may be more formally assessed using tools such as the Galveston Orientation and Amnesia Test (GOAT).[111] The Ranchos Los Amigos Scale is often used to describe a patient's level of awareness, cognition, behavior, and interaction with the environment after a TBI (Table 55-3).[112] Patients who are mobile, but confused or agitated, will likely require a secured inpatient setting.

Predicting outcomes after TBI is extremely challenging because of imprecise classification systems. In addition, issues such as heterogeneity of injury patterns, premorbid cognitive and physical functioning, family support, and psychosocial factors all play differential roles in recovery.[113] Reports indicate that 38% to 80% of patients experiencing mild TBI will develop postconcussive syndrome, characterized by headache, fatigue, anxiety, and impaired memory, attention, and concentration.[114] The best predictor of outcome after TBI is the patient's speed of recovery and response to treatment; therefore, monitoring patient performance in multiple functional domains is important. Furthermore, an extended duration of loss of consciousness immediately following TBI has been negatively correlated with long-term rehabilitative potential.[115] Numerous outcome instruments are currently in practice including the Glasgow Outcome Scale (GOS), Functional Independence Measure (FIM), Community Integration Questionnaire (CIQ), Craig Handicap Assessment and Reporting Technique (CHART), and Disability Rating Scale (DRS). For a more comprehensive reference on TBI outcome tools, the reader is referred to the National Institute of Neurological Disorders and Stroke's Traumatic Brain Injury Common Data Element Standards.[116]

Treatment

A comprehensive discussion of treatment strategies for individuals with TBI is beyond the scope of this chapter. Trauma teams should consider the effects of immobility as described earlier and apply the appropriate rehabilitation principles. Patients with severe TBI should be transferred to a specialized rehabilitation facility as soon as medically feasible. Comprehensive acute inpatient rehabilitation programs provide intensive medical, physical, cognitive, and behavioral therapy regimens, which are coordinated in an interdisciplinary fashion.[117] Because of the frequent association of other sensory disturbances, these treatment teams are often augmented by highly skilled audiologists, neuropthalmologists, optometrists, and vision rehabilitation specialists. In addition, music and art therapists may be invaluable in not only engaging the patient in therapy, but also in improving cognitive and communication therapies. Transfer to a skilled nursing facility may

TABLE 55-2: Traumatic Brain Injury Classification

Injury severity	Glasgow Coma Scale	Posttraumatic amnesia	Structural imaging	Loss of consciousness	Alteration of consciousness
Mild	13–15	<24 h	Normal	0-30 min	A moment up to 24 h
Moderate	9–12	1–7 d	Normal or abnormal	>30 min and <24 h	>24 h
Severe	3–8	>7 d	Normal or abnormal	>24 h	>24 h

TABLE 55-3: Ranchos Los Amigos Scale

Cognitive level	Outcome	Patient response
I	No response	No response to sounds, sights, touch, or movement
II	Generalized response	Limited response, which is inconsistent and nonpurposeful; responses to sounds, sights, touch, or movement
III	Localized response	Inconsistent but purposeful response in a more specific manner to stimuli; may follow simple commands
IV	Confused and agitated	Confused and often frightened; overreactions to stimuli by hitting or screaming; highly focused on basic needs (eg, eating, toileting); difficulty following directions
V	Confused and inappropriate	Appears alert and responds to commands; easily distracted by the environment; frustrated and verbally inappropriate; focused on basic needs
VI	Confused and appropriate	Follows simple directions consistently; may have some memory but lacks details, attention span of about 30 min
VII	Automatic and appropriate	Follows a set schedule; does routine self-care without help; attention difficulty in distracting or stressful situations; problems in planning and following through
VIII	Purposeful and appropriate	Realizes difficulties with thinking and memory; less rigid and more flexible thinking; able to learn new things; demonstrates poor judgment; may need guidance for decisions

be necessary for those with impairments that prohibit transfer to an acute inpatient rehabilitation facility (eg, unable to tolerate a minimum of 3 hours of rehabilitation per day).[118,119] Patients who sustain severe trauma but deny TBI or cognitive difficulties may still be determined to have significant cognitive deficits during formal neuropsychological testing. Common symptoms of TBI include headache, visual and hearing disturbances, balance difficulties, poor sleep, irritability, and impaired cognition.[108,111] In addition, comorbidities such as depression, PTSD, and generalized anxiety disorder often accompany TBI and have overlapping symptoms.[118]

Pharmacologic interventions for neuroprotection and management of neurobehavioral disorders following TBI continue to lack significant scientific evidence in the medical literature. Neuroprotective agents seek to prevent death of neurons after injury. While some agents have shown promise in animal studies, large clinical trials in humans have not revealed strong evidence in support of a single agent. In particular, although thought to be effective in preventing secondary injury after TBI, level I evidence now exists demonstrating that the use of high-dose methylprednisolone in individuals with severe TBI is contraindicated due to increased mortality risk.[119]

In addition, numerous medications have been advocated to help facilitate recovery of functional deficits after TBI. Clinicians should consider the following pharmacologic management: (1) for *arousal*, methylphenidate, amantadine, modafinil, and zolpidem; (2) for *attention and memory*, methylphenidate, dextroamphetamine, amantadine, physostigmine, and donepezil; and (3) for *agitation, irritability, and aggression*, propranolol, quetiapine, clozapine, valproate, and antidepressants.[120]

Posttraumatic seizures (PTS)/epilepsy occur in 2% to 47% of patients with TBI. PTS are typically characterized as *immediate* (within the first 24 hours), *early* (within the first week), or *late* (occurring after the first week). Risk factors for early PTS include intracerebral hematoma, subdural hematoma in children, younger age, severity of injury, and alcoholism, whereas risk factors for late PTS include early PTS, intracranial bleed, severity of injury, and age more than 65 years.[121] Management of seizures is usually achieved with antiepileptic drugs such as phenytoin, levetiracetam, carbamazepine, and valproate, although these should be monitored for their frequent side effects, including fatigue, dizziness, and lightheadedness.[122]

Patients with TBI are also at significant risk for developing HO, DVT/PE, spasticity, bowel and bladder incontinence, and skin breakdown. The reader should refer to discussion of these topics earlier in the chapter.

BURN INJURIES (SEE CHAPTER 51)

Introduction

Burns often occur simultaneously with other traumatic injuries including orthopedic injuries, TBI, SCI, or amputations. Severe disability, altered body image, and numerous physical and medical complications often lead to a diminished quality of life among survivors of burns.[123] Burn injuries account for 40,000 hospital admissions annually in the United States and are the fifth most common cause of unintentional death.[124] Advances in early resuscitation techniques, topical chemotherapy, early wound excision, isolation practices, infection control, antibiotics, and grafting techniques have contributed to the improved survival rates from severe burns.[125]

Classification

Burns are classified by size and thickness. The size of a burn is measured as a percentage of total body surface area, with the *rule of nines* providing a rough estimation of the area that has been burned in an adult. Using this rule, the head and

neck and both upper extremities account for 9% each of the total body surface area, the lower extremities and the anterior and posterior trunk are 18% each, and the perineum and genitalia are 1%. Thus, an estimate of the total body surface area involved in a burn can be quickly calculated. The thickness of a burn is classified as superficial, partial thickness, or full thickness. A superficial burn affects only the epidermis, whereas a partial-thickness burn extends through the epidermis to part of the dermis. A full-thickness burn affects the epidermis and entire dermis and may also involve underlying muscle, tendon, fascia, or bone. [125,126]

Complications

After acute treatment, the focus of burn care shifts to rehabilitation and restoration of function. Attention to the prevention and treatment of the following complications is an important aspect of burn rehabilitation.

HYPERTROPHIC SCARRING

Excessive scarring following burns may result in significant joint contractures and disfigurement, negatively impacting functional capabilities and quality of life. Despite little evidence of its efficacy, the most widespread method of preventing excessive scarring is the application of pressure garments. Other preventative measures include splinting, stretching, and range-of-motion exercises.[127]

WEAKNESS AND PROTEIN CATABOLISM

Following severe burns, a dramatic increase in protein catabolism results in weakness, decreased exercise tolerance, and functional deficits. Treatment and prevention consist of strength training and endurance exercises, which may be effective in increasing strength and function.[128] In addition to exercise programs, treatment with anabolic agents such as oxandrolone has been observed to reduce or prevent weakness in a burn population.[129]

HEAT INTOLERANCE

The ability to regulate and tolerate heat is often decreased following burn injury.[130] The mechanism for heat intolerance may be rooted in changes in central and peripheral thermoregulation; however, studies have suggested the involvement of still yet unknown factors.[131] Despite the uncertainty surrounding the etiology of heat intolerance in burn patients, it must be recognized and incorporated into the rehabilitation program of this population.

PAIN AFTER BURN INJURIES

Pain after a burn depends on the depth of the injury. In a partial-thickness burn, nerve endings in the dermis may remain intact, resulting in significant pain. In contrast, pain may be less or absent in areas of full-thickness burns because of loss of nerve endings. Approximately 35% of burn survivors continue to report significant pain more than a year following the injury (see the earlier section "Pain Management").[125]

AMPUTATION(S)

Despite aggressive limb preservation procedures after a burn, the extent of tissue damage or secondary complications such as infection or ischemia may mandate amputation. The combination of comorbid burns and amputation presents unique rehabilitation challenges, especially with regard to the prosthetic socket interface and skin breakdown.

PSYCHOLOGICAL COMPLICATIONS

Following burn injuries, emotional complications including depression, body image dissatisfaction, and PTSD may complicate recovery and rehabilitation. Furthermore, hypertrophic scarring may result in significant facial or limb disfigurement, leading to significant dissatisfaction with body image and difficulty with community reintegration. In the 1 month after a burn injury, 54% of patients report depression, whereas 43% of patients continue to report emotional distress 2 years after injury.[132] PTSD has been reported to occur in 13% to 25% of patients with burn injuries. Although there is little evidence for specific treatment recommendations, it has been established that "debriefing" sessions may actually be harmful or increase the rate of PTSD following traumatic events.[133] The recognition and treatment of psychological complications of burn injuries are crucial to the design and implementation of a successful rehabilitation program.

AMPUTATION

Introduction

In the United States, approximately 2 million people live with limb loss. Demographic projections estimate that by the year 2050, nearly 3.6 million Americans will be living with major limb loss (1 in 144 persons).[134] These high estimates are due to vascular occlusive diseases, which have been known to cause approximately 82% of amputations and account for nearly 30,000 new cases annually. The majority (>60%) of these patients also have diabetes mellitus.[135,136] Traumatic amputations from war wounds have accounted for over 1700 service members losing a major limb from wounds sustained in either Iraq or Afghanistan.[137] In addition to their distinct mechanism of injury (blast), these injured service members represent a unique patient population when compared to other civilians with acquired limb loss in terms of demographics, location of amputation, and presence of comorbid injuries.[138] Trauma remains the highest contributor to pediatric and upper limb amputations, whether in civilian or military populations. In fact, 68.6% of all traumatic amputations occur in the upper limb. Numerous physical, psychological, and functional challenges accompany major limb loss and create additional challenges for successful rehabilitation and reintegration.

The decision to amputate or salvage a limb depends on the extent of injury and tissue viability. Evidence suggests that, at 2 and 7 years after injury, there are no significant functional outcome differences between those who undergo limb salvage surgery and those who undergo amputation. Limb salvage

patients, however, are more likely to have longer hospital stays, more operative procedures, and a higher complication rate in the short term. Additionally, long-term follow-up of both groups demonstrates a lower quality of life compared with age-matched controls.[139] Individuals with acquired major limb amputation have a higher lifetime incidence of various pain syndromes (eg, residual limb pain, PLP, back pain), skin problems in the residual limb, overuse injuries, cardiovascular disease, and diabetes mellitus.[138] Of particular concern for children with limb loss are psychological acceptance, altered self-image, and the development of bony overgrowth of the amputated limb.

Treatment

For a comprehensive review of amputee care, the reader is referred to the textbook titled *Military Medicine: Care of the Combat Amputee*.[140] Although there have been great advances in the rehabilitation methods and prosthetic devices that are currently available for individuals with major limb amputation, the acute medical and surgical care of these patients has longlasting implications for community reintegration and quality of life. Decisions such as optimizing limb length, balancing muscles, appropriately managing transected nerves, and achieving adequate soft tissue coverage are fundamental surgical principles that will greatly affect prosthetic fitting and training. Aggressive acute pain management, physical and occupational therapy, and balance and gait training, along with reduction of cardiovascular risk and nutritional counseling, will likely reduce long-term complications. Introduction of a prosthesis early during the course of treatment is essential, especially for individuals with upper limb loss, in order to promote lifelong bimanual activity and help avoid overuse injuries of the intact limb. Prosthetic fitting and training for children with amputation(s) are especially challenging and should be guided by the child's developmental milestones (eg, reaching, standing, and walking). It is important to introduce play, sport, and recreational activities with appropriate adaptive equipment to help facilitate socialization and reintegration into the community as well.

PERIPHERAL NERVE INJURIES AND COMPLICATIONS

Introduction

Traumatic injuries to the peripheral nervous system may contribute to a significant loss of function and independence, which may not be readily evident during the initial trauma screen. Peripheral nerve injuries may occur as a complication of medical care. Reported causes have included improper bed positioning, compressive casts, poor-fitting orthotics, excessive pressure during surgery, or inadvertent needle sticks. Common sites of nerve injury include the brachial plexus, ulnar nerve at the elbow, and peroneal nerve at the fibular head.

Cognitive impairment or injury to the spinal cord may limit the ability to fully assess the peripheral nervous system. In addition, confounding conditions such as a critical illness neuropathy or myopathy may contribute to sensory or motor dysfunction, especially for patients requiring extended intensive care. Electrodiagnostic testing may be helpful in assessing the presence and extent of peripheral nerve damage as well as establishing the prognosis for recovery. Typically, nerve injuries are classified as either complete or incomplete. *Neuropraxia* refers to an incomplete injury, characterized by demyelination, and has an excellent prognosis for recovery. Damage to the axon (*axonotmesis*) signifies a more severe injury with a poorer prognosis. Axon regeneration can be estimated to occur at a rate of 1 to 5 mm/d or 1 inch per month.

Prevention and Treatment

A discussion of repair or grafting for peripheral nerve injuries is beyond the scope of this chapter; however, if repair is undertaken, proper postoperative positioning, splinting, and activity precautions should be explained to the patient and treatment team to help support healing and prevent damage. Peripheral nerve care and injury prevention require serial neurologic examinations, attention to patient positioning, and frequent monitoring of pressure-sensitive areas. Positioning is particularly important during surgical procedures. Frequent turning by nursing staff may be necessary if the patient's injuries do not allow independent changes in position. Special attention is required when placing casts or external fixation devices. The use of ultrasound to guide interventional procedures may help to avoid inadvertent iatrogenic injuries.

Trauma, Medicine, and the Law

Kenneth L. Mattox • Carolynn Jones

KEY POINTS

- When in doubt and time and life are running out, *treat.*
- Have specific instructions for judicial intervention and emergency psychiatric detention available in the trauma center.
- Be mindful of Hippocrates's admonition, "Which ought not be spoken of abroad, I will not divulge, as reckoning that all should be kept secret."
- Compliance with local reporting laws is essential to avoid potential criminal penalty and civil liability.
- The police department's duty is containment and control, whereas the trauma team's duty is care and cure. To each his own.
- Avoidance of malpractice claims depends on the exercise of skill based on knowledge of reasonable, ordinary, prudent physicians under similar circumstances.
- An unfavorable outcome does not, of necessity, imply or result in a legal lawsuit; if such were the case, 50% of all attorneys in court cases would be so guilty.
- Standing orders, best practices, protocols, guidelines, and electronic recommended practices all have value, but the ultimate hallmark of the professional is the exercise of sound judgment in any particular case.
- Records must be made for the patient's benefit, not for the attending physician, hospital, attorneys, or quality surveillance. Corrections to records can be made, dated, and timed, but the original entry must not be removed.
- Freely use consultation and escalation of concerns when indicated. There are always persons, processes, and resources to provided unknown, unfamiliar, or clarified information.

INTRODUCTION

Interactions between the medical and legal professions increase in both complexity and number with each passing year. No longer is the focus only on fear of being sued, testifying in court, and preparing for a deposition. In-hospital legal counsels, now in most hospitals, add another dimension and play a significant role in any medicolegal situation. This chapter will focus on the major concerns a physician must have when treating an injured patient—the intersection/interaction among trauma, forensic medicine, and the law. The trauma patient with physical and emotional injuries can bring legal issues, some of which can be more challenging to the trauma team than the clinical problems. Legal issues can range from civil rights to criminal law, and the team needs to have some basic knowledge to appropriately address medicolegal issues that may arise. Despite differing and ever-changing laws from state to state, some basic guiding concepts can be set forth.[1]

CONCEPTS, PRINCIPLES, AND DEFINITIONS

It should be noted that legal and medical definitions or concepts may differ and that such variances are important to medical personnel interacting with forensic and legal personnel, especially in a courtroom, deposition, or adversarial situation. Some general definitions are as follows:

- Abandonment—Terminating care of a patient without assuring that a continuum of the same or higher level of care exists.
- Assault and/or battery—Unlawful touching of a person or patient without appropriate consent for that contact.
- Confidentiality—Prohibits the health care provider from disclosing information about the patient's case to others without permission. Also, providers and health care systems are encouraged to take steps to ensure that only authorized access occurs, which, in this era of the

electronic medical record, can be challenging. Additionally, state law requires reporting certain communicable/infectious diseases, as well as suspected cases of child, dependent adult, and elder abuse, and gunshot wounds. What is reportable can change, and the health care provider must be cognizant of requirements where he or she practices.

- Competence—Ability of a patient to understand the questions put to them by health care personnel and to understand the implications of the treatment recommendations and decisions made.
- Negligence—Deviation from an accepted standard of care that would be rendered by a similar practitioner under similar circumstances.

Duty to Treat

In the "modern" version of the Hippocratic Oath, the phrase **"…there is the obligation to all my fellow human beings, to treat those of sound mind and body as well as the infirm"** establishes the tone of the regulations for a duty to treat any patient who presents with an immediate, life-threatening condition.[2] Wide interpretation and discrepancies exist regarding "duty to treat," depending on urgency of clinical condition, availability of appropriately skilled clinicians, availability and infrastructure of the treating facility, and availability of a higher level of care within the geographic area. In addition, the availability of funding for hospitals and clinicians has resulted in local, state, and federal regulations to protect patients, practitioners, and hospitals. Once a patient enters a treatment facility and is found to have an immediate, life-threatening condition on initial evaluation, the obligation to continue the treatment is understood, as is the now established physician–patient and hospital–patient relationship. That relationship continues until physician or patient terminates, by mutual consent, until services are no longer needed, or until the physician properly withdraws from the relationship.[3] The Emergency Medical Treatment and Active Labor Act (EMTALA), passed by Congress in response to hospitals refusing to treat patients based on their ability to pay, requires hospitals and physicians to provide a medical screening examination and stabilizing treatment for patients who present with an emergency medical condition to a hospital with a dedicated emergency department.[3,4] The physician's duty to treat and/or stabilize the patient for transfer to a facility with a higher level of care is clear. Should a physician misrepresent a patient's condition to facilitate a transfer or violate any requirements of EMTALA, civil penalties exist, including fines and exclusion from participating in Medicare and Medicaid programs.[3,4] The Americans with Disabilities Act of 1990 prohibits the denial of an individual's access to health care based on a disability, unless providing said care poses a direct threat to the health and safety of others that cannot be eliminated by adequate precautions.[3,5] Implicit in these laws is that inability to pay is not an acceptable (or legal) reason for nontreatment of any patient presenting with a life-threatening condition. While implicit to all emergency facilities, this is especially pertinent to designated trauma centers of all levels that provide care to critically injured patients.

The duty to treat a patient does not change, even if the patient is the perpetrator of a violent crime. The fact that the patient was injured or injured others while driving intoxicated or while wielding a gun is irrelevant. The physician has a duty and ethical obligation to treat the patient, regardless of the situation surrounding the injury.

Consent

Numerous terms and concepts apply to the many consent issues involved in patient care. Appropriate informed consent protects the legal rights of patients and guides the ethical practice of medicine. Since the risk of litigation often depends on patient dissatisfaction due to lack of communication with the physician, strong practices for informed consent may actually prevent such suits from being filed.[6,7] *The informed consent process should be documented thoroughly, using an electronic medical record, procedure-specific consent forms, patient education materials, and other options whenever possible*.[7] Except in urgent life-threatening situations, at its simplest, consent is required whenever a health care provider intends to render care to a patient.[6] The physician's (and hospital's) duty extends beyond obtaining a patient's signature. Informed consent includes providing enough knowledge to the patient about the procedure, the risks and benefits, and any alternative treatments for the patient to make an "informed" decision.[8,9] As outlined by The Joint Commission, this process has several components, which include the nature of care, medications, procedures, possible risks and benefits, and any limitations on confidentiality of information learned from or about the patient.[10] As one enters an emergency center or is admitted to the hospital, consent to be evaluated and treated is usually obtained. Many patients do not completely read the "fine print" above this simple signature block and are often in a hurry to get on with an emergency evaluation. Beyond this simple entrance signature, additional informed consent is required for more detailed treatment (such as an operation) once that more complex treatment is known to be required.

EXPRESS CONSENT

A patient directly communicates his or her permission for recording a history, having a physical examination or tests, and treating the conditions discovered. The doctor or other knowledgeable health care worker must describe the reason for the examination and treatment, the treatment to be rendered, the risks of such treatment, and possible side effects and complications. The consent form should include the physician's name, location of the treatment, and date and time of treatment, as well as a description of the treatment. Oral (without any written or electronic documentation) consent is difficult to prove/defend in a court of law.

IMPLIED CONSENT

In contrast to express consent, implied consent is when a patient's actions and the facts and circumstances of the situation act as the patient's consent for the medical treatment. For example, a patient who extends their arm to have blood drawn has given presumed or implied consent in an emergency situation[8]; as another example, when a patient presents with traumatic injuries and cannot understand or communicate and a family member cannot be reached, it is assumed that consent to lifesaving emergency treatment would be desired. Of course, if this patient should present with a living will or an advanced directive specifically requesting that no heroic lifesaving measures be undertaken, there is no implied consent.[10] Often, only after a blood transfusion has begun, does the team become aware that the patient or his or her family is opposed to such intervention. In these cases, the intervention is stopped, and the situation is carefully documented. The members of the treating team should, if time permits, attempt to ascertain the presence of any advanced directive or official treatment requests.

In obtaining consent, there are several considerations for the surgeon. In certain circumstances, minors, for example, may provide consent without parental involvement.[11] Individual state regulations also outline other situations in which minors may give consent, such as treatment for sexually transmitted infections, abortions, contraception, and prenatal care.[11] It is incumbent upon health care providers to know the laws and policies of their state and hospital.

WAIVER OF CONSENT

In certain cases of emergency care, federal regulations allow the local institutional review board to approve a consent procedure, which does not include, or which alters, some or all of the elements of informed consent, or to waive the requirement to obtain any informed consent. Most complete waivers of consent involve studies in which there are minimal risks to subjects, but complete waivers are also possible in emergency care and a few other circumstances. In such circumstances, it is appropriate to inform the patient and the family as soon as possible after the emergency and after treatment has been rendered. The surgical team should then obtain written documentation that the patient and/or family understands and gives consent, assent, or understanding.

SURROGATE CONSENT

Both state and hospital policies define who (and in what priority) may give informed consent in defined circumstances for patients whose clinical condition does not allow them to speak for themselves or understand the implications of the information given to them. In the event a patient lacks the capacity to consent, health care decisions may be made by the patient's legal representative such as a parent, family member, guardian, or another with medical power of attorney.[8] Hospital policies define the priority of surrogate consent, and these policies usually reflect local or state laws.

Competency in medicine is different from the legal connotation. Competency or capacity refers to the patient's ability to understand what is best and right for him or her, and the decision is autonomous.[10] Competency is generally not an issue unless the patient suffers from a cognitive deficit, such as Alzheimer disease. Substance abuse or withdrawal from a substance that has caused altered mental status will affect competency, as well.[9] All attempts should be made to obtain consent. For example, hospital administrators may assist when there is an issue with competency and no patient representative is available. Under such circumstances, an *ad litem* (court-appointed) representative of the patient might be considered. Local, state, and federal regulations exist defining the process and payment for *ad litem* representation.

REFUSAL OF CONSENT

The adult patient who fully understands the implications of his or her decision has the right to refuse to be examined, to be admitted to undergo laboratory tests or procedures, or to be treated in other ways.[10] Under some circumstances, local law or hospital policy requires the local ethics committee or a legal *ad litem* attorney to become involved, especially if the adult refusing treatment has minor children or is mentally incompetent. When evaluation and/or treatment is refused, it is important to carefully and completely document the conditions of the refusal and the various persons involved in advising and interacting with the patient. While troubling and frustrating for the physician, the right to refuse treatment must be recognized and respected. Refusal to consent is usually reserved for a patient who has reached majority. In the case of a parent issuing a "refusal to consent or treat" for a minor child, the legal system often becomes involved with hospital administrations and physicians to determine what is permissible. In refusal to consent situations, the physician must consider competency a subjective assessment, and judgment of such falls to medical professionals.[12] The physician must ensure all information is provided and any questions answered so the patient or surrogate has the data to make an informed decision.

Health Insurance Portability and Accountability Act, the Electronic Medical Record, and Social Media

Federal law (Health Insurance Portability and Accountability Act [HIPAA]), state laws, and hospital policy protect patient privacy, hospital medical records, and physician confidentiality in matters of peer review. With the introduction of the electronic medical record (EMR) and ever-expanding availability of social media networks/devices, new and stricter surveillance and control have become necessary to assure privacy and confidentiality.

All hospital and personal electronic devices (eg, computers, smart phones, smart pads) have the capacity for misuse and transmission, deliberately or accidentally, of sensitive patient or medical staff information to public social networks or

hackers. Internal controls must be in place for surveillance, detection, and rapid response if violations are discovered.

Many hospitals have developed policies and protocols to allow, and even encourage, use of smart phones to take appropriate photographs of forensic, intraoperative, pathologic, and other material that is clinically significant. Software and "apps" exist that then allow secure transfer of this data to the EMR, with subsequent deletion of the material from the original source. Health care providers must be aware of HIPAA social media rules and should receive training specific to same.

Forensic and Medical Implications

Forensic and legal issues surface daily in trauma care but may be overlooked or unidentified due to the urgency of the situation. Health care providers are able to and, indeed, need to provide lifesaving measures and "think forensically" at the same time. By considering the forensic and legal implications, evidence that may be vital to the outcome of a legal case is preserved without impeding appropriate medical care.

Trauma team and law enforcement activities repeatedly intersect in various locations for a variety of reasons including system and organizational regulation and review, patient complaints and undesirable results, and quality and peer review, to name a few.

Each year, over 1.6 million lives are lost worldwide to violence, and countless others sustain injury.[1] By understanding the law and the health care forensic implications of the law, identifying and preserving evidence during the course of evaluation and treatment, and accurately describing wounds, the physician is an indirect advocate for the patient and may provide information that will be used by law enforcement and the justice system.

The very nature of traumatic injuries leads one to consider forensic or legal implications. For example, preserving the clothing of a gunshot victim may be critical to the outcome of courtroom proceedings. Obtaining blood samples from a potentially intoxicated driver is considered essential in some political jurisdictions. The local laws concerning a hospital or physician's rights and responsibilities in ordering laboratory data for the sole purpose of obtaining forensic evidence are inconsistent, and clinicians must be cognizant of hospital, local, and state regulations. Traditionally, forensic issues have not received much, if any, priority, since lifesaving measures are the primary objective; however, physicians and other providers are quite able to render necessary care while also taking care to appropriately preserve evidence.

Forensic Nursing and Trauma Systems

Proper evidence collection and preservation may be accomplished with the assistance of forensic nursing. The forensic nurse is specially educated and trained in both the health care and legal arenas and provides direct services to patients and providers.[13] Those include injury identification and documentation, forensic photography, evidence collection, death investigation, and addressing the psychosocial needs of the patient and family. The forensic nurse may be present in the trauma room to collect and preserve evidence and document injuries through photographic means or using body diagrams.[14,15] For example, clothing that is removed is handed to the forensic nurse, who places and appropriately labels each piece in separate containers to prevent contamination. In addition, bullet fragments removed during surgery may be given to the forensic nurse, who ensures chain of custody and releases the evidence to the investigating agency.

Patients presenting with traumatic injuries may not be able to provide a history of the precipitating event. The forensic nurse anticipates the types of evidence that need to be preserved, and his or her presence in the trauma room allows the surgeon to focus on lifesaving measures, while confident that evidence is appropriately preserved. Information including photographs obtained for forensic purposes is logically available during the trauma quality review process. Also, once identification markers have been removed (HIPPA requirements), such materials might also be very helpful in clinical scientific preparations for publication.

Injury Identification

The trauma center evaluates injuries and underlying nontrauma conditions, assesses risks, and classifies and grades injuries. This latter task using an established injury classification schema such as those developed by professional organizations (American Association for the Surgery of Trauma, American College of Surgeons, and others) may impact later legal actions. It is not always immediately clear, however, that a wound is caused from a blunt or penetrating source or even the identity of a specific wounding agent. Therefore, the final coding by the trauma service is determined at the end of the hospital admission.

For cases involving gunshot wounds when it is known or suspected the patient may have been the shooter, bagging the hands for later examination by forensic investigators is advocated, if possible.

When bullets and fragments are removed during emergency treatment, they are evidence. In preserving the evidence and assuring appropriate "chain of evidence," there are several cautions and principles to follow when removing a metallic foreign body:

- Avoid using a metal instrument to extract the metal foreign body. Metal on metal creates "scoring" on the missile that might distort the forensic evidence.
- Avoid dropping a metallic missile into a metal container for the same reason. The foreign body should be gently placed into a plastic specimen cup available in hospitals, assuring that patient labels are on the side and cap of the specimen cup.
- Do not scratch your initials and the date on the foreign body. Use appropriate/approved methods of documentation, in accordance with the established hospital policy of managing forensic evidence and the chain of custody.

- The physician removing the foreign body should record the details of the foreign body removal, to whom the missile was given, and the instructions given to this individual.
- The person *receiving* the foreign body and placing it into the plastic cup should also document the same in the record, as well as to whom the container was given (hand-off).
- The exact process and the offices where forensic evidence is maintained are determined by each hospital and clearly stated in that hospital's "Chain of Evidence" policy.

With victim's clothing, avoid cutting through defects or holes, which can destroy evidence. Cuts should be made around the defect or along the seam, and individual items of clothing should be placed in separate paper bags. The top of the bag is then folded over, sealed with tape, and labeled with the examiner's initials. If available, the forensic nurse can expedite and assure proper procedure in handling, photographing, packaging, and labeling clothing. Once bagged, the clothing will be released to law enforcement or stored in a locked area of the hospital.

INTERACTIONS WITH UNIFORMED OFFICERS (POLICE, FIREMEN, OTHERS)

In the course of their normal activities, law enforcement and medical professionals will find themselves in juxtaposition and occasional confrontation as to who has specific authority in some instances. Even with existing policy from local or state law, law enforcement agencies, hospitals, or state medical boards, it is probable that such laws or policies may be in opposition or have different interpretations.

Blood Specimen Collection for Law Enforcement Purposes

In some instances, the patient is the alleged perpetrator of a crime. Primarily for legal rather than clinical reasons, there is a need to identify any illegal substances or high levels of alcohol, since toxicology results impact charges and sentencing of defendants. Forensic toxicology studies are then performed in crime laboratories where assays identify and quantify submitted specimens. It should be remembered that obtaining specimens for legal reasons is different from routine laboratory testing. Local and state laws differ with regard to the need for permission from a patient to obtain blood, urine, tissue, or exhaled air specimens. All members of the treating team should know the dictates of local/state law, as well as related individual hospital policies. When laws and/or policies do mandate consent from a patient/surrogate consent, the physician must assure that the patient's cognitive condition allows for informed consent. Some states have mandatory requirements, while others require a search warrant or court order for collection of specimens.[16]

Blood samples should be obtained within 3 to 4 hours of a trauma incident to provide accurate blood alcohol content, and it is critical to assure that time of specimen collection is accurately recorded.[16] Commercial specimen collection kits are available to aid in collection and chain of custody.

Chain of Custody

Chain of custody is the "paper trail" that documents each person who has custody and control of a particular piece of evidence or a specimen. The chain begins with the person who collects the evidence and continues with each subsequent person who handles the evidence until it reaches the crime laboratory. The following information must be documented in the medical record[16]:

- Each person who handled the specimen(s)
- Name and badge number of the officer receiving the specimen/evidence
- Other law enforcement agency personnel who might be present
- Date and time the specimen/evidence is released

Failure to maintain and appropriately document the chain of custody opens the door for attorneys to dispute the validity of the evidence.

Sexual Assault Examinations

Victims of sexual assault most often seek examination in a trauma center or emergency department. During the examinations, collections are made from physical evidence, and biologic specimens are obtained.[17] Such collections are saved per protocols and submitted to law enforcement officials. The responsibility of the trauma service is to assure that the patient's clinical needs are met and that appropriate collections are performed to comply with the hospital's protocols for sexual assault examinations.[17-19]

Officers Entering Health Facilities

Uniformed officers may be in a health facility as contract security officers, because they were called by hospital personnel, or because there is a personnel safety issue. Hospital operations and policies are usually under the direction of the administration and the medical staff. When uniformed officers enter the buildings under emergency conditions, however, the duty of emergency management shifts to the uniformed officers with tight communication and input from the hospital's incident command.

Fire Alarms

Fire in any public building is a crisis, whether notification is caused by a public alarm or an internal fire box alarm. Such an alert or alarm from a hospital prompts an immediate response from local and regional fire stations. Then, fire chiefs and police authorities enter the hospital with practiced protocols in action. The fire chief who responds to a hospital

fire alarm is in charge of hospital operations and functions and will issue safety orders to maximize employee and patient safety.

Active Shooter in a Public Place

Protocols regarding an active shooter in a hospital are widely distributed and practiced. During such an event, it is local security officers and uniformed police who are responsible for security operations within the hospital and will issue directions that will maximize personnel safety. Ideally, local police officers will have drilled with in-hospital security officers as well as with administrative and clinical personnel, including physicians. There have been ethical and moral concerns from physicians and nurses regarding abandoning helpless patients with the "run, hide, fight," policy. New collaborative protocols interacting with uniformed officers to produce an initial "contain and control" environment, especially in the emergency center, obstetrics, operating room, and intensive care units, are being investigated and implemented.[20]

Officers Accompanying Prisoners

The laws and rules regarding prisoners' rights do not change because they are in the hospital; however, the prisoner as a patient has the usual rights regarding privacy, confidentiality, and so on.

Undocumented Aliens as Patients

One recent area of concern relates to persons who are in the United States without official or legal visas or papers and who become patients. Concern exists among clinicians that immigration officers might learn of such "undocumented aliens" and "extract" them from the hospital or request that they be dismissed prematurely from the hospital. As in all areas of clinical concern, a well-understood hospital policy should be created regarding the clinical responsibilities for such patients.

LEGAL CONSIDERATIONS DURING DISASTERS

The principles of interaction between medicine and the law should not change in the face of a disaster. The principles relating to licensure, credentialing, and consent continue to apply, even in extreme or special circumstances. The fact that a physician (or other health worker) may be from an outside geographical or political jurisdiction does not remove the organizational and personal responsibility to comply with local credentialing and licensing laws. During disasters, the flow of supplies, equipment, and personnel may be altered, but the responsibility for the physician and the clinical team to comply with professionalism and standard best practices within their capability and resources still applies. Record keeping may be a challenge, but detailed and accurate records must be the undisputed goal during these times.

During a disaster, all personnel working in the hospital are subject to the bylaws and policies of the hospital, as well as state and local law. All questions relating to medical authority, supervision, coordination, and action during the time of a declared disaster in regional shelters are subject to the regional incident command structure and its medical branch. Any outside agency must function under the authority of the regional authority, unless subject to a federal law.

INTERACTING WITH ATTORNEYS

Hospital Bylaws, Committees, Credentialing, and Policies

As part of any hospital, clinic, or health department function, and especially in any trauma care facility, it is axiomatic that surgeons and other trauma team members will interact with attorneys on a frequent basis. Most hospitals, medical schools, and medical facilities have an in-house or consulting legal counsel that assists, among other things, in the preparation of bylaws, policies and procedures, credentialing, outside regulatory review, and the interpretation of local, state, and federal laws. These attorneys are hospital employees, and the interests of the hospital are their primary concern. The medical staff bylaws govern and "belong to" the organized medical staff. As bylaws are revised to adapt to changing regulations and policies, it is imperative that the bylaws committee members review all in careful detail, with the goal of keeping the bylaws in the best interest of the organized medical staff. In some instances, it is advisable for the organized medical staff to employ their own legal counsel to assure that the medical staff's interests have not been compromised when bylaws are written or modified.

Professional Liability, Depositions, and Testifying in Court

Despite best intentions to practice the highest quality of medicine possible, dissatisfaction, complications, and misadventures will occur in all treatment environments. At the hospital level, such events are reviewed during the hospital quality review process, including mortality and morbidity meetings, performance improvement committees, peer review committees, and sentinel event committees. Except for criminal cases, the minutes and proceedings of these reviewing entities are protected from discovery. Physicians should participate in these hospital activities, including reviews of their own cases. In the course of caring for trauma patients, being named in a malpractice suit, being asked to peer review records of another physician, and being asked to testify in court about an injury are not uncommon. On receipt of a subpoena, the first step is to contact your attorney and/or in-house counsel and insurance carrier. From that moment on, talk to no one else about the case without the advice and/or presence of your attorney. Preparatory to a deposition, review all related records to the depth and detail you would in preparing for a board exam.

At the time of a deposition or court testimony, listen carefully to every question asked and answer that question. Do not volunteer any additional information (even when sorely tempted)! If you do not understand the question, so indicate. If you are interrupted by the judge or an attorney, stop talking (in mid-sentence, if necessary) and listen carefully to the nature of any objection or interruption. Do not continue until your attorney or the judge advises you to do so. You may ask that a previous response or question be read back to you by the court recorder. If you have authored or co-authored published articles, be prepared to defend your writings.

The two categories of witnesses are "fact" and "expert." A fact witness is called to enter into the record facts as they remember them, discover them in the medical record, or otherwise glean information. An expert witness is certified by the court as having special knowledge and is called upon to elaborate on information pertinent to the case from the vantage of his or her special knowledge, background, and experience. An expert witness might also be a fact witness, but not usually vice versa. Again, the expert witness must be prepared to have all he or she ever said, wrote, or did come under very careful scrutiny.

V

MANAGEMENT OF COMPLICATIONS AFTER TRAUMA

This page intentionally left blank

57

Principles of Critical Care

Lena M. Napolitano • Raul Coimbra • Jay Doucet • Leslie Kobayashi

KEY POINTS

- The primary goal of critical care in the trauma patient is restoration of hemodynamic stability and organ function via continuation of early trauma care, hemostatic resuscitation, organ support, and specific injury management.
- The ultimate goal of optimal intensive care unit (ICU) care is to achieve zero preventable deaths after injury.
- High-intensity ICU physician staffing is associated with significantly reduced ICU and hospital mortality and significantly lower failure to rescue rates.
- Although Advanced Trauma Life Support has standardized trauma care in the initial hour after injury, there is little standardization subsequently in the ICU.
- ICU admission order sets should be used to optimize early ICU care on admission.
- Damage control resuscitation and massive transfusion protocols decrease mortality from hemorrhagic shock, which is the most common cause of early mortality in trauma.
- National evidence-based guidelines should be used to guide postinjury ICU care.
- Daily goals checklist and the ABCDEF Bundle enhance ICU patient safety and progress.
- All preventive strategies should be implemented to prevent hospital-acquired infections.
- Traumatic brain injury management is based on the Brain Trauma Foundation guidelines.
- Septic shock has a mortality rate of 40%; the Surviving Sepsis Campaign (SSC) guidelines and 2018 SSC bundle provide recommendations to improve outcomes.
- Acute respiratory distress syndrome (ARDS) has a high mortality rate, and use of national ARDS guidelines reduces mortality.

INTRODUCTION

We have had great advances in the care of the injured patient from prehospital and emergency department care to care in the intensive care unit (ICU). Care in the ICU is designed to provide optimal resuscitation, reestablish homeostasis, and minimize secondary and iatrogenic complications (particularly organ failure). Over the past 20 years, critical care has matured greatly, resulting in dramatically higher survival rates for our critically injured patients. Excluding early deaths in the operating room, most trauma hospital deaths will occur in the ICU. In the ICU, the outcome of critically injured patients is dependent on a solid understanding of the pathophysiology and evolution of traumatic injuries, optimal postinjury resuscitation, and prevention of complications. Meticulous attention to detail in all ICU care provided to trauma patients is essential if we are to achieve the ultimate goal of *zero preventable trauma mortality*.

MORTALITY IN TRAUMA

Despite an organized system of trauma care in the United States, the number of trauma deaths increased by 22.8% from 2002 to 2010 for those age 25 years and older, with a concurrent increase in the US population of 9.7%. The largest increase in trauma deaths was in the 50- to 60-year-old cohort.[1] The two most common causes of early trauma mortality are hemorrhagic shock and traumatic brain injury, both of which require extensive ICU care. The 2016 National Academies of Sciences, Engineering, and Medicine report, "A National Trauma Care System: Integrating Military and Civilian Trauma Systems to Achieve Zero Preventable Deaths After Injury,"[2] presents a vision for a national trauma care system driven by the clear and bold aim of zero preventable deaths after injury and minimal trauma-related disability.

Standardization of evidence-based ICU care in trauma is of vital importance with a goal to improve trauma outcomes.

Studies have documented low compliance rates (10%–40%) with standardized protocols in trauma. It has been confirmed that major deviations from guideline-based clinical care are associated with significantly higher mortality after injury and increased organ failure.[3] The implementation of standard operating procedures (SOPs) in the Glue Grant documented significant improvements in morbidity and mortality rates with increasing compliance with published SOPs.[4] Although we have standardized trauma care in the initial hour after injury with use of Advanced Trauma Life Support, there is little standardization subsequently.[5]

Although major quality improvement initiatives have been undertaken at the national level to improve care at trauma centers (American College of Surgeons [ACS] Trauma Quality Improvement Program [TQIP]), major variations in outcomes between trauma centers persist.[6] The fact that some hospitals perform better than others suggests that some patients are not receiving the best possible care, which may result in preventable deaths. A recent study estimated that if all hospitals delivered the highest quality of care to trauma patients, an estimated 167,746 lives (95% confidence interval [CI], 164,534–170,861 lives) could potentially be saved. This report focused on preventable in-hospital trauma deaths, which were presumed due to differential quality of care.[7]

Although evidence-based practice guidelines are recognized to minimize unwarranted health care variation and promote best practices, guideline publication alone does not guarantee practice change. The best method to improve in-hospital and ICU trauma care is to implement patient care protocols and bundles of care developed from evidence-based guidelines.

In the past several years, increasing emphasis has been placed on quality of care indicators and physician staffing models for ICUs. A modern surgical ICU provides evidence-based critical care using protocols, algorithms, clinical practice guidelines (CPGs), and checklists; uses cutting-edge technology for physiologic monitoring; and has a robust quality improvement process to continuously evaluate its outcomes and identify opportunities for improvement. This chapter reviews principles of critical care essential to the management of the injured patient and important critical care and trauma national and international guidelines to provide optimal evidence-based ICU care to improve trauma patient outcomes.

PHYSICIAN STAFFING AND MODELS OF CARE IN THE INTENSIVE CARE UNIT

A growing body of scientific evidence suggests that quality of care in hospital ICUs is strongly influenced by (1) whether "intensivists" are providing care, and (2) how the staff is organized in the ICU. Intensivists are familiar with the complications that can occur in the ICU and, thus, are better equipped to minimize errors.

Several patterns of ICU organization are currently in use. The closed ICU model relies on an attending intensivist and critical care team for ICU patient care. Comprehensive management including responsibility for all orders and procedures is assumed by the ICU team, with other services providing care as consultants as required by the clinical condition of the ICU patient. In the open ICU model of care, individual physicians manage their ICU patients, depending on their institutional privileges. Consultative involvement of a board-certified intensivist is at the discretion of each primary attending physician and is not required or expected. Many ICUs use a semiopen, collaborative care model in which the ICU is staffed with attending intensivists and an ICU team who are responsible for writing ICU orders, but who also coordinate care and communicate closely with primary surgeons and their teams. There are often specific areas of designated critical care autonomy, such as the management of mechanical ventilators, invasive hemodynamic monitoring, pain management, and sedation. Although the ultimate responsibility for the patient remains with the primary attending surgeon, ICU patient care is a collaborative effort. This model combines the advantages of critical care expertise for trauma and surgery patients while maintaining primary surgical service responsibility for overall patient management. This is consistent with the Guidelines for the Optimal Care of the Injured Patient recommended by the ACS Committee on Trauma for Level I trauma centers.[8]

There is now substantial evidence examining the relationship between ICU staffing models and patient outcomes. Mortality rates are significantly lower in hospitals with closed ICUs managed exclusively by board-certified intensivists. A recent distinction has been made between high-intensity and low-intensity physician staffing ICU models. A high-intensity model involves 24/7 dedicated ICU physician staffing and mandatory ICU team involvement with patient management and includes closed ICUs and most semiopen ICUs. In contrast, open units typically use low-intensity ICU physician staffing. In a meta-analysis of 26 studies, high-intensity ICU physician staffing was associated with significantly reduced hospital and ICU mortality (relative risk [RR], 0.71 [95% CI, 0.62–0.82] for hospital mortality; RR, 0.61 [95% CI, 0.5–0.75] for ICU mortality) for both adults and children.[9]

Similar results were found in a study of the effect of high-intensity ICU staffing on outcomes following major trauma.[10] Using prospective cohort data from 68 trauma centers and after adjusting for differences in baseline patient characteristics, the RR of death in intensivist model (closed and semiopen) ICUs was 0.78 (95% CI, 0.58–1.04) compared with an open ICU model. The effect was greatest in the elderly (RR, 0.55; 95% CI, 0.39-0.77), in units led by surgical intensivists (RR, 0.67; 95% CI, 0.50–0.90), and in designated trauma centers (RR, 0.64; 95% CI, 0.46–0.88). The authors concluded that injured patients are best cared for using an intensivist model of dedicated critical care delivery, a criterion that should be considered in the verification of trauma centers.

The mortality rate among surgical patients who develop complications, called *failure to rescue*, is also reduced by the presence of intensivists in the ICU. Failure to rescue is a quality measure that looks at the hospital mortality rate of surgical patients with complications. Hospitals with intensivists on their rapid response teams or in their ICUs have lower failure

TABLE 57-1: Leapfrog Group Intensive Care Unit (ICU) Physician Staffing (IPS) Standard

Hospitals fully meeting the IPS Standard will operate adult or pediatric general medical and/or surgical ICUs and neuro-ICUs that are managed or co-managed by intensivists who:

1. Are present during daytime hours and provide clinical care exclusively in the ICU; and,
2. When not present on site or via telemedicine, return notification alerts at least 95% of the time (1) within 5 minutes and (2) arrange for a physician, physician assistant, nurse practitioner, or a FCCS-certified nurse to reach ICU patients within 5 minutes.

to rescue rates.[11] The presence of surgical intensivists also reduces complications and improves National Surgical Quality Improvement Program general surgery quality measures.[10]

Current ICU staffing requirements for hospitals with adult or pediatric ICUs were developed and implemented by The Leapfrog Group, recommending the ICU Physician Staffing (IPS) Standard (Table 57-1).[12] Unfortunately, only 47% of hospitals reporting in the 2015 Leapfrog Hospital Survey have the recommended intensivist coverage in place and met the Leapfrog IPS Standard.

CONTINUOUS QUALITY IMPROVEMENT IN THE SURGICAL INTENSIVE CARE UNIT

Quality assurance and performance improvement in a surgical ICU are complex processes requiring the ongoing identification of outcome measures or performance indicators, data collection and analysis, and the development of action plans to correct deficiencies and subsequent monitoring. The underlying goal of delivering high-quality ICU care also depends on specialization (critical care specialists), provider education and training, excellent communication, and collaborative interaction between specialty and ancillary services. Existing critical care quality assurance programs have used a variety of clinical indicators or "filters" as a measure of the quality of care. These indicators may reflect process measures (eg, percentage of eligible patients receiving venous thromboembolism [VTE] prophylaxis in a timely manner) and outcome measures (eg, number of central line-associated bloodstream infections or ventilator-associated pneumonia cases). Illness severity indices have been developed for risk adjustment to aid in predicting outcomes in critically ill patients and are used as benchmarking tools, allowing participating units to compare their actual ICU outcomes with those predicted.

The ACS TQIP[13] is a recent addition to the many quality improvement collaboratives that have been established in surgery. Now in its ninth year in 2018, ACS TQIP uses risk-adjusted benchmarking to provide over 800 participating hospitals with accurate national comparisons.[14] Aggregate outcomes by center are reported, as well as outcomes in two distinct subsets: multisystem blunt trauma and penetrating trauma. Additional TQIP reports focus on patients with traumatic brain injury (TBI) or shock or the elderly population. TQIP reports regarding the processes of care are also provided, including the use of intracranial pressure (ICP) monitors for TBI patients, the use and timing of angiography for shock patients, and timing of VTE pharmacologic prophylaxis.

In addition to improved instruments for assessing critical care outcomes, the development and implementation of clinical protocols and CPGs directed at reducing undesirable treatment variability are being linked to ICU performance improvement. Protocols and guidelines, once developed and implemented, can later be analyzed in terms of their clinical efficacy and cost-effectiveness and can be modified further to improve efficiency.

The effectiveness of CPGs has been demonstrated for a variety of conditions including ventilator weaning, pneumonia, nutrition, and sedation. Most institutions experience difficulties with the implementation of CPGs, since it requires the development of brief protocols or bundles of care. Current methods of improving implementation and compliance with CPGs include ongoing education, defined order sets, the assignment of some management responsibilities to specialized teams (eg, nutrition and respiratory therapy), and the use of advanced practice providers (nurse practitioners and physician assistants) in the ICU.

Several fields in medicine, motivated by an increased awareness of errors in medical care delivery, have incorporated lessons learned from aviation to clinical practice to improve quality and patient safety. A checklist is just one of the tools used in the aviation industry that have been tested in many ICUs to potentially improve safety, quality, and consistency of ICU care.[15]

Daily Goals Checklist in the Intensive Care Unit

A daily goals checklist for morning ICU rounds is an excellent aid to ensure optimal communication among all ICU personnel. A recent study examined the use of a daily goals checklist in a 15-bed closed ICU in a tertiary care, university-affiliated hospital that provided care for medical-surgical ICU patients. The daily goals checklist was perceived to improve the management of ICU patients by creating a systematic, comprehensive approach to patient care and by setting individualized daily goals. The daily goals checklist also enhanced patient safety and daily progress by improving interprofessional communication and practice and encouraging momentum in recovery from critical illness. Daily goals checklist review also prompted teaching opportunities for multidisciplinary learners on morning rounds.[16]

A checklist using the mnemonic FASTHUG (feeding, analgesia, sedation, thromboembolic prevention, head of the bed elevation, stress ulcer prophylaxis, and glucose control), which is reviewed daily during multidisciplinary ICU rounds to ensure protocol adherence, has been effective.[17] Similarly,

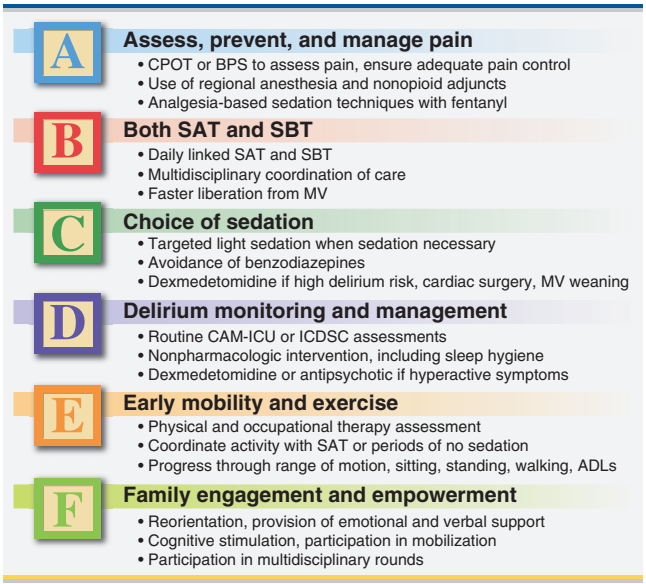

FIGURE 57-1 The ABCDEF Bundle. ADLs, activities of daily living; BPS, Behavioral Pain Scale; CAM-ICU, Confusion Assessment Method for the Intensive Care Unit; CPOT, Critical Care Pain Observation Tool; ICDSC, Intensive Care Delirium Screening Checklist; MV, mechanical ventilation; SAT, spontaneous awakening trial; SBT, spontaneous breathing trial.

implementation of the Pain, Agitation, and Delirium (PAD) Guidelines is facilitated in many ICUs via the ABCDEF Bundle (Fig. 57-1).[18] The ICU Liberation Collaborative[19] is a real-world large-scale quality improvement initiative to implement the Society of Critical Care Medicine (SCCM) PAD Guidelines across 76 ICUs using the ABCDEF Bundle.

In a study of 6064 patients in seven community hospitals, implementation of the ABCDEF Bundle was associated with significantly improved outcomes. For every 10% increase in total bundle compliance, patients had a 7% higher odds of hospital survival (odds ratio [OR], 1.07; 95% CI, 1.04–1.11; P <.001). Likewise, for every 10% increase in partial bundle compliance, patients had a 15% higher hospital survival (OR, 1.15; 95% CI, 1.09–1.22; P <.001). These results were even more striking in a sensitivity analysis removing ICU patients identified as receiving palliative care (12% and 23% higher odds of survival per 10% increase in bundle compliance, respectively; P <.001). Patients experienced more days alive and free of delirium and coma with both total bundle compliance (incident rate ratio, 1.02; 95% CI, 1.01–1.04; P = .004) and partial bundle compliance (incident rate ratio, 1.15; 95% CI, 1.09–1.22; P <.001).[20]

STANDARD TRAUMA/SURGICAL INTENSIVE CARE UNIT ADMISSION PROCEDURES

When a trauma patient is initially admitted to the ICU, a standard and meticulous assessment must be completed by the ICU team to assess all injuries and current physiologic state, ensure that all invasive lines and catheters are in appropriate position, and institute appropriate lifesaving resuscitation and organ-supportive treatment strategies. Standardized trauma/surgical ICU admission orders are required to ensure optimal care (Table 57-2).

The first priority during ICU admission is to assess for ongoing hemorrhagic shock and need for damage control

TABLE 57-2: Trauma/Surgical ICU Admission Orders

Obtain CXR, assess ETT position, thoracic/lung injuries
Obtain abdominal x-ray if NGT present
Peripheral venous lines—assess/document
Central venous lines—assess/document or insert if indicated
Arterial lines—assess/document or insert if indicated
ICU admission, ICU labs, including ABG; evaluate baseline lactate if ongoing resuscitation
If ongoing/past hemorrhage, obtain ROTEM/TEG to assess trauma-induced coagulopathy
Massive transfusion protocol if ongoing hemorrhage
Hypothermia reversal protocol if hypothermia present
Mechanical ventilation comprehensive orders
Sedation if intubated—assess, determine optimal medications (propofol, fentanyl)
Vital signs—frequency; continuous ECG, pulse oximetry, and temperature monitoring
Arterial line and central venous pressure monitoring
Neurologic checks and vascular checks—frequency
NGT/OGT to low continuous suction
Chest tubes to –20 cm H_2O continuous suction
Foley catheter to dependent drainage
Intake/output every 1 hour
Spine precautions, if necessary
HOB elevated >30° for VAP prevention
VTE prophylaxis: pneumatic compression devices and pharmacologic prophylaxis
Stress ulcer prophylaxis if risk factors (intubated/mechanical ventilation, coagulopathy)
Supplemental oxygen therapy
Intracranial pressure (ICP) monitoring if TBI and ICP monitor in place
Glucose management protocol, serial blood glucose monitoring
Anemia management protocol if hemorrhage control achieved
Intravenous maintenance fluids; ICU electrolyte protocol if normal creatinine
Activity: early mobility versus bedrest or other activity restrictions
Daily weights
Consult physical therapy, occupational therapy, social services, geriatrics
Order additional radiologic studies as required based on injuries sustained

ABG, arterial blood gas; CXR, chest x-ray; ECG, electrocardiogram; ETT, endotracheal tube; HOB, head of bed; ICU, intensive care unit; NGT, nasogastric tube; OGT, orogastric tube; ROTEM, rotational thromboelastometry; TBI, traumatic brain injury; TEG, thromboelastography; VAP, ventilator-associated pneumonia; VTE, venous thromboembolism.

TABLE 57-3: National and International Damage Control Resuscitation (DCR) Guidelines

Guideline	Recommendations
Eastern Association for the Surgery of Trauma Damage Control Resuscitation Guideline	• We recommend the use of a MT/DCR protocol in hospitals that manage such patients and recommend that the protocol target a high ratio of plasma and platelets to RBCs. This is best achieved by transfusing equal amounts of RBCs, plasma, and platelets during the early, empiric phase of resuscitation. • We cannot recommend for or against the use of recombinant factor VIIa based on the available evidence. • We conditionally recommend the in-hospital use of TXA early in the management of severely injured bleeding patients.
Joint Trauma System Clinical Practice Guidelines on Damage Control Resuscitation	Hemostatic resuscitation with blood products for the early treatment of hemorrhage in trauma. DCR is limited to keep blood pressure at approximately 90 mm Hg, preventing renewed bleeding from recently clotted vessels. Plasma is used as a primary resuscitation fluid in at least a 1:1 or 1:2 ratio with PRBCs. Ongoing hemorrhage is treated with use of MT protocol for blood product resuscitation. Crystalloid use is minimized.
ACS TQIP Massive Transfusion in Trauma Guidelines	Recommend a foundation ratio in acute trauma resuscitation: • Transfuse in a ratio between 1:1 and 1:2 plasma to RBCs.
Major Trauma: Assessment and Initial Management Guideline	• Transfuse 1 single donor apheresis unit or random donor platelet pool for each 6 units of RBCs. • For patients with active bleeding, use a restrictive approach to volume resuscitation until definitive early control of bleeding has been achieved.
National Clinical Guideline Centre (UK), National Institute for Health and Care Excellence (UK): Clinical Guidelines, February 2016	• For adults, use a ratio of 1 unit of plasma to 1 unit of RBCs to replace fluid volume. • In hospital settings, do not use crystalloids for patients with active bleeding • For patients with active bleeding, start with a fixed-ratio protocol for blood components and change to a protocol guided by laboratory coagulation results at the earliest opportunity. • Use intravenous TXA as soon as possible in patients with major trauma and active or suspected active bleeding. Do not use intravenous TXA more than 3 hours after injury in patients with major trauma unless there is evidence of hyperfibrinolysis. • Hospital trusts should have specific major hemorrhage protocols.

ACS, American College of Surgeons; MT, massive transfusion; PRBCs, packed red blood cells; RBC, red blood cells; TQIP, Trauma Quality Improvement Program; TXA, tranexamic acid; UK, United Kingdom.

resuscitation because hemorrhage is the most common cause of early mortality in trauma. As the initial assessment is completed, if intravenous access is inadequate, the ICU team will place additional central venous access for blood product resuscitation and arterial line for hemodynamic monitoring. The initial arterial blood gas on ICU admission provides significant information regarding degree of shock (arterial lactate, base deficit). Baseline viscoelastic testing (rotational thromboelastometry or thromboelastography) on ICU admission also provides information regarding the presence of trauma-induced coagulopathy and possible need for specific blood products or factors to assist with early definitive hemorrhage control. The ICU team must be able to provide minute-to-minute resuscitation as provided in the emergency department and in the operating room.

DAMAGE CONTROL RESUSCITATION AND MASSIVE TRANSFUSION GUIDELINES

For patients with hemorrhagic shock, a liberal transfusion strategy with hemostatic damage control resuscitation (DCR) is required until hemorrhage control is achieved. Trauma-related deaths due to hemorrhage occur early, with median times to hemorrhagic death of 2 to 2.6 hours in four prospective resuscitation trauma studies.[21] Based on these data and outcome studies comparing transfusion ratios, multiple national and international guidelines for DCR have been developed (Table 57-3).

Most recently, it was confirmed that the prehospital administration of thawed plasma resulted in a lower 30-day mortality compared to standard care resuscitation (23.2% vs 33.0%; difference, –9.8 percentage points; 95% CI, –18.6% to –1.0%; $P = .03$) in injured patients at risk for hemorrhagic shock during air medical transport. Kaplan-Meier curves showed an early separation of the two treatment groups that began 3 hours after randomization and persisted until 30 days after randomization (log-rank χ^2 test, 5.70; $P = .02$).[22]

The Joint Trauma System Clinical Practice Guidelines on Damage Control Resuscitation were the first DCR guidelines developed and implemented in combat casualty care in 2004 and recommended hemostatic resuscitation with blood products for the early treatment of hemorrhage in trauma.[23] DCR is limited to keep blood pressure at approximately 90 mm Hg, preventing renewed bleeding from recently clotted vessels. Plasma is used as a primary resuscitation fluid in at least a 1:1 or 1:2 ratio with packed red blood cells (RBCs). Ongoing hemorrhage is treated with use of a massive transfusion (MT) protocol (Fig. 57-2) for blood product resuscitation. Crystalloid use is minimized.

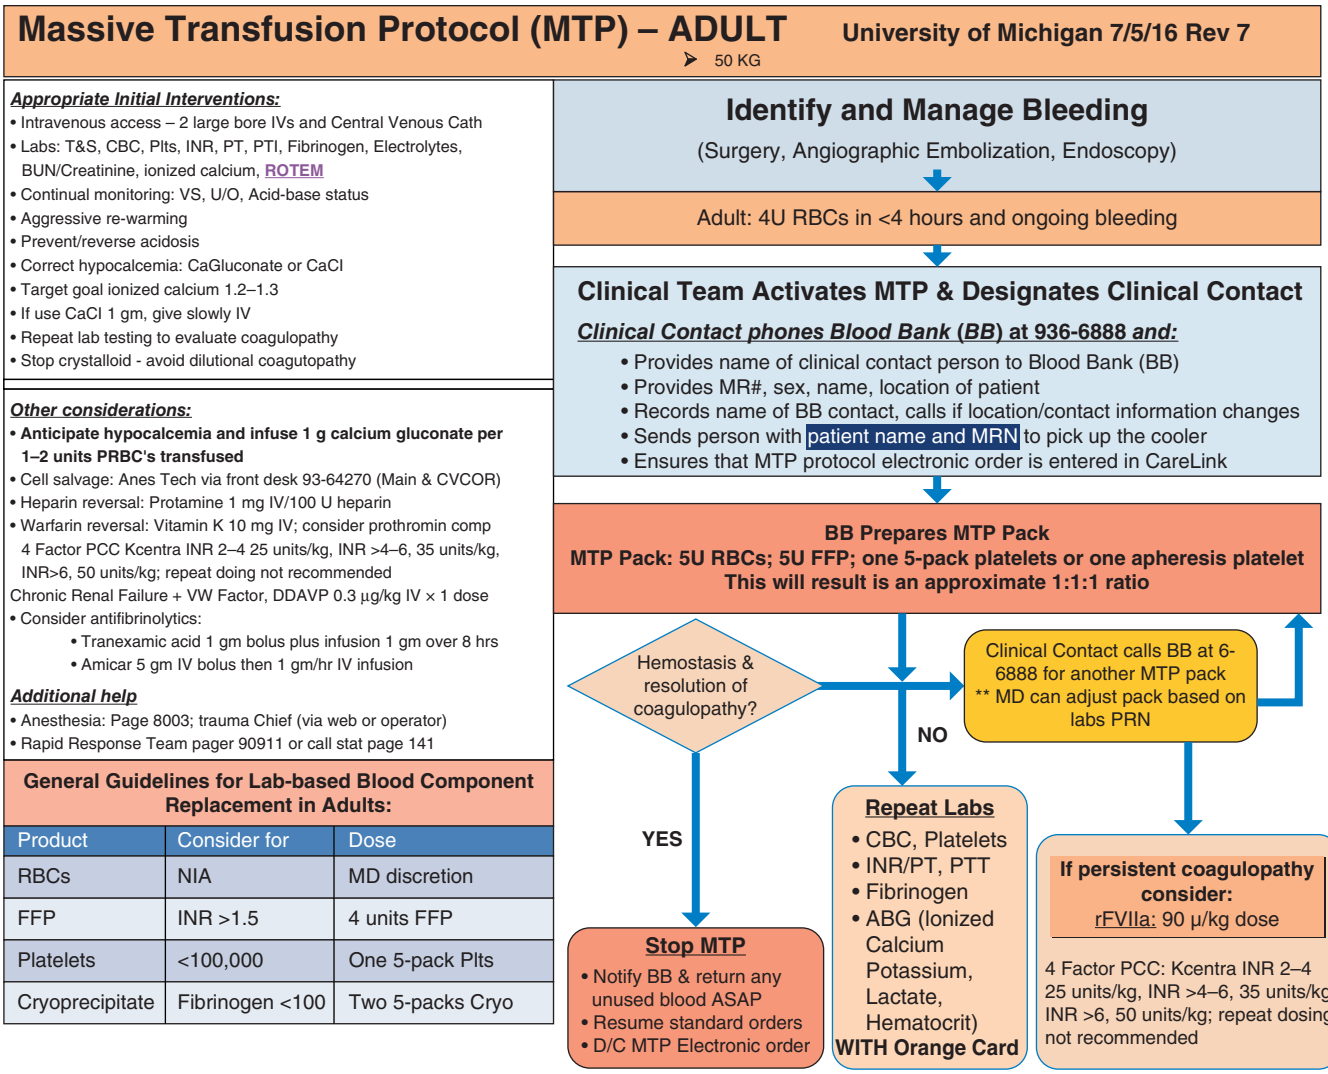

FIGURE 57-2 University of Michigan massive transfusion and damage control resuscitation (DCR) protocol. (Reproduced from the University of Michigan.)

The recent Eastern Association for the Surgery of Trauma Damage Control Resuscitation Guidelines recommend the use of an MT/DCR protocol to target a high ratio of plasma and platelets to RBCs, best achieved by transfusing equal amounts of RBCs, plasma, and platelets during the early empiric phase of resuscitation.[24] This guideline included 31 studies that met criteria for quantitative meta-analysis. This analysis confirmed that mortality decreased with use of an MT/DCR protocol versus no protocol (OR, 0.61; 95% CI, 0.43–0.87; $P = .006$) and with a high ratio of plasma to RBCs and platelets to RBCs (relatively more plasma and platelets) versus a low ratio (OR, 0.60; 95% CI, 0.46–0.77; $P < .0001$; OR, 0.44; 95% CI, 0.28–0.71; $P = .0003$). They concluded that DCR can significantly improve outcomes in severely injured bleeding patients.

The ACS TQIP Massive Transfusion in Trauma Guidelines also recommend a foundation ratio in acute trauma resuscitation: "transfuse in a ratio between 1:1 and 1:2 plasma:RBC; transfuse one single donor apheresis unit or random donor platelet pool for each 6 units RBCs."[25]

The National Institute for Health and Care Excellence Guideline on Major Trauma: Assessment and Initial Management for the United Kingdom provides guidance on the assessment and management of major trauma, including resuscitation following major blood loss associated with trauma. It includes an important section on management of hemorrhage and management of shock, and the guidelines are similar to the ACS TQIP Guidelines.

Optimal dose, timing, and ratio of blood products in MT are still controversial with a recent systematic review (including 16 randomized controlled trials) concluding that "there is insufficient basis to recommend a 1:1:1 over a 1:1:2 ratio or standard care for adult patients with critical bleeding requiring massive transfusion," and additional high-quality studies are warranted.[26]

PHYSIOLOGIC MONITORING IN THE INTENSIVE CARE UNIT

Intensive physiologic monitoring can be provided in the ICU to provide optimal critical care. Monitoring devices can be used to determine if the patient has stable organ function and to detect anomalies that may indicate impending organ dysfunction. In recent years, there has been a dramatic increase in the ability to monitor a wider variety of physiologic parameters. Monitors can be useful in determining if a patient's trajectory is deviating from the anticipated or optimal course; however, all data obtained from physiologic monitors require interpretation and integration with the overall clinical picture by the critical care team. Monitoring itself can be associated with serious complications, including device-related complications and errors in interpretation that lead to errors in clinical decision making and treatment. The questions that must be addressed with any form of monitoring include "When?" (indication and timing), "What?" or "How much?" (which specific monitoring tools or techniques), and "Why?" (an analysis of the associated risks and benefits).

Hemodynamic Monitoring (See Chapter 58)

Hemodynamic monitoring is directed at assessing the results of resuscitation and used as a guide to reestablishing and maintaining tissue and organ perfusion. The restoration of normal arterial blood pressure, central venous pressure (CVP), pulmonary arterial (PA) pressure, and cardiac output (CO) provides some reassurance that there is adequate organ perfusion. This reduces the likelihood of death and serious morbidity due to complications of hemorrhagic shock including postinjury inflammatory response syndrome and multiple organ failure. However, the phenomenon of regional circulation and inadequate perfusion of specific organs, particularly the gut, in the presence of normal arterial pressures remains a concern. New types of monitors are becoming available that can monitor CO and intravascular volume status in a relatively noninvasive fashion and may be able to determine perfusion at the tissue level.[27]

ARTERIAL PRESSURE MONITORING

Noninvasive blood pressure monitoring is widely available using automated blood pressure cuffs. These devices can be set to perform repetitive blood pressure measurements as frequently as every minute. However, they are usually considered insufficient in patients with significant hypotension due to poor sensitivity at low blood pressures as well as the intermittent nature of the readings. Insertion of an arterial intraluminal catheter or arterial line allows instantaneous measurement and continuous display of arterial blood pressure, even at very low blood pressures.

Arterial lines have a wide variety of indications (Table 57-4) and are the preferred method of arterial blood pressure management in patients receiving continuous infusions of vasoactive drugs as they allow better drug titration. Arterial lines are typically placed in the radial artery, although they can also be placed in the dorsalis pedis, femoral, or axillary arteries. Infection of arterial lines is less common than that of central venous lines; however, sterile technique should still be used to avoid the risk of catheter-related bloodstream infections. Thrombotic complications can also occur at any arterial line site and may lead to tissue ischemia, including loss of digits. This is particularly common in patients with prolonged hypotension or sepsis or who have been treated with vasopressors. Although Allen tests are frequently performed before the insertion of a radial arterial line, these do not exclude the possibility of this complication.

Minimally invasive continuous arterial pulse waveform analysis devices are available that quantify pulse pressure variability (PPV), and stroke volume variation (SVV) by analyzing the variations in arterial waveform with respiration and the area under the arterial pressure waveform. These devices can also use the calculated stroke volume to provide an

TABLE 57-4: Indications (Suggested) for Hemodynamic Monitoring

Arterial line monitoring
Shock states (any)
Cardiac
Septic
Neurogenic
Hypovolemia/hemorrhage
Monitoring intraoperatively/postoperatively
Head injury
Serial monitoring of ABG
Labile hemodynamic status
Respiratory failure
Hypertensive crisis
Vasoactive drug infusions
High-risk or elderly trauma patient
Central venous pressure monitoring
Volume status in acute head injury
Complex trauma/pelvic fracture
Shock dates
Acute renal failure
Vasoactive drug infusions
Monitoring during acute ICU hemodialysis
Cardiac pacing
Elderly trauma patient
Massive transfusion
Pulmonary contusions
PA catheter monitoring
Refractory septic and cardiogenic shock states
Severe hypoxemia, pulmonary edema/embolism/ARDS
High-risk intraoperative monitoring

Moderate or mixed venous O_2 (Svo_2)
Diagnoses: explained shock, hypoxemia, renal failure

ABG, arterial blood gas; ARDS, acute respiratory distress syndrome; ICU, intensive care unit; PA, pulmonary artery.

estimate of CO without need of a PA catheter. Recent meta-analyses found that PPV and SVV of at least 11% to 13% both had excellent ability to identify critically ill patients who were likely to respond to fluid challenge with an area under the curve (AUC) of 0.94 and 0.84, respectively.[28,29] However, it should be kept in mind that PPV and SVV are most reliable in patients on mechanical ventilation with no spontaneous respirations and may be less reliable in patients with arrhythmias, patients with spontaneous respirations, and those on low tidal volume ventilation.

CENTRAL VENOUS PRESSURE MONITORING

Monitoring CVP is most useful in patients at high risk of over- or underresuscitation. These include patients with limited cardiac reserve, including the elderly and those with cardiac disease. Patients with TBI are another group in whom CVP monitoring is frequently performed to avoid hypotension associated with underresuscitation or overresuscitation resulting in increased cerebral edema. Although guidelines suggest CVP goals between 8 and 12 mm Hg,[30] these end points may be less reliable in patients on positive-pressure ventilation, making trends of CVP over time in response to therapy, rather than static measurements, more useful in guiding overall resuscitation.

The central venous catheter can also be used to obtain a mixed venous blood gas measurement. Since the mixed venous oxygen saturation ($Scvo_2$) is usually slightly lower in the superior vena cava as compared with that in the inferior vena cava due to the relatively low oxygen consumption (Vo_2) of the kidneys, the blood oxygen saturation obtained from a central venous catheter is usually slightly higher than that obtained from a PA catheter. Central venous catheters that have an oximetric tip can measure the saturation of blood at the tip of the central venous catheter or $Scvo_2$, allowing continuous measurement of this marker of global perfusion.

ECHOCARDIOGRAPHY

The formal transthoracic echocardiogram (TTE) is extremely valuable in assessing the function and structure of the heart and its components including valves and chambers. Limited TTE can also detect such conditions as pneumothorax and pleural effusions.[31] However, in about 50% of trauma patients, it is difficult or impossible to perform a complete TTE due to chest trauma, subcutaneous air, obesity, or surgical dressings. Transesophageal echocardiography (TEE) can overcome many of these limitations and can be used in the detection of such injuries as blunt aortic rupture and blunt myocardial injury.[12,17-19] Frequent use of TEE in the ICU can be limited, however, due to availability, cleaning requirements, and the skill required by the operator. However, there are now US Food and Drug Administration (FDA)–approved TEE devices using a disposable probe that can be left in the esophagus or stomach for up to 72 hours, allowing for repeated exams over time. Studies of this catheter demonstrate excellent image quality and utility in directing therapeutic decision making.[32]

Focused critical care echocardiography (CCE) is now essential in provision of optimal ICU care, and the ability to perform a prompt bedside TTE on ICU arrival for all trauma patients is extremely helpful in determining their cardiac function on ICU admission, particularly in geriatric trauma patients.[33] CCE provides unique morphologic and functional information in real time to determine the specific etiology of shock and/or cardiac dysfunction in ICU patients, as in Fig. 57-3. CCE identified that one patient had shock and cardiac dysfunction due to hypovolemia and responded to fluid resuscitation, whereas the other patient had shock and cardiac dysfunction due to acute cor pulmonale and required administration of inhaled nitric oxide and diuresis to improve cardiac performance.

CCE is performed and interpreted by the intensivist at the bedside to help in the diagnostic workup and to guide therapy for patients with acute circulatory and respiratory failure. CCE includes expertise in both TTE and assessment of preload and volume status by assessment of inferior vena cava diameter and compressibility. Due to the statement of educational standards, the validation of echocardiography against alternative hemodynamic monitoring tools, and continuous technologic improvement, CCE is increasingly being considered as an unparalleled technique to hemodynamically assess critically ill patients since it can be performed bedside and in a serial manner to assess response to therapies instituted.

Basic CCE should be part of the initial training of all intensivists, whereas advanced CCE is an optional component of competency since it requires a more extensive and specific training. The National Board of Echocardiography announced that the first administration date for the new Examination of Special Competence in Critical Care Echocardiography was Tuesday, January 15, 2019 (https://www.echoboards.org/EchoBoards/News/2019_Adult_Critical_Care_Echocardiography_Exam.aspx).

PULMONARY ARTERY CATHETERS

The Swan-Ganz PA catheter was first introduced in 1970; however, in the mid-1990s, many studies questioned their efficacy and reported complications including pulmonary infarction and pulmonary artery thrombosis, perforation, bleeding, and pseudoaneurysm. More recent studies have not demonstrated increased major adverse sequelae associated with the PA catheter.[35] However, these studies also failed to demonstrate any significant improvement in outcomes associated with the use of PA catheters. Currently, PA catheters are primarily used in patients who have known or suspected myocardial disease or dysfunction.

An alternative to invasive PA catheter placement is the FloTrac/Vigileo system (Edwards Lifesciences, Irvine, CA), which uses arterial waveform analysis to calculate SVV, stroke volume, and CO. Meta-analyses confirm that this technology has better concordance with PA catheter and echocardiographic estimates of CO, with a percentage of error less than or equal to 30%. However, optimal concordance only occurs in patients with normal ejection fraction (≥40%) and systemic vascular resistance (SVR). Other minimally invasive devices use

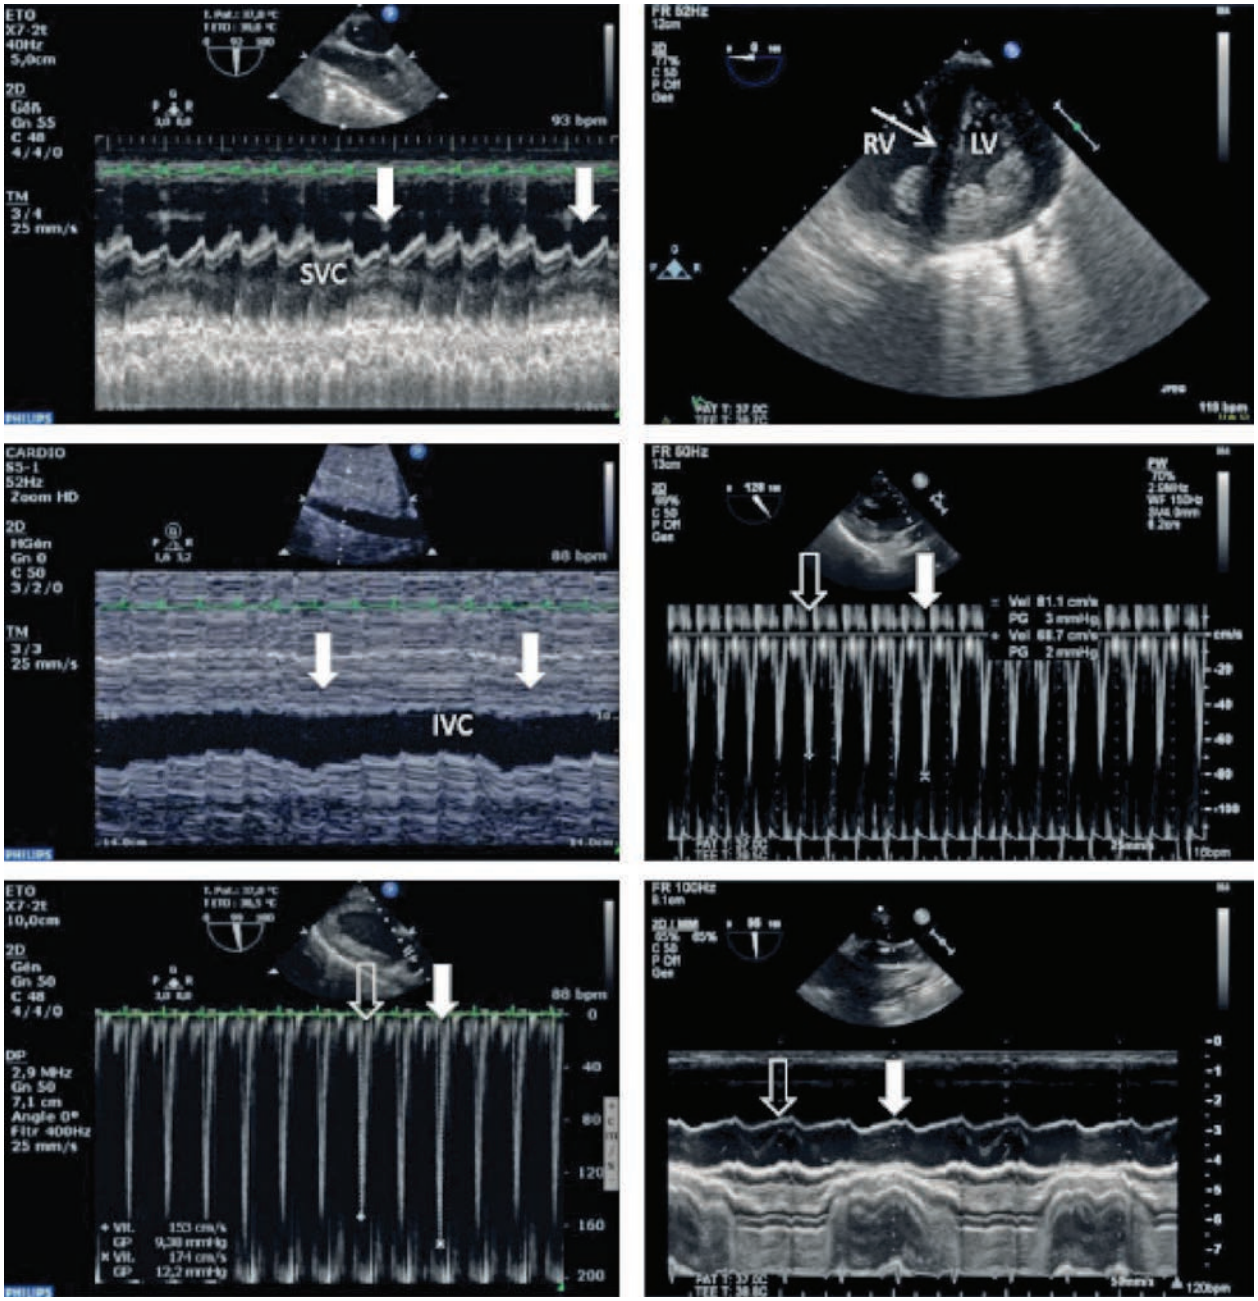

FIGURE 57-3 Focused critical care echocardiography (CCE) by transthoracic or transesophageal approach. IVC, inferior vena cava; LV, left ventricle; RV, right ventricle; SVC, superior vena cava. (Reproduced with permission from Vignon P. What is new in critical care echocardiography? *Crit Care.* 2018;22:40.)

arterial waveform analysis in conjunction with lithium dilution (LiDCO, Cambridge, United Kingdom) and thermodilution (PiCCO, PULSION Medical System, Munich, Germany) to estimate SVV and CO. However, these devices require placement of a central venous catheter and calibration every 8 hours and are also less accurate among patients with arrhythmias, valvular disease, depressed cardiac function, and high or low SVR.[35]

BIOIMPEDANCE CARDIOGRAPHY

Transthoracic impedance, also known as bioimpedance cardiography, uses an electrical current applied to the thorax. Changes in bioimpedance to this current are used to measure heart rate, left ventricular ejection fraction, and intrathoracic fluid content and calculate stroke volume, CO, and SVR. However, the technology is limited by patient movement and arrhythmias and is inaccurate in pregnancy, obesity, pleural fluid or gas, heart failure, severe valvular disease, and pulmonary edema. A new device is available that uses impedance electrodes on the outside surface of an endotracheal tube, the Endotracheal Cardiac Output Monitor (ECOM; ConMed, Irvine, CA). This allows impedance measurements without interference from abnormalities or motion of the chest wall.

However, studies have demonstrated an inability to accurately estimate or trend CO when compared to thermodilution.[36]

A number of other hemodynamic monitoring methods are available for use in the ICU (Table 57-5), and each ICU must review the optimal technology for use in their individual ICU based on the patient population, knowledge and experience of the staff, and willingness to increase use of central venous lines, which might increase risk for central line–associated bloodstream infection.

Neurologic Monitoring (See Chapter 22)

One of the principal indications for admission to the ICU for trauma patients is the need for frequent neurologic

TABLE 57-5: Overview of Hemodynamic Monitoring Methods in the ICU

Method	Examples of commercial name	Calibrated or not	Major advantages	Major disadvantages
Invasive methods				
Pulmonary artery catheter		Calibrated	Direct measurements in right atrium and pulmonary circulation	Delay in determining CO, most invasive, and risks involved
Less-invasive methods				
Transpulmonary thermodilution	PiCCO® VolumeView®/ EV1000® LiDCO®	Calibrated	Intermittent and continuous CO, added variables	Need for specialized arterial and central venous line, LIMITS (PiCCO® system)
Ultrasound flow dilution	COstatus®	Calibrated	Continuous CO, added variables, can detect intracardiac shunts	Requires AV loop
Pulse contour and pulse pressure variation	FloTrac®/Vigileo® ProAQT®/Pulsionflex® LiDCOrapid®/pulseCO® Most Care®/PRAM	Non-calibrated	Continuous CO	Lack accuracy in unstable patients or during use of vasoactive drugs
Partial CO_2-rebreathing	NiCO®	Non-calibrated	No need for intravascular devices	Only in sedated patients under volume control ventilation, interference from pulmonary disease
Transesophageal echocardiography		Operator dependent	Real-time images of the cardiac structures and blood flow	Learning curve, (low) risk of complications
Esophageal Doppler		Operator dependent	Real-time CO and afterload data, added variables	Risk of dislocation
Non-invasive methods				
Transthoracic echocardiography		Operator dependent	Direct measurement of CO and visualization of cardiac structures	Ultrasound characteristics often suboptimal in ICU patients
Non-invasive pulse contour systems	T-line® ClearSight®/Nexfin®/ Physiocal® CNAP®/VERIFY®	Non-calibrated	Non-invasive, simple tool	Less accurate, needs more validation
Bioimpedance		Non-calibrated	Simple tool, providing data concerning CO and fluid overload	Changes intrathoracic fluid content and SVR influence measurements
Estimated continuous cardiac output®	esCCO®	Non-calibrated	Uses widely available variable to estimate CO	Is only estimate, inadequate accuracy
Ultrasonic cardiac output monitoring®	USCOM®	Non-calibrated	Short learning curve and only few risks	Only estimate, uses standard valve areas which can differ in patients

AV loop, arteriovenous fistula; CO, cardiac output; ICU, intensive care unit; SVR, system vascular resistance.

assessments in those with known or suspected TBI. There are two goals for monitoring in TBI: first, the avoidance of secondary brain injury by avoidance of hypoxia and hypotension and maintenance of cerebral perfusion; and second, the detection of increased ICP due to cerebral edema or expanding intracranial hematomas. Reassessment should be done frequently as subtle changes may herald increases in ICP or cerebral ischemia. Severe TBI is a common cause of trauma mortality.

ICP MONITORING

ICP monitoring with a ventriculostomy catheter or subdural bolt is a common practice in most major centers for patients who have a neurologic exam that is unavailable or unreliable following TBI. The Brain Trauma Foundation (BTF) guidelines[37] recommend early and aggressive monitoring of ICP and the calculated cerebral perfusion pressure (CPP), which is the difference between the mean arterial pressure and ICP. Monitoring of the ICP and CPP can be used to guide therapy such as vasopressors, sedation, paralysis, hyperosmolar therapy, or cerebrospinal fluid drainage and to provide surveillance for increasing cerebral edema or intracranial hemorrhage (Fig. 57-4). Adherence to the BTF guidelines, including compliance with placement of ICP monitors, has been associated with improved mortality in patients with TBI.[38-40]

STAGE 1

Admission to the ICU
Ventilation PaO_2 ≥11 kPa, $PaCO_2$ 4.5–5.0 kPa
Sedation
Analgesia ± paralysis
30° head of bed elevation
Intravenous fluids ± inotropes to maintain MAP ≥80 mm Hg

Ventriculostomy ± CSF drainage
Surgical removal of SOL
± Prophylactic anticonvulsants

STAGE 2

Mannitol (maintain serum osmolarity <315 mOsm)

Hypertonic saline (avoid in hyponatremic patients, caution in patients with cardiac or pulmonary problems)

Inotropes to maintain CPP >60 mm Hg

Monitor blood magnesium levels and replace as required

Barbiturates not permitted
± Therapeutic hypothermia

STAGE 3

Barbiturate therapy

Decompressive craniectomy

FIGURE 57-4 Management of severe traumatic brain injury by Brain Trauma Foundation Guidelines. CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; ICU, intensive care unit; MAP, mean arterial pressure; SOL, space occupying lesion.

Investigational noninvasive monitoring systems for ICP include transocular ultrasound monitoring of optic nerve sheath diameter.[41] The optic nerve sheath is an extension of the intracranial dura matter and has been shown to become distended with elevated ICP. Continuous transcranial Doppler ultrasound, brain tissue oxygen, and cerebral microdialysis monitoring are other investigational approaches for ICU monitoring of TBI that may contribute to decision making and eventually improve outcomes in these patients.[42]

RESPIRATORY FAILURE AND MECHANICAL VENTILATION (SEE CHAPTER 59)

General Principles

The need for mechanical ventilation is the most common indication for admission to the ICU. The general principles for intubation and mechanical ventilation are the following:

1. Secure and establish an airway.
2. Decrease the work of breathing (WOB).
3. Improve oxygenation.
4. Improve ventilation (carbon dioxide [CO_2] gas exchange) and maintain control of partial pressure of arterial CO_2 ($Paco_2$), especially in TBI.
5. Anticipate worsening respiratory status or airway patency such as the need for large-volume resuscitation, severe neck/thoracic trauma, upper torso/facial burns, and inhalation injury.

Current ventilator technology is diverse and advanced; however, the essential physical principle of mechanical ventilation is pushing oxygen-rich air into the lungs by positive pressure and removal of waste CO_2 by reduced pressure. Ventilator management can change rapidly; therefore, a nucleus of critical care expertise is needed not only to optimize respiratory support, but also to interpret acute changes in pulmonary mechanics that can often be a harbinger of systemic pathology.

MONITORING OF GAS EXCHANGE

Rapid assessment of arterial oxygen tension (Pao_2) is essential for both evaluating and managing the adequacy of alveolar–arterial oxygen gas exchange. Oxygen (O_2) is driven from the alveolar airspace into the pulmonary capillaries along a diffusion gradient between the respective tissue beds. Calculating the efficiency of pulmonary oxygen exchange can be cumbersome since the equation for the A–a gradient requires alveolar and arterial CO_2 concentrations, shunt fraction, water vapor pressure, and body temperature. A more convenient and simple bedside index of oxygen exchange is the partial pressure of oxygen (Pao_2)/fraction of inspired oxygen (Fio_2) (P/F) ratio that adjusts for a fluctuating Fio_2 and helps in defining lung injury. The use of pulse oximetry to determine arterial oxygen saturation (Sao_2) has replaced continuous arterial blood gas measurements as a real-time, noninvasive method to assess

arterial oxygenation. There are limitations to Sao_2, and its nuances are important in interpreting the significance of an absolute Sao_2 percentage. First, because of the kinetics of oxygen–hemoglobin binding, Sao_2 and the oxygen dissociation curve are sigmoidal and not linear. Therefore, small changes in Sao_2 may reflect a much larger drop in Pao_2. Second, under instances of carbon monoxide poisoning or severe circulatory shock, oxygen delivery will be abnormally low despite a near-normal Sao_2.

In addition to oxygenation-adequate ventilation, end-tidal (Et) CO_2, and resultant arterial CO_2 tension (pco_2) have important physiologic and clinical implications and must be monitored in mechanically ventilated patients. The immediate detection of CO_2 through qualitative capnography relies on the lower pH of $EtCO_2$-rich air changing the color of pH-sensitive filter paper in the capnograph. As a rule, a disposable capnograph remains purple if $EtCO_2$ is less than 0.5% and turns yellow when $EtCO_2$ is greater than 2.0%.[43] Normal $EtCO_2$ is greater than 4%; therefore, capnography turns yellow when the endotracheal tube is positioned in an airway. This device is very sensitive unless the patient is in circulatory arrest and adequate pulmonary perfusion is compromised. The presence of a large volume of acidic gastric contents may give a false impression of successful endotracheal intubation in some cases of esophageal intubation. In these circumstances, initial detection of $EtCO_2$ decreases rapidly with subsequent tidal volumes. Continuous quantitative capnography analyzes $EtCO_2$ and, depending on the alveolar–arterial gradient, can give an indication of the arterial pco_2. In patients without preexisting pulmonary disease, the normal alveolar–arterial gradient is between 1 and 3 mm Hg. Using quantitative capnography can be helpful in brain injury where hyperventilation may curtail rising ICP. However, $EtCO_2$ measurements are affected by pulmonary dead space fraction and pulmonary perfusion that can be greatly altered in cases of hemorrhagic shock, thoracic trauma, and increased airway resistance. In a prospective study of 180 recently intubated trauma patients, $EtCO_2$ measurements were correlated with pCO_2 from blood gas analysis.[44] Using regression analysis, there was a direct correlation between $EtCO_2$ and pco_2; however, patients ventilated with an $EtCO_2$ of 35 to 40 mm Hg were likely to have a pCO_2 greater than 40 mm Hg 80% of the time and a pco_2 greater than 50 mm Hg 30% of the time. In severely injured patients, when an increase in pulmonary shunt may exist, the measurement of pCO_2 through blood gas analysis remains the most accurate measure of assessing adequacy of ventilation.

Causes of hypoventilation can be multifactorial. Increased dead space from pulmonary contusion, acute respiratory distress syndrome (ARDS), pulmonary embolism, and oversedation can be contributing factors causing hypercapnia, especially during the weaning phase of mechanical ventilation.

ASSESSMENT OF LUNG MECHANICS AND INSPIRATORY/EXPIRATORY PRESSURE

Assessing pulmonary mechanics can significantly aid in diagnosing and treating a patient's sudden or progressive pulmonary insufficiency. One of the most important parameters to measure is compliance and the ability to distinguish between static and dynamic compliance. Compliance, the change in volume produced by a change in pressure, is calculated based on measurements taken from the ventilatory circuit itself. In general, a sudden decrease in compliance will mean a concomitant rise in both plateau pressure (PP) and peak inspiratory pressures (PIP) for a given tidal volume (V_T) as seen in pneumothorax or abdominal compartment syndrome. However, measuring the individual changes of either static or dynamic compliance may indicate a specific pulmonary pathology.

PULMONARY COMPLIANCE

In static compliance, the change of volume produced is measured from the inspiratory hold pressures or plateau pressure using the following formula: $Compliance_{static} = V_T/PP - PEEP$ (positive end-expiratory pressure). Static compliance reflects the alveoli and chest wall, rather than the airways. Cases of decreased static compliance (normal = 50–100 mL/cm H_2O) with normal or elevated PIP generally indicate intra-alveolar pathology such as ARDS, ALI, or pulmonary edema.

Dynamic compliance uses the PIP ($Compliance_{dynamic} = V_T / PIP - PEEP$) to estimate resistance of the airways. Sudden decreases in dynamic compliance or a measured difference between static and dynamic compliance reflects increased airway resistance during bronchospasm, mucous plugging, kinked endotracheal tube, or foreign body aspiration.

PRESSURE–VOLUME CURVES

A well-accepted principle in mechanical ventilation is the importance of increasing alveolar recruitment to improve oxygenation. Assessment of the pressure–volume curve in mechanical ventilation has been used to determine the mean pressure needed for the inflection point, or P_{flex} (Fig. 57-5). This point represents the critical pressure needed to open collapsed alveoli and corresponds to the zone of optimal alveolar recruitment. The pressure reading at the inflection point may reflect an optimal PEEP setting. In ARDS and pulmonary edema, the normal pressure–volume curve is shifted, leading to de-recruitment of alveolar units and increasing pulmonary

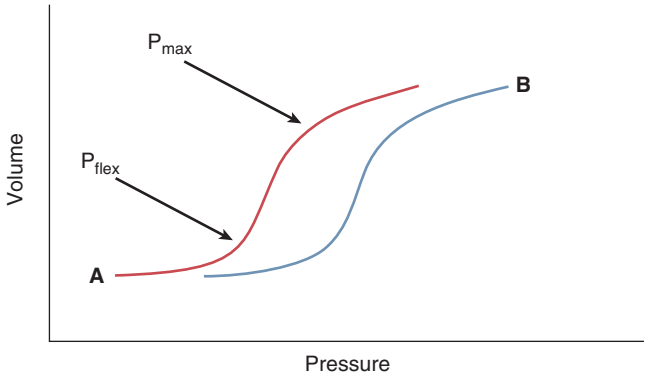

FIGURE 57-5 Pressure–volume curves.

shunt. During these instances, increasing driving pressure and PEEP are often used to maximize gas exchange.

VENTILATORY CAPACITY

Ventilator capacity encompasses the ability of a patient to generate muscular forces needed to meet the ventilatory work required for physiologic demand. Assessing ventilatory capacity in the mechanically ventilated patient can be an important physiologic indicator of clinical improvement and can be used to predict successful extubation, particularly in patients who have been intubated for prolonged periods of time or have neurologic (spinal cord injury and myasthenia gravis) or mechanical (flail chest and rib fractures) injury affecting the thorax. Forced vital capacity and negative inspiratory force (NIF) are the most frequently measured indices of ventilator capacity. A normal vital capacity is between 65 and 75 cm^3/kg depending on ideal body weight and sex. The NIF estimates inspiratory muscle strength, and a value of –25 to –30 cm H_2O is indicative of adequate inspiratory force to maintain airflow after extubation.[45]

Mechanical Ventilation Modes

Spontaneous breathing uses negative intrathoracic pressure to fill alveoli (Fig. 57-6). In contrast, mechanical ventilation uses positive pressure to fill alveoli. Positive-pressure mechanical ventilation can improve gas exchange by recruiting atelectatic alveoli, increasing functional residual capacity, and reducing areas of ventilation/perfusion mismatch, thereby decreasing pulmonary shunt fraction. Negative effects of mechanical ventilation vary according to ventilatory mode; however, adverse effects common to all positive-pressure modes include barotrauma, ventilator-induced lung injury, and impairment of CO from decreased venous return. It is important to understand the physical mechanics with different modes of mechanical ventilation since correct management will reduce duration of mechanical ventilation and improve patient outcomes. In choosing the ideal mode of mechanical ventilation for an individual patient, it is helpful to evaluate the patient's current oxygenation, ventilation, pulmonary compliance, muscular strength, and mental status.

MANDATORY VOLUME CONTROL VENTILATION

Both continuous mandatory ventilation (CMV) and assist-control (AC) mode ventilation are preset volume-cycle modes that deliver a fixed tidal volume at a specific respiratory frequency. The individual names of these modes are commonly referenced interchangeably; however, CMV delivers a set tidal volume exclusive of a patient's ventilatory effort, whereas AC synchronizes delivery of a set tidal volume to each patient-initiated breath. Consequently, an awake and breathing patient will have episodes of dysynchrony causing significant discomfort, breath stacking, or barotrauma. Because of this, CMV is rarely used. In AC, the ventilator recognizes a patient-triggered breath (either flow or pressure mediated) and delivers a synchronous, identical preset tidal volume (Fig. 57-7). Most modern ventilators are "flow triggered"; a continuous flow of gas passes around the breathing system, and patient inspiration deflects this flow and triggers the ventilator. AC modes also have a set rate to assure ventilation in an apneic, paralyzed, or heavily sedated patient; in these circumstances, AC becomes indistinguishable from CMV. In an awake or lightly sedated patient, full synchronous respiratory support will be achieved with each initiated breath, thereby decreasing WOB and assuring adequate ventilation. Awake or agitated patients may trigger several full tidal volume breaths, causing high minute ventilation and respiratory alkalosis.

SYNCHRONIZED VENTILATION MODES

Synchronous intermittent mandatory ventilation (SIMV) is similar to AC but allows for spontaneous ventilation in addition to the preset breaths (Fig. 57-8). In contrast to AC ventilation, where every patient-initiated breath receives the full tidal volume, SIMV mode allows for respiratory work between the preset tidal volumes. The degree of ventilatory support can be increased or decreased by adjusting the set rate and amount of pressure support delivered by the ventilator with patient breaths. SIMV can be useful in reducing minute ventilation in patients who are significantly overbreathing during AC ventilation causing respiratory alkalosis.

Excessive airway pressures (>30 cm H_2O) can increase the incidence of barotrauma and lung injury, especially in states

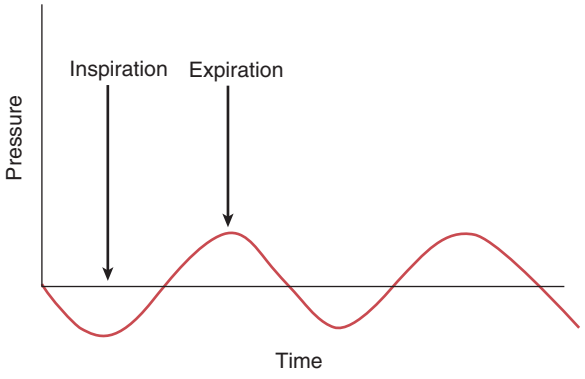

FIGURE 57-6 Spontaneous mode of breathing.

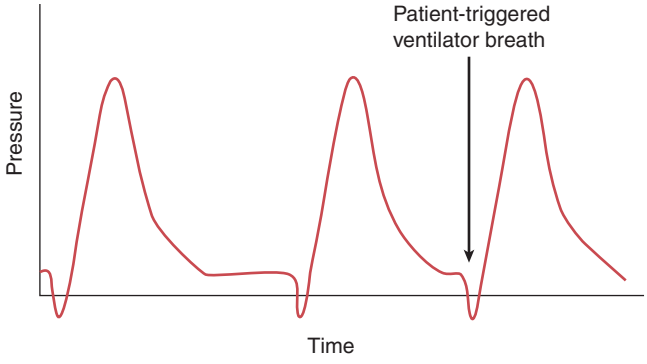

FIGURE 57-7 Assist-control (A/C) mode ventilation.

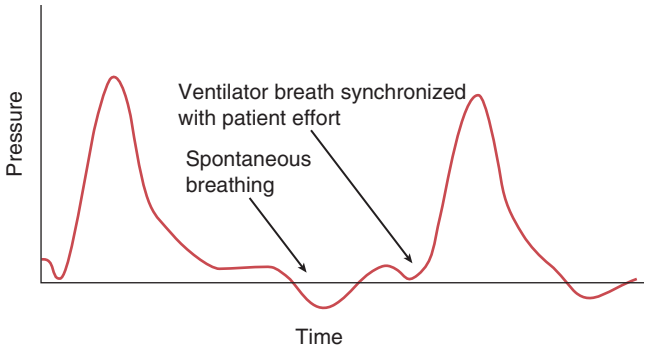

FIGURE 57-8 Synchronous intermittent mandatory ventilation (SIMV).

of decreased pulmonary compliance. Pressure-regulated volume control ventilation modulates the inspiratory flow pattern during a volume-controlled breath, thus reducing PIP. This flow pattern ("decelerating inspiratory flow") is in contrast to pure AC/CMV modes where there is constant inspiratory flow resulting in a continuous rise in airway pressure.

Pressure support ventilation (PSV) provides a baseline level of inspiratory airway pressure and decreases the WOB by augmenting spontaneous respiration (Fig. 57-9). The patient, therefore, is aided in overcoming the resistance of the ventilatory circuit and has complete control over the rate and tidal volume. Each PSV breath is supported by a specific flow limited by a preset pressure that is triggered by patient inspiration. Because this mode requires spontaneous breathing, PSV can only be used in lightly sedated or awake patients without paralytic therapy or neuromuscular disease. Although PSV can be used as a sole ventilation mode, it is most frequently used during ventilator weaning (see the later section "Weaning from Mechanical Ventilation"). Since national guidelines currently recommend light sedation of intubated patients, PSV ventilation can be used as the primary mode and has the advantage of maintaining endogenous diaphragmatic function in ICU patients, preparing them for extubation.

PRESSURE-CONTROL VENTILATION

In patients with ALI/ARDS with poor pulmonary compliance, the limitations of volume-cycled ventilation are increasingly recognized. To achieve a specific preset tidal volume, progressively higher airway pressure must be delivered as compliance worsens, increasing the likelihood of barotrauma. In contrast to volume control, time-cycled pressure control (PC) ventilation delivers breaths at a fixed flow rate dictated by a preset pressure (driving pressure). Regardless of pulmonary or chest wall elasticity, the PIP is fixed and will not exceed the set driving pressure; however, the delivered tidal volume will vary as a function of compliance. PC is useful in ARDS patients to limit plateau pressures below 30 cm H_2O and maintain low tidal volume ventilation.[46] Despite the theoretical advantages of using pressure modes of ventilation in patients with poor compliance, the literature to date has failed to identify a statistically significant benefit to mortality or barotrauma with either mode of ventilation.[47]

In conventional AC/CMV mode, the inspiratory-to-expiratory ratio is approximately 1:2, thereby minimizing airway pressures and allowing adequate ventilation. In severely hypoxic patients, the ratio can be reversed (2:1 or higher)—inverse ratio ventilation (IRV). In principle, IRV allows maximal recruitment of alveoli by increasing the inspiratory time. When using IRV, it also is important to be cognizant of rising intrinsic PEEP and mean airway pressures that can lead to barotrauma, hypercapnia, or a decrease in venous return affecting CO.

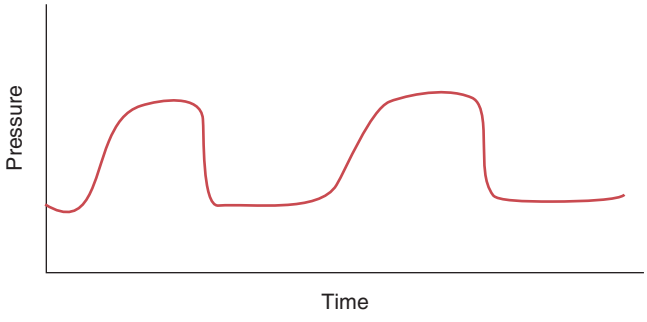

FIGURE 57-9 Pressure support (PS) ventilation.

AIRWAY PRESSURE RELEASE VENTILATION

Airway pressure release ventilation (APRV), or bilevel ventilation, is essentially continuous positive airway pressure (CPAP) ventilation with the exception that the pressure setting is generally higher (P_{high}) for a longer duration (T_{high}) than typical CPAP and there is a short "release" of high pressure (T_{low} and P_{low}), allowing for ventilation and CO_2 exhalation. The long duration of P_{high} (as long as 6 seconds) may improve alveolar recruitment, functional residual capacity, and gas exchange by increasing mean airway pressure without the expense of high PIP. APRV's greatest benefit is the presence of a floating release valve that allows for patients to breathe spontaneously during the prolonged P_{high} phase, which may provide greater patient comfort and decrease need for sedation. Studies have demonstrated safety and improved oxygenation with APRV, and some have shown a mortality benefit compared to other modes of ventilation when lung-protective strategies are used.[48] Time-controlled adaptive ventilation is a new preemptive ventilation strategy recommended to "cast" the lung maintaining homogeneous ventilation using an extended time at inspiration and a brief time at expiration.[49]

Respiratory Failure

PULMONARY CONTUSION AND HYPOXEMIA

Parenchymal disease is the most common cause of hypoxemia, including aspiration pneumonia, hospital-acquired pneumonia, pulmonary contusion, or ARDS. Pneumothorax and/or hemothorax may also manifest as hypoxemia but generally occur during the early phase of resuscitation.

Pulmonary contusion consists of a direct injury to the lung, and the contusion evolves over the first 24 hours as alveolar hemorrhage and edema accumulate, such that the P_{O_2} progressively decreases during that time period. The contused lung has leaky capillaries, and aggressive fluid resuscitation, particularly with colloids, may result in further deterioration of pulmonary function. A restrictive fluid strategy is recommended to prevent severe hypoxemia in patients with pulmonary contusion. The biggest pitfall in the management of pulmonary contusions is failure to anticipate injury progression. Computed tomography (CT) scanning of the chest can be used to estimate the amount of injured lung and potential need for mechanical ventilation.[50]

SEVERE HYPOXEMIA AND ARDS

It is very important to identify ARDS early in the ICU after injury because the associated mortality rate of severe ARDS (P/F ratio ≤100) is high (40%). The Berlin definition of ARDS (see Table 59-4) classifies ARDS into mild, moderate, and severe categories and includes specific amounts of PEEP at which the P/F ratio is calculated.

Other Options in Respiratory Failure

PRONE POSITIONING

Poorly or nonaerated lung units localize in dependent lung zones while in the supine position. Prone positioning improves gas exchange and ventilation/perfusion mismatch by expanding atelectatic portions of the lung akin to the zones of West. Prone positioning also prevents ventilator-induced lung injury by prevention of alveolar hyperinflation, more homogeneous distribution of transpulmonary pressure and ventilation, and prevention of atelectotrauma through improved alveolar recruitment compared to supine positioning. The most recent meta-analysis confirmed a significant survival benefit and improved oxygenation with prone positioning in ARDS patients with severe hypoxia.[51] However, prone positioning may be associated with complications, including pressure ulcer and endotracheal tube dislodgment.

The PROSEVA (Proning in Severe ARDS Patients) trial[52] confirmed a significant survival benefit with the prone position protocol (prone position for 16 hours per day) compared to patients who remained supine. Patients in the prone group underwent their first prone positioning session within 55 ± 55 minutes after randomization. The average number of sessions was 4 ± 4 per patient. Twenty-eight-day mortality (16.0% vs 32.8%; P <.001) and 90-day mortality (23.6% vs 41.0%; P <.001) were both significantly decreased in the prone group. Due to the effectiveness and simplicity of placing patients in a prone position, the early use of prone positioning should be considered in all patients with moderate to severe ARDS.

PHARMACOLOGIC AGENTS

Two agents used to improve hypoxia in severe ARDS are inhaled nitric oxide and inhaled epoprostenol. The mechanism of action is likely related to the relaxation of vascular smooth muscle in the lung, thereby improving shunt fraction and optimizing the ventilation/perfusion ratio by selectively vasodilating aerated lung zones. Clinical trials have shown both agents to transiently improve oxygenation, but neither agent has been shown to improve survival.[53] Other pharmacologic therapies for ARDS, including sildenafil, corticosteroids, and exogenous surfactant, have not been shown to be consistently efficacious.

NEUROMUSCULAR BLOCKADE

A multicenter, double-blind trial of 340 patients with severe ARDS confirmed that early administration of a neuromuscular blocking agent (cisatracurium) improved 90-day survival and increased time off mechanical ventilation without increasing muscle weakness compared to placebo.[54] Enthusiasm for this approach is tempered with concern because current data do not address long-term follow-up for critical illness polyneuropathy and long-term mortality.

To address these issues, the Clinical Trials Network for the Prevention and Early Treatment of Acute Lung Injury (PETAL) launched the ROSE (Reevaluation of Systemic Early Neuromuscular Blockade) trial, a large, multicenter randomized controlled trial comparing early neuromuscular blockade and deep sedation with lighter sedation and no routine neuromuscular blockade. The estimated study completion date for all final data collection of the ROSE trial is April 2019.[55]

Current national guidelines by the American Thoracic Society and the Society of Critical Care Medicine recommend increasing intensity of treatment intervention for increasing severity of ARDS, with low tidal volume ventilation and higher PEEP in mild and moderate ARDS, and consideration of evidence-based treatment strategies including neuromuscular blockade, prone position, inhaled nitric oxide, recruitment maneuvers, and venous-venous extracorporeal membrane oxygenation (ECMO) in severe ARDS (P/F ratio ≤100) by Berlin criteria (Fig. 57-10).[56] For ICUs that manage severe ARDS and serve as regional ECMO referral centers, it is helpful to have an ARDS algorithm (Fig. 57-11; also see Fig. 59-4) for optimal evidence-based ARDS treatment.[43]

Weaning from Mechanical Ventilation

Managing and weaning a patient from mechanical ventilation are highly variable and the duration and success of weaning is dependent on each specific clinical scenario. It is additionally important to separate the principles of weaning from extubation despite the fact that the terminology is used interchangeably. As a set of general principles (1) weaning should be considered early in the course of a ventilated patient, (2) pressure support weaning is well tolerated, and (3) spontaneous breathing trial is the best diagnostic test to assess progress of weaning and determine if the patient is ready for liberation from mechanical ventilation and extubation.

Several factors influence successful weaning, including the type of injury sustained, preexisting medical problems,

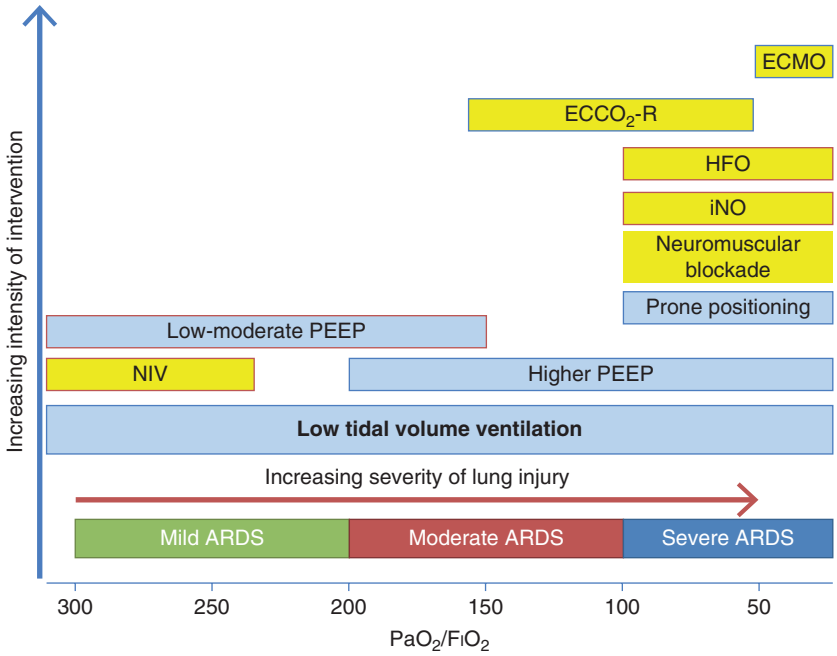

FIGURE 57-10 Increasing intensity of treatment intervention. ARDS, acute respiratory distress syndrome; $ECCO_2$-R, extracorporeal carbon dioxide removal; ECMO, extracorporeal membrane oxygenation; HFO, high-frequency oscillation; iNO, inhaled nitric oxide; NIV, noninvasive ventilation; PEEP, positive end-expiratory pressure.

patient toxicology, and the general state of health. Weaning should be directed toward decreasing WOB and improving ventilatory capacity (Table 57-6).

WOB is a function of the force required to expand the airways, lungs, and chest wall to an appropriate volume in order to meet oxygen and physiologic demands (pressure × volume/time). Excess WOB may be secondary to inappropriate ventilator settings, increased airway resistance, and decreased pulmonary or thoracic wall compliance. Additionally, increased WOB may also reflect higher CO_2 production from sepsis, fever, or overfeeding.

METHODS AND PROTOCOLS FOR WEANING

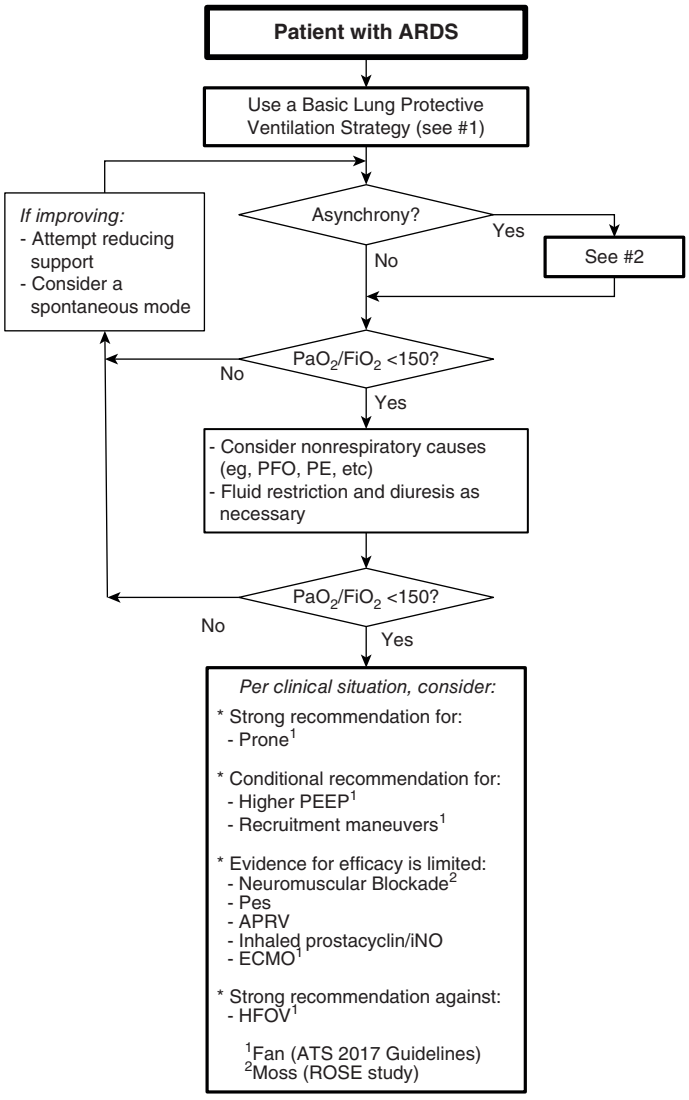
The process of weaning can be long and variable and may account for over 40% of total ventilator time.[44] There remains a lack of uniformity in weaning protocols, and there is a paucity of data available to support standardization. Nevertheless, weaning should focus on conditioning and strengthening the muscles of breathing. The methodology of weaning has evolved in the past three decades from a physician-driven approach to a modern protocol-based approach. Options include a "stepwise" methodology where patients' ventilatory assistance (pressure support or rate) is decreased in a stepwise manner. However, in the stepwise approach, there is no set period of unassisted respiratory exercise, and this approach may prolong mechanical ventilation, leading to chronic fatigue and deconditioning. This method is in contrast to the "sprint" approach (spontaneous breathing trials) where intermittent trials of spontaneous breathing are used once or twice daily and an assessment of WOB and ventilatory capacity is determined accordingly.

In an effort to empirically evaluate optimal weaning techniques, the Spanish Lung Failure Collaborative Group analyzed four weaning methods in an important, large (n = 546), multicenter, prospective trial. Patients were randomized in a stepwise progressive mode: (1) intermittent mandatory ventilation (IMV) where patients had a set mean frequency of 10 breaths/min and decreased, (2) pressure support (PS) where support was initially a mean of 18 cm H_2O and decreased; or into an intermittent spontaneous breathing method, (3) greater than 2/day with PS less than 5 cm H_2O, or (4) once-daily T-piece for 2 hours only. Both of the spontaneous breathing methods had higher rates of successful weaning than the stepwise methods.[57] Among the three most popular weaning modes, T-piece wean, PS wean, and IMV wean, current data suggest a trend toward longer duration of ventilation with IMV weaning compared to spontaneous trials; however, it is important to note that few data have shown any link between weaning method and mortality.[58]

The benefit of a formal protocol to hasten weaning is clear.[59] These protocols reduce physician practice variability and have been shown in several studies and meta-analyses to reduce ventilator and ICU days and weaning duration. Implementing an aggressive weaning protocol should incorporate the Screen, Trial, Exercise, Evaluate, and Report (STEER) principle. Using this protocol, a team of highly trained respiratory therapists, in conjunction with the ICU team, implement the following daily regimen on each mechanically ventilated patient:

Overview of ARDS Ventilator Management Strategies

University Hospital Respiratory Care
Michigan Medicine, Ann Arbor MI



1: Basic Lung Protective Ventilation

- ARDS Network ventilation strategy:
  a. Use VCV or PCV, targeting VT 6 mL/kg PBW
  b. Maintain Pplat ≤30 cm H_2O
     - Reduce VT to 5 or 4 mL/kg if necessary
  c. PEEP/FiO_2 per table (see bottom of page)
- Consider maintaining driving pressure ≤12-15 cm H_2O
- If consolidation is asymmetrical, consider placing 'good lung' in dependent position

2: Patient-Ventilator Asynchrony

* Consider minor ventilator adjustments (eg, flow rate & pattern, inspiratory pause)
* Assess potential to treat with pharmacologic agents (eg. sedation, NMB), especially in pt with severe ARDS and strong respiratory drive (double-trigger)
* For double-triggering, consider increasing VT 1 mL/kg (max 8 mL/kg), provided Pplat ≤30 cm H_2O
* For flow asynchrony, consider a variable flow pressure breath mode of ventilation:
  - Volume targeted PC (PRVC, VC+, Autoflow)
  - Pressure control, pressure support

FiO_2/PEEP Tables

Lower PEEP/Higher FiO_2 table

Step:	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
FiO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0	1.0
PEEP	5	5	8	8	10	10	10	12	14	14	14	16	18	18	20	22	24

Higher PEEP/ Lower FiO_2 table (from ROSE study)

Step:	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
FiO_2	0.3	0.4	0.4	0.4	0.4	0.4	0.4	0.5	0.5	0.5	0.6	0.7	0.8	0.8	0.9	1.0	1.0
PEEP	5	5	8	10	12	14	16	16	18	20	20	20	20	22	22	22	24

Consider Lower PEEP for patients with low PEEP-responsiveness potential (ie, P/F ≥150); Higher PEEP if higher PEEP-responsiveness potential (P/F <150) or BMI >35

Prone Positioning

* Consider after initial 12-24 hrs of stabilization
* Use 16 hr/day (generally 4 pm to 10 am)
* Discontinue when:
  - Instability in prone position
  - Supine × 4 hr, PaO_2/FiO_2 >150 on FiO_2 ≤0.60 & PEEP ≤10

Higher PEEP

* For pts with PaO_2/FiO_2 <150, consider higher PEEP table

Recruitment Maneuvers

* Consider for pts with clear de-recruitment, negative Ptp or PaO_2/FiO_2 <150
* Recommend PCV with: 1) 40/20-25 for 1-3 min (as tolerated) or 2) delta-P of 15 and increase PEEP by 5 up to PIP of 40
* If CPAP method used, limit to 15-30 seconds
* Provider should be at bedside if pressures >40 cm H_2O used

Neuromuscular Blockade

* No benefit of routine use of NMB in moderate-severe ARDS.
* Consider use if significant asynchrony and concern for VILI.

Esophageal Pressure (Pes) Guided Therapy

* Informs of transpulmonary end-inspiratory (Ptp-plat) and end-expiratory (Ptp-PEEP) pressures
* Requires AVEA ventilator & placement of Pes catheter

Airway Pressure Release Ventilation (APRV)

* Increases Pmean with lower Pplat; lacks outcomes benefit
* Concern for P-SILI in pt with strong respiratory drive

Inhaled Nitric Oxide (iNO)

* Start at 10 ppm
* If positive response (improved oxygenation) or brought in by Survival Flight:
  - Maintain at 10 ppm and reduce FiO_2 down to 0.8, then titrate iNO down, or consider Veletri or iloprost, per Respiratory Care policy
* If no response, discuss with team to consider stopping

NOTE: *iNO is a very costly drug compared to alternatives*

Extracorporal Membrane Oxygenation (ECMO)

* Absolute contraindications: irreversible pulmonary process
* Evaluate, but lower survival if on vent 7-10 days pre-ECMO
* Consider if: PaO_2/FiO_2 <50 ×3 hrs or <80 ×6 hrs, or pH <7.25 w/ $PaCO_2$ >60 ×6 hrs

High Frequency Oscillatory Ventilation (HFOV)

* Strong recommendation against routine use; may have benefit if PaO_2/FiO_2 <64; goal is to increase Pmean

FIGURE 57-11 Acute respiratory distress syndrome (ARDS) mechanical ventilation algorithm. (Reproduced from the University of Michigan.)

TABLE 57-6: Factors Contributing to Respiratory Failure

Physiologic factors	Causes
Thoracic injury	Pain, disruption of chest wall stability (flail chest), large hematomas, persistent pneumothorax/hemothorax
Abdominal injury	Pain, disruption of abdominal accessory muscles, abdominal hypertension or compartment syndrome, ascites
Spinal cord injury	Loss of diaphragm and accessory motor strength, loss of airway protection capacity
Excessive agitation/anxiety	Inappropriate sedation or analgesia, post-TBI effects, acute alcohol or drug withdrawal, sepsis
Decreased pulmonary compliance	ARDS/ALI, edema, pulmonary fibrosis, empyema, severe pneumonia
Increased airway resistance	Bronchospasm, endotracheal obstruction or narrowing, mucus plugging of airway or bronchioles
Refractory hypoxia	Pneumonia, pulmonary emboli, ARDS/ALI, sepsis, barotrauma, pneumothorax/hemothorax
Hypercapnia	Sepsis, overfeeding syndrome, inadequate weaning parameters or settings
Malnutrition/metabolic	Persistent catabolic state, respiratory muscle atrophy, electrolyte abnormalities, pulmonary edema
Cardiac insufficiency	Decreased cardiac output (MI, blunt contusion, preexisting disease) causing hypoxia or pulmonary edema

ALI, acute lung injury; ARDS, acute respiratory distress syndrome; MI, myocardial infarction; TBI, traumatic brain injury.

- **S**creen for weaning contraindications (hypoxia, fevers, hemodynamic instability, high WOB, uncontrollable ICP, and sedation)
- **T**rial of minimum support breathing (ie, PS <5 cm H_2O)
- **E**xercise according to set protocol (ie, a 2-hour PS trial or T-piece trial)
- **E**valuate progress
- **R**eport the results to the ICU team

The Clinical Practice Guideline for Liberation from Mechanical Ventilation in Critically Ill Adults provides discrete evidence-based recommendations for all ICU patients (Table 57-7).[60]

EXTUBATION

The weaning process begins shortly after mechanical ventilation is initiated. However, extubation, the final removal of the artificial airway, should not be confused with weaning. Liberation from mechanical ventilation should be considered if the following parameters are met:

1. Reversal of underlying cause of respiratory failure
2. Adequate oxygenation (P/F ratio >150–200 with PEEP <5–8 cm H_2O, FIO_2 <0.4–0.5, and pH >7.25)
3. Hemodynamic stability
4. The capability to initiate a respiratory effort

TABLE 57-7: Guideline for Liberation from Mechanical Ventilation

Recommendation	Strength of recommendation	Certainty in the evidence (ie, quality of evidence)
1. For acutely hospitalized patients ventilated >24 h, we suggest that the initial SBT be conducted with inspiratory pressure augmentation (5-8 cm H_2O) rather than without (T-piece or CPAP).	Conditional	Moderate certainty in the evidence
2. For acutely hospitalized patients ventilated >24 h, we suggest protocols attempting to minimize sedation.	Conditional	Low certainty in the evidence
3. For patients at high risk for extubation failure who have been receiving mechanical ventilation for >24 h, and who have passed a spontaneous breathing trial, we recommend extubation to preventive NIV.	Strong	Moderate certainty in the evidence
4. For acutely hospitalized patients who have been mechanically ventilated for >24 h, we suggest protocolized rehabilitation directed toward early mobilization.	Conditional	Low certainty in the evidence
5. We suggest managing acutely hospitalized patients who have been mechanically ventilated for >24 h with a ventilator liberation protocol.	Conditional	Low certainty in the evidence
6a. We suggest performing cuff leak test in mechanically ventilated adults who meet extubation criteria and deemed high risk for PES.	Conditional	Very low certainty in the evidence
6b. For adults who have failed a cuff leak test but are otherwise ready for extubation, we suggest administering systemic steroids at least 4 h before extubation. A repeat cuff leak test is not required.	Conditional	Moderate certainty in the evidence

CPAP, continuous positive airway pressure; NIV, noninvasive ventilation; PES, postextubation stridor; SBT, spontaneous breathing trial.

TABLE 57-8: Criteria for Extubation

Criteria	Physical findings
Ability to maintain oxygenation	O_2 saturation above 95% with F_{IO_2} <0.4 on minimal CPAP or T-piece
Ability to maintain ventilation	RSBI <100 f/V_t, NIF >–30 cm H_2O, forced TV >10 mL/kg, $Paco_2$ <45mm Hg on minimal CPAP or T-piece
Ability to maintain airway	Appropriate mental status, adequate strength, intact gag and cough, positive endotracheal leak with deflated cuff
Ability to clear secretions	Paucity of secretions, adequate gag and cough reflex, adequate strength
Physiologic considerations	No indication of sepsis, adequate sedation and analgesia, no anticipated decrease in mental status

CPAP, continuous positive airway pressure; NIF, negative inspiratory force; RSBI, rapid shallow breathing index.

Prediction of successful extubation varies greatly, and factors that impact on successful extubation include tidal volume, NIF, vital capacity, rapid shallow breathing index (RSBI), and minute ventilation.[61] Patients with RSBI >105 breaths/min/L are 95% likely to fail, whereas those with an RSBI of less than 100 breaths/min/L are 80% likely to succeed.[61] Additional criteria should be considered when deciding upon extubation, including ability to protect the airway, secretion control, and sustainability (Table 57-8). TBI patients can be particularly difficult to manage because neurologic symptoms can change, making criteria for airway and secretion control difficult to evaluate. A Glasgow Coma Scale (GCS) score of greater than 8 is generally associated with the greatest extubation success. In TBI patients, early tracheostomy may be a consideration to establish definitive airway control (see the later section "Tracheostomy").

UNPLANNED EXTUBATIONS

Despite rigorous patient observation and appropriate sedation, unplanned extubations (UEs) remain a serious complication, with a reported incidence of 0.1 to 3.6 events per 100 intubation days.[62] Consequences of UE include aspiration, pneumonia, vocal cord trauma, hypoxia, cardiopulmonary arrest, and death. Risk factors for UE include male gender, chronic obstructive pulmonary disease, agitation, lower sedation, and less experienced nurses. UEs require reintubation in 33% to 58% of cases, with the majority (62%–74%) occurring within 1 hour. When required, reintubation increases mortality. Predictors of reintubation include GCS less than 11, age greater than 65 years, P/F ratio of less than 200, and pneumonia. Preventing UE requires attention to endotracheal tube security, particularly during transfers, bedside procedures, or prone positioning. Adequate sedation and analgesia are paramount, and physical restraints, especially in patients with high sedative tolerance, may be temporarily necessary. Protocols and checklists to prevent UE including nursing and physician education, standardization of procedures, patient surveillance, and identification of high-risk patients can reduce the risk of UE by 22% to 53%. An emergency ICU protocol should be in place for UE because reintubation may be difficult and a team of experts with appropriate experience that can provide a surgical airway should be immediately present.

NUTRITION SUPPORT (SEE CHAPTER 62)

Current national guidelines indicate the need for nutritional assessment, support, and monitoring for ICU patients.[63] Early enteral nutrition, which may help preserve gut mucosal barrier function, is the preferred approach for trauma patients. Nutritional assessment should begin with an assessment of the degree of preinjury malnutrition as well as current requirements. The literature to date suggests serial weight measurements and serum albumin do not predict outcomes in the critically ill. Calculation of the Nutrition Risk in the Critically Ill (NUTRIC) score is the best nutritional assessment measure for ICU patients. Indirect calorimetry (metabolic cart) provides an assessment of caloric requirements and metabolic rate to determine optimal nutrition requirements by calculation of the respiratory quotient (RQ). The RQ can be used to determine the prominent nutritional substrate being used, with excess carbohydrates leading to RQs of 1.0 or more and RQs below 0.8 indicating possible excess lipid utilization.

GLYCEMIC CONTROL IN THE INTENSIVE CARE UNIT

Hyperglycemia with or without insulin resistance is common in critically ill patients. Studies have also shown that hyperglycemia in trauma patients correlates with higher mortality rates.[64] The trial by van den Berghe et al[65] demonstrated that tight glucose control (≤110 mg/dL) with intensive insulin therapy improved mortality and reduced complications such as infection rate, multiorgan failure rate, ventilator days, and morbidity. However, the intensive insulin regimen initially proposed by van den Berghe et al[65] was associated with increased hypoglycemia and failed to show a mortality benefit in subsequent multi-institutional studies, including the Glucontrol and Normoglycemia in Intensive Care Evaluation Survival Using Glucose Algorithm Regulation (NICE-SUGAR) trials.[66,67] In the NICE-SUGAR trial, 90-day mortality was increased in patients assigned to intensive insulin therapy, as compared with an intermediate target range for blood glucose. Current national guidelines recommend improved glucose control in ICUs; however, a moderate protocol (goal glucose level ≤180 mg/dL) is recommended

to prevent hyperglycemia without inducing higher mortality or hypoglycemic events.[68]

PREVENTION OF HOSPITAL-ACQUIRED INFECTIONS (SEE CHAPTER 21)

Mortality after trauma in the ICU is frequently related to infection. Infections may be related to specific injuries (eg, open fractures), specific procedures required (eg, anastomotic leak after intestinal resection and anastomosis), or hospital-acquired infections (HAIs) during ICU management (eg, ventilator-associated pneumonia [VAP], central line–associated bloodstream infection [CLABSI], and catheter-associated urinary tract infection [CAUTI]). In a study using multiple regression analysis, the most common predictors of infection were central venous catheters, mechanical ventilation, chest tubes, and open fractures.[56] Patients at risk for infections after injury should be routinely tested by culture and examined for clinical indications such as fever, leukocytosis, change in physical examination, pyuria, and development of purulent sputum or new infiltrate on chest x-ray. HAIs (VAP, CLABSI, and CAUTI) have standardized definitions by the National Healthcare Safety Network and the Centers for Disease Control and Prevention. All HAI preventive strategies should be implemented in optimal ICU care and treatment, including VAP prevention (Table 57-9).[69]

The decision to start presumptive (empiric) antibiotics should be based on risk factors, the expected sequelae of injury, and prior infections. Presumptive treatment should be started, if indicated; stopped at a defined end point for culture-negative patients; and appropriately deescalated when final culture information and sensitivities are available. Fungal sepsis should be considered in patients with prolonged ICU stays, multiple prior antibiotic therapies, and immunosuppression. Measurement of procalcitonin levels when a fever workup is initiated can be helpful in determining the likelihood of infection as the etiology of fever in the ICU.

TABLE 57-9: Ventilator-Associated Pneumonia Prevention Strategies

Ventilator bundle: 10 elements
1. Adherence to hand hygiene guidelines
2. Daily assessment of readiness to wean
3. Elevation of head of bed between 30° and 45°
4. Lack of gastric overdistention
5. Subglottic suctioning (CASS endotracheal tubes)
6. Endotracheal cuff pressure of at least 20 cm
7. Stress ulcer prophylaxis
8. Comprehensive oral care with chlorhexidine
9. Prevent condensate in ventilator circuits
10. Deep vein thrombosis prophylaxis

CASS, continuous aspiration of subglottic secretions.

Infectious Complications

Two particularly troublesome and expensive nosocomial infections that occur during critical care after major trauma are CLABSI and VAP. One of the principal issues regarding VAP is its effect on outcome after major injury. There is evidence that pneumonia may exacerbate multiple organ failure and ARDS and could be associated with increased mortality, as has been found in other studies. CLABSI rates range from 1.2 to 5.6 per 1000 central venous catheter days with a marked increase in risk after 9 catheter days. CLABSIs are also associated with longer length of stay, increased cost, and an attributable mortality of 12% to 25%.[70]

ANEMIA PREVENTION AND MANAGEMENT IN THE INTENSIVE CARE UNIT

One source of anemia well within the control of the surgical intensivist is phlebotomy-related blood loss. Average ICU phlebotomy losses were 436 mL for all ICU patients and 679 mL for patients with an ICU length of stay of at least 4 days.[71] Studies have also demonstrated that small changes in the amount of blood drawn, as little as 3.5 mL/d, can significantly increase risk for blood transfusion in the ICU. All efforts should be made in the ICU to reduce the number of serial labs, eliminate unnecessary studies, and use low-volume adult or pediatric testing tubes for all necessary tests. Blood reinfusion devices (eg, the SafeSet device) should be used on all arterial lines to avoid discard of waste blood with diagnostic laboratory testing. Additionally, technology such as continuous noninvasive hemoglobin monitors may avoid unnecessary serial blood tests and reduce the percentage of patients receiving transfusions as well as the average volume of blood transfused per patient.

Blood transfusions are common in the ICU for treatment of anemia, with 30% to 62% of critically ill patients receiving an average of 2 to 4 units of packed red blood cells. Blood transfusions independent of shock or injury/disease severity are associated with worse outcomes. Increased infection, multiple organ dysfunction, and mortality are directly correlated with the amount of blood transfused.[72] Lowering target hemoglobin from 10–12 to 7–9 g/L was associated with improved outcomes in ICU patients in the Transfusion Requirements in Critical Care (TRiCC) study.[73] The TRiCC trial results have been reaffirmed by multiple subsequent studies and meta-analyses in various ICU and surgical populations including cardiac disease, respiratory failure, and those on mechanical ventilation. In addition to improved survival, restrictive transfusion strategies were associated with reductions in rebleeding, acute coronary syndrome, pulmonary edema, and bacterial infections without adversely affecting functional recovery.[74,75]

Despite initial support for liberal transfusion among septic patients, subsequent studies have failed to demonstrate any benefit to transfusion triggers above 7 g/L within this

population. The Surviving Sepsis Campaign Guidelines from 2016 support a transfusion trigger of less than 7.0 g/dL with a target hemoglobin concentration of 7 to 9 g/dL.[15]

The appropriate trigger for patients with TBI remains unclear.[76] However, recent studies have demonstrated increased mortality with transfusions in TBI patients with hemoglobin levels greater than 10 g/dL, no benefit in neurologic outcome, and a significantly increased risk of thromboembolic events and transfusions with a trigger of 10 g/dL when compared to a trigger of 7 g/dL.[77,78]

The 2016 Clinical Practice Guidelines for Red Blood Cell Transfusion Thresholds from the American Association of Blood Banks (AABB)[79] recommended the following: (1) it is good practice to consider the hemoglobin level, the overall clinical context, patient preferences, and alternative therapies when making transfusion decisions regarding an individual patient; and (2) a restrictive RBC transfusion threshold in which the transfusion is not indicated until the hemoglobin level is 7 g/dL is recommended for hospitalized adult patients who are hemodynamically stable, including critically ill patients, rather than when the hemoglobin level is 10 g/dL (strong recommendation, moderate quality evidence). A restrictive RBC transfusion threshold of 8 g/dL is recommended for patients undergoing orthopedic surgery or cardiac surgery and those with preexisting cardiovascular disease (strong recommendation, moderate quality evidence). The restrictive transfusion threshold of 7 g/dL is likely comparable with 8 g/dL, but randomized controlled trial evidence is not available for all patient categories. These recommendations do not apply to patients with acute coronary syndrome, severe thrombocytopenia (patients treated for hematologic or oncologic reasons who are at risk of bleeding), and chronic transfusion-dependent anemia (not recommended due to insufficient evidence).

Erythropoiesis-Stimulating Agents

The anemia of critical illness resembles that of chronic inflammatory disease; low circulating erythropoietin levels and high hepcidin levels are the causative factors, which result in iron-restricted erythropoiesis.[80] Erythropoiesis-stimulating agents (ESAs; epoetin-alfa and darbepoetin) are used for treatment of anemia due to chronic kidney disease but are currently not indicated for the treatment of anemia of critical illness. Initial clinical trials (EPO-1 and EPO-2) documented improved hemoglobin levels or transfusion reduction compared to placebo without use of a transfusion protocol.[81,82] Subsequent studies (EPO-3) confirmed an increase in hemoglobin with ESA treatment without a reduction in transfusions.[83] A subset analysis of the trauma patients in the EPO-2 and EPO-3 studies suggested there was an approximately 50% reduction in 29-day trauma mortality with ESAs in the trauma cohort.[84] This survival benefit was redemonstrated in patients with TBI.[85-87]

A recent meta-analysis[88] included nine eligible studies that randomly assigned 2607 critically ill patients after trauma to an ESA or placebo (or no ESA). Compared with placebo (or no ESA), ESA therapy was associated with a substantial reduction in mortality (risk ratio, 0.63; 95% CI, 0.49–0.79; P = .0001, I = 0%). In patients with TBI, ESA therapy did not increase the number of patients surviving with moderate disability or good recovery (risk ratio, 1.00; 95% CI, 0.88–1.15; P = .95; I = 0%). With the dosing regimens employed in the included studies, ESA therapy did not increase the risk of lower limb proximal deep venous thrombosis (risk ratio, 0.97; 95% CI, 0.72–1.29; P = .78; I = 0%). The authors concluded that the administration of ESAs to critically ill trauma patients was associated with a significant reduction in mortality without an increase in the rate of lower limb proximal deep venous thrombosis. Given the worldwide public health significance of these findings, additional research to validate or refute these findings is required.

PAIN, AGITATION, AND DELIRIUM IN THE INTENSIVE CARE UNIT

Patients with traumatic injury may be suffering severe pain and may require directed and effective analgesia. Significant trauma may lead to prolonged critical illness, mechanical ventilation, and long-term sedation. Many trauma patients also have a history of substance abuse and are at risk for acute withdrawal symptoms and may have opiate and benzodiazepine tolerance. Inadequate control of pain, agitation, and delirium (PAD) can lead to patient suffering, additional complications, and unnecessarily prolonged intubation, mechanical ventilation, and ICU stay. Consensus CPGs exist for management of PAD[89] and were updated in 2018.[90-92]

The need for adequate analgesia and sedation must be balanced against the risks of oversedation. Oversedation may result in hemodynamic instability, increased length of stay and costs, increased respiratory complications including VAP, and possibly long-term decreases in cognitive function. Oversedation may also increase the risks of delirium and possibly posttraumatic stress disorder. Delirium is related to increased length of hospital stay, increased health care costs, and higher mortality. ICU care may lead to pain and discomfort due to catheters, drains, endotracheal tubes, and performance of routine nursing care such as airway suctioning, physical therapy, dressing changes, and an enforced mobilization. Most academic ICUs have adopted algorithms for assessment and management of PAD. An example of an ICU patient assessment and management PAD algorithm is shown in Fig. 57-12.

Pain and Choice of Parenteral Opioid for Analgesia

Pain is almost universal in trauma patients; it has been described as an unpleasant sensory or emotional experience that is associated with tissue damage or described in terms of tissue damage. Many patients later recall unrelieved pain when interviewed about their ICU stays. It is a standard of practice to regularly and frequently assess pain; this is readily

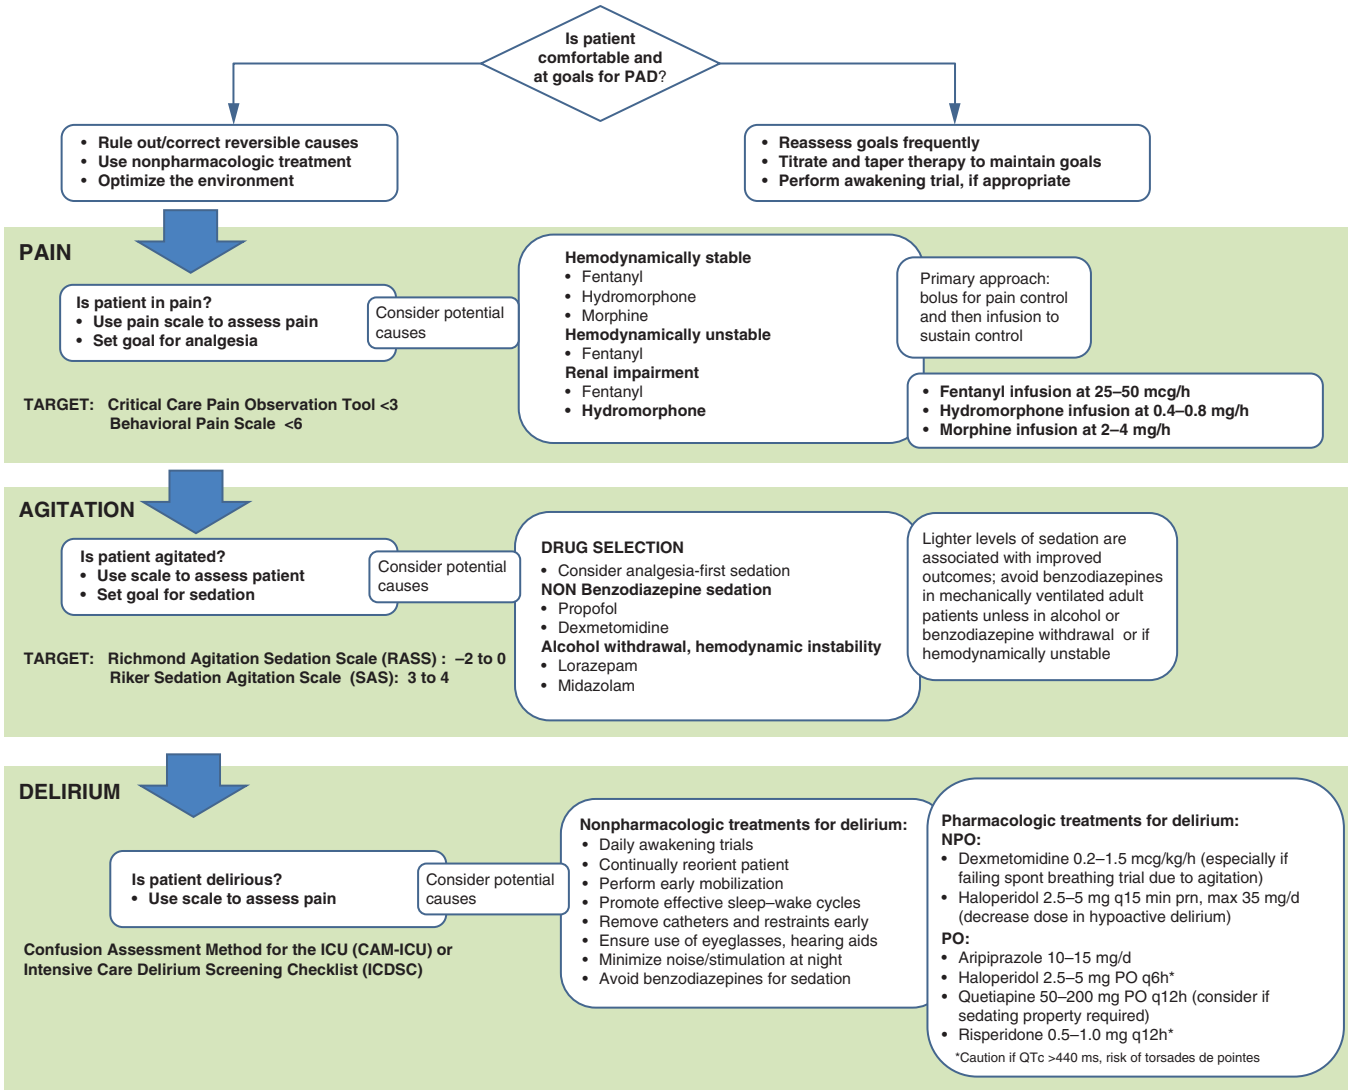


FIGURE 57-12 Algorithm for pain-agitation-delirium (PAD) management in the University of California, San Diego surgical intensive care unit (ICU). NPO, nothing by mouth; PO, oral.

accomplished by the use of validated pain scores. The Joint Commission has labeled the pain score "the fifth vital sign." The Behavioral Pain Scale (BPS) and the Critical-Care Pain Observation Tool (CPOT) are the most valid and reliable behavioral pain scales for monitoring pain in medical, postoperative, or trauma (except for TBI) adult ICU patients who are unable to self-report and in whom motor function is intact and behaviors are observable.[93,94] Parenteral opioids have a long history of efficacy and safety for pain and ICU patients. Because bioavailability and efficacy are variable in ICU patients, the intravenous route is to be used whenever possible. Intramuscular and subcutaneous routes should be avoided due to irregular absorption and highly variable serum levels. Patient-controlled analgesia may be of great utility in patients able to use it due to the self-control and immediate administration provided to the patient. Recent guidelines have recommended preferred parenteral agents in the treatment of pain for adult ICU patients. Table 57-10 lists characteristics of the preferred agents in the SCCM PAD guideline: morphine, fentanyl, and hydromorphone (Dilaudid).

Morphine remains the most commonly used opioid analgesic in the ICU setting due to clinician familiarity in dosing and low cost. It penetrates the blood–brain barrier slowly due to its poor lipid solubility. This results in a delayed peak effect and a long-acting effect as compared with more lipid-soluble agents such as fentanyl. Morphine does not have a direct negative inotropic effect; however, it has predictable effects of arterial and venous dilation. These effects suggest morphine may be advantageous in the hemodynamically stable or hypertensive patient with myocardial ischemia or cardiogenic pulmonary edema. Disadvantages of morphine and other opioid agonists are the opioid receptor–associated side effects, the most serious of which is centrally mediated respiratory depression. Other effects include sedation, nausea, and

TABLE 57-10: Suggested Intravenous Opioid Doses for Adult ICU Patients[a]

Agent	Approximate equivalent single IV dose (mg)	Typical infusion rate	Onset peak effect (min)	Duration	Average price per day[a]	Comments
Fentanyl	100–200 mcg	50–200 mcg/h	2–5 min	0.5–2 h	$26/d at a rate of 100 mcg/h	Fastest onset and shortest duration, least hemodynamic effect.
Hydromorphone	1.5–2 mg	0.2–3 mg/h	20–30 min	3–4 h	$23/d at a rate of 1.6 mg/h	5–10× more potent by weight than morphine.
Morphine	10 mg	2–10 mg/h	20–30 min	3–4 h	$20/d at a rate of 10 mg/h	Avoid in hypotension. Active metabolite accumulates in renal dysfunction. May cause itching due to histamine release (not a true allergy). Decreases preload, which may be beneficial in pulmonary edema.

[a]UCSD Medical Center 2/2015, will vary depending on institution.
ICU, intensive care unit; IV, intravenous.

sphincter of Oddi spasm. Adverse effects can be reversed if necessary with careful titration of the opioid receptor antagonist naloxone. Naloxone must be administered with care because access effect is associated with undesirable hemodynamic effects such as hypertension, tachycardia, and myocardial ischemia as well as acute pulmonary edema. Morphine is also associated with a non–receptor-associated effect of histamine release, and this can result in undesired hypotension, tachycardia, and possibly exacerbating bronchospasm in patients with reactive airway disease. Prolonged use of morphine, especially in renal impairment, can result in the accumulation of a metabolite, morphine-6 glucuronide, and may result in a prolonged sedative effect.

Fentanyl is a lipid-soluble synthetic opioid. Fentanyl is 10 times more potent than morphine and has a more rapid onset of action, requiring vigilance with its use. It is also inexpensive, with costs similar to morphine. With small doses, the duration of action is short due to redistribution. When large doses are administered, especially by continuous infusion, termination of effect requires elimination, probably due to the saturation of poorly perfused adipose tissue. The pharmacokinetics of fentanyl are not much altered by the presence of cirrhosis, and clearance appears to remain normal in renal failure. Hemodynamically, fentanyl maintains cardiovascular stability and does not have significant negative inotropic effect. In the presence of high sympathetic tone, fentanyl may decrease blood pressure indirectly by decreasing central sympathetic output. Fentanyl also predictably causes a decrease in heart rate by a central vagotonic effect. The receptor-associated side effects of fentanyl and their management are the same as described for morphine. Unlike morphine, fentanyl does not release histamine and therefore may be a better choice in patients who are hemodynamically unstable or who have reactive airway disease. For ICU patients, fentanyl has been recommended as an alternative to morphine in situations of hemodynamic instability, known allergy to morphine, or previous histamine release with morphine.

Hydromorphone is a semisynthetic opioid agent that is lipophilic and 5 to 10 times more potent than morphine. Time to onset of action and duration of action are similar to those of morphine, and hydromorphone's terminal half-life is 184 minutes. Hydromorphone appears to have minimal hemodynamic effect and does not result in release of histamine. Like morphine and fentanyl, hydromorphone is inexpensive and is recommended as a third-line agent after morphine and fentanyl.

Agitation

The SCCM PAD guidelines recommend regular assessment and response to therapy.[90] The appropriate target level of sedation is a calm patient who can be easily aroused with maintenance of the normal sleep–wake cycle. Some patients require deeper levels of sedation to facilitate mechanical ventilation or reduce ICP. Use of a sedation scale such as the Richmond Agitation Sedation Scale (RASS) or Riker Sedation Agitation Scale (SAS) is common in most ICUs.[95] The choice of intermittent or continuous sedation is important; intermittent sedation relies on recognition of agitation and subsequent administration of a sedative. Continuous sedation reduces the likelihood of delay in administration of sedatives; however, continuous sedative infusions for ICU patients have been shown to increase the duration of mechanical ventilation and length of ICU stay. Weaning of patients from mechanical ventilation is often hampered by oversedation.

The benzodiazepines (midazolam and lorazepam) have previously been the most commonly used agents in the ICU for sedation. Propofol and dexmedetomidine have expanded the number of agents available for ICU sedation. The provision of anxiolysis and amnesia are of major importance for

critical care patients undergoing intermittently painful procedures or mechanical ventilation. It has been demonstrated that the majority of patients surviving prolonged mechanical ventilation found memory of the experience to be unpleasant.

The PAD guidelines recommend the use of propofol or dexmedetomidine and reduced use of benzodiazepines for sedation due to a possible increased risk of delirium. A meta-analysis of six trials ranked as moderate to high quality suggested that sedation with benzodiazepines may increase ICU length of stay by approximately 1.62 days (P = .0007) and duration of mechanical ventilation by 1.9 days (P <.00001) compared with nonbenzodiazepine sedation.[96] Benzodiazepines may have their greatest utility in the ICU for procedural sedation and in management of substance abuse withdrawal. Characteristics of commonly used benzodiazepines, dexmedetomidine, and propofol are found in Table 57-11.

Propofol is a lipid-soluble alkyl phenol intravenous anesthetic that is insoluble in water and formulated in a lipid emulsion. It has hypnotic, amnestic, and antiemetic properties but is devoid of analgesic effect. Propofol has minimal active metabolites, even with repeated administration. The sedative effect is rapid and predictable, and recovery occurs quickly when the drug is terminated. Compared to benzodiazepines, duration of mechanical ventilation is significantly shorter (2.6 days) in patients sedated with propofol.[96] Propofol has predictable hemodynamic effects, including arterial and venous dilation, decreased inotropic effect, and decrease in systolic blood pressure by 20% to 30%. Propofol given as a loading dose will cause profound ventilatory depression and may induce hypotension. For this reason, propofol is limited to mechanically ventilated patients only.

The 2018 SCCM PAD guidelines recommend the use of either propofol or dexmedetomidine over benzodiazepines for sedation in critically ill, mechanically ventilated adults. Patients on propofol for longer than 24 hours or requiring high doses need to be monitored carefully for propofol infusion syndrome. Hypertriglyceridemia and lipid-induced pancreatitis have been reported during prolonged infusion of propofol in the ICU, suggesting that serum triglyceride levels should be monitored in these patients. A lipid solution of propofol also supports rapid bacterial growth at room temperature, and a number of postoperative bacteremias have been linked to poor administration technique.

Dexmedetomidine is an imidazole compound that is a highly selective agonist of the α_2-adrenergic receptor with eight times greater affinity than clonidine. It is also shorter acting than clonidine, allowing use as an intravenous infusion. Initially evaluated as an anesthetic, it was found to be associated with excess bradycardia and hypotension. Lower doses produce reliable sedation, and dexmedetomidine is approved in the adult ICU patient as a sedative infusion. Patient selection and proper drug infusion are needed to avoid significant hemodynamic effects. Avoiding the initial bolus dose can reduce the incidence of significant bradycardia and hypotension on administration. Dexmedetomidine produces sedation but easy arousal, analgesic-sparing effect, and minimal depression of the respiratory drive. These characteristics are unique in that patients appear to be sedated but are readily roused and interactive and can follow commands. This makes the drug highly suited for patients who are being weaned from the ventilator, especially those who become agitated when other sedation is reduced. Dexmedetomidine is cost-effective because it reduces patient ventilator days, delirium, and ICU length of stay as compared with midazolam.

Monitoring and Daily Awakening

Monitoring of sedation within the ICU can be performed by the Ramsey or RASS scales (Table 57-12). The scales have midrange scores that indicate a calm, cooperative patient, with high and low scores indicating excess agitation or oversedation. A common sedation scale should be used throughout the institution for consistent and effective use. Daily interruption of continuous intravenous sedation until awakening of mechanically ventilated patients decreases duration of mechanical ventilation and ICU length of stay. Combination of daily awakening with spontaneous breathing trials results in patients spending less time on mechanical ventilation, less time in a sedative coma, and less time in the ICU and in the hospital. Daily awakening trials are most effective when following a standardized nurse-driven protocol. Patients who should be excluded from a daily awakening trial include those with increased ICP or neuromuscular blockade, those with hemodynamic instability, those requiring high levels of ventilatory support, and those who are post–coronary artery bypass grafting.

The daily awakening period should be synchronized with spontaneous breathing trials; in a study of 336 mechanically ventilated ICU patients, doing so achieved significant reduction in ventilator-free days and ICU and hospital length of stay.[97] The daily awakening also provides an opportunity for early exercise and mobilization (physical and occupational therapy) (Table 57-13). A recent study of early mobilization during daily awakening in 104 mechanically ventilated patients demonstrated increased independent functional status at hospital discharge, shorter duration of delirium, and increased ventilator-free days during the 28-day follow-up period compared with controls.[98]

The 2018 PAD Guidelines suggest using light sedation (vs deep sedation) in critically ill, mechanically ventilated adults. A recent trial of no sedation[99] in mechanically ventilated patients compared no sedative medications with control patients on continuous midazolam drips. Most of the eligible ICU patients could not be enrolled because they had medical indications for deep sedation. Patients in the no sedation group were allowed morphine boluses and had frequent nonpharmacologic antianxiety interventions such as reassurance by nurses and reassessment by physicians of pain orders and the need for tubes and catheters. Patients in the no sedation group had significantly shorter duration of mechanical ventilation and hospital and ICU length of stay but also had increased delirium and increased use of haloperidol.

TABLE 57-11: Suggested Intravenous Sedation Agents for Adult ICU Patients[a] (San Diego Patient Safety Council)

Agent	Typical IV bolus dose	Typical infusion rate	Onset peak effect	Duration	Average price per day[a]	Comments
Propofol	0.03–0.15 mg/kg (max 20 mg)	5–80 mcg/kg/min	1–2 min	<20 min	$36/d at a rate of 50 mcg/kg/min	Fastest onset and shortest duration. Avoid in hypotension. Dose/rate related hypotension/ bradycardia. Avoid IV push bolus due to increased risk of hypotension (if bolus required and low risk of hypotension, limit dose to 10–20 mg). Monitor triglycerides. Provides 1.1 kcal/mL. Monitor for propofol-related infusion syndrome.
Dexmedetomidine	Bolus not recommended: 1 mcg/kg over 20 min	0.2–1.5 mcg/kg/h	30 min	2–4 h	$408/d at a rate of 0.8 mcg/kg/h	No respiratory depression—consider for patient failing spontaneous breathing trial due to agitation/anxiety. Dose/rate related hypotension and bradycardia–bolus not recommended. May cause hyper/hypotension. 10 times cost of midazolam, may not be suitable during resuscitation due to hypotensive effect.
Lorazepam	1–3 mg	2–10 mg/h	15–20 min	2–4 h	$38/d at a rate of 4 mg/h	Slower onset but longer duration. Risk of propylene glycol toxicity with high doses (anion-gap acidosis, ↑ serum creatinine, ↑ lactate). Monitor serum osmolality if rate >6 mg/h and consider possible PG toxicity if osmol gap >10–15. Lorazepam is associated with increased risk of delirium and should be avoided in elderly and mechanically ventilated patients.
Midazolam	1–6 mg	1–10 mg/h	5–10 min	1.5–2 h	$70/d at a rate of 8 mg/h	Fast onset—amnestic effect. Active metabolite accumulates in renal dysfunction. Midazolam 2–3 mg is approximately equivalent to 1 mg lorazepam. Midazolam is associated with increased risk of delirium and should be avoided in elderly and mechanically ventilated patients.

[a]UCSD Medical Center 2/2015, will vary depending on institution.

ICU, intensive care unit; IV, intravenous; PG, propylene glycol.

TABLE 57-12: Richmond Agitation Sedation Scale (RASS)

Target RASS value	RASS description
+4 Combative	Combative, violent, immediate danger to staff
+3 Very agitated	Pulls or removes tubes or catheter; aggressive
+2 Agitated	Frequent nonpurposeful movement; fights ventilator
+1 Restless	Anxious, apprehensive but movements not aggressive or vigorous
0	Alert and calm
−1 Drowsy	Not fully alert, sustained awakening to voice (eyes open and contact >10 s)
−2 Light sedation	Briefly awakens to voice (eye opening and contact <10 s)
−3 Moderate sedation	Movements or eye opening to voice (but no eye contact)
−4 Deep sedation	No response to voice; moves or eyes open to physical stimulation
−5 Unarousable	No response to voice or physical stimulation

TABLE 57-13: Daily Awakening Trials—Summary Recommendations

Components recommended for a Daily Awakening Trial:
- Consistency—should follow a standardized nurse-driven protocol
- Continuity—need to ensure a set time for the patient during daylight hours
- Coordination—need to ensure Daily Awakening Trial is coordinated with other disciplines, specifically physical therapy, occupational therapy, and respiratory therapy activities

Exclusions to a Daily Awakening Trial:
- Increased intracranial pressure issues
- Neuromuscular blockade
- Pressure-regulated pulmonary ventilation with an inverse ratio
- Coronary artery bypass graft immediate postoperation

Process for weaning drug (per drug)[a]:
- Target—use sedation scale targets (−1 on the RASS)
- Sedatives—decrease by 50% or off
- Narcotics—consider reducing narcotics if still sedated (or SAS of 3–4)

Assess as part of Daily Awakening Trial:
- Pain
- Agitation
- Delirium
- Spontaneous Breathing Trial/rapid shallow breathing index

If continued sedation required, start at lower dose than previously—50% of original or lowest effective dose during titration—the most recent titration dose (before reaching −1 RASS)
- Bolus and titrate up to reach target goal as appropriate; do not resume at previous rate

[a]Abort Daily Awakening Trial if patient becomes physiologically unstable during procedure.

RASS, Richmond Agitation Sedation Scale; SAS, Riker Sedation Agitation Scale.

Delirium

Delirium is defined as fluctuation in mental status such as inattention, disorganized thinking, hallucinations, disorientation, and an altered level of consciousness. It occurs in up to 65% of hospitalized patients and up to 87% of patients admitted to the ICU. Delirium in the elderly patient is associated with a doubling of mortality. Delirium can increase hospital length of stay and increase health care cost. There has been discussion of ICU delirium rates as being a possible quality measure.

Delirium must be considered when assessing pain and sedation in the ICU. Delirium is further defined as follows: (1) *hyperactive* delirium: characterized by hypervigilance, restlessness, anger, irritability, and uncooperativeness, and associated with better overall outcomes; (2) *hypoactive* delirium: the more common and deleterious, characterized by a lack of awareness, decreased alertness, sparse or slow speech, lethargy, decreased motor activity, and apathy; and (3) *mixed* delirium: apparent in patients with a mixed clinical picture. Hypoactive delirium may be mistaken for depression or stupor and therefore is often not recognized, which may contribute to higher 6-month mortality of 32.0% versus 8.7% for mixed delirium.[100]

Delirium occurs in patients typically 24 to 72 hours after admission to the ICU. Preexisting risk factors for delirium include cognitive impairment, chronic illness (including hypertension), age greater than 65 years, depression, smoking, alcoholism, and severity of illness. Risk factors arising during hospitalization include congestive heart failure, sepsis, prolonged restraint use, immobility, withdrawal from substance abuse, seizures, dehydration, hyperthermia, head trauma, intracranial mass lesions, and use of lorazepam, midazolam, morphine, fentanyl, and propofol.

Assessment of delirium should be carried out in association with pain and sedation assessments and can be facilitated by the use of a validated delirium score such as the Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) or the Intensive Care Delirium Screening Checklist (ICDSC); these tools may be most usefully administered during a daily awakening.[90] In addition, the patient should be assessed for QTc prolongation on electrocardiogram (ECG) if therapy is being considered because many antidelirium agents are associated with QTc prolongation and risk of torsade de pointes. CAM-ICU and ICDSC allow rapid consistent assessment for altered level of consciousness, disorganized thinking, inattention, and other delirium features.

Nonpharmacologic measures are the primary treatment used to manage delirium and include daily awakening trials, continuous reorientation of the patient by nursing staff, keeping clocks and calendars visible to the patient, promoting effective

sleep–awake cycles, timely removal of restraints and catheters, ensuring use of glasses and hearing aids, minimizing ICU noise and stimulation, and avoiding use of benzodiazepines. There are no double-blind, randomized, placebo-controlled trials that are adequately powered to prove the efficacy or safety of any antipsychotic agent in the management of delirium in ICU patients, although these are still commonly used by intensivists in the United States (Table 57-14).[101] The 2018 PAD Guidelines recommend dexmedetomidine, which may be especially useful in patients failing spontaneous breathing trials secondary to agitation. Haloperidol is *not* currently recommended and has been associated with a reduced seizure threshold, extrapyramidal reactions (dyskinesia), and laryngeal dystonia. It has also been associated with malignant neuroleptic syndrome. Large doses of intravenous haloperidol should only be administered in a monitored critical care setting and with monitoring of QTc intervals. Oral agents are longer acting and include aripiprazole, risperidone, or oral haloperidol. These agents are associated with QTc prolongation and should only be administered if the measured ECG QTc is less than 440 milliseconds. Another oral delirium agent with greater sedative properties is quetiapine; it is not strongly associated with QTc prolongation.

TRACHEOSTOMY

Tracheostomy in a chronically ventilated patient can offer several advantages including improved oral care, improved pulmonary toilet, decreased sedation requirements, improved patient comfort, decreased oral and vocal cord trauma, decreased airway resistance and dead space, and the ability to more aggressively wean ventilation. However, tracheostomy can be complicated by infection, subcutaneous emphysema, hemorrhage, tracheal stenosis, tracheoinnominate and tracheoesophageal fistula, and tracheomalacia.

Significant controversy exists regarding optimal timing for tracheostomy. Definitions of early tracheostomy and late tracheostomy vary, with early tracheostomy ranging from 48 hours to 8 days and late tracheostomy generally being greater than 10 days. Early tracheostomy confers no mortality benefit and results in no difference in pneumonia or ventilator duration in most studies, including the largest TracMan trial.[102] Based on evidence from recent large randomized trials, it is reasonable to wait at least 10 days to be certain that a patient has an ongoing need for mechanical ventilation before consideration of tracheostomy.[103]

Early tracheostomy may be effective in patients with a TBI, particularly when an airway is required but the patient does not have the need for mechanical ventilation. Tracheostomy may be performed via open or percutaneous method (see Atlas Figure 14). The technique used should be based on patient needs and clinician experience as multiple large studies in heterogeneous ICU populations have shown both methods to be safe and effective, with a possible morbidity benefit to percutaneous methods over open techniques. Percutaneous tracheostomy with flexible bronchoscopy guidance is recommended and is easily performed at the bedside in the ICU.[104]

COMPLICATIONS AND PITFALLS IN THE INTENSIVE CARE UNIT

Critical care complications interpose a substantial cost burden to the health care institution and society and worsen patient outcomes. There is increasing public awareness of this issue; preventable complications are often reportable to regulatory authorities, and many insurers, including Medicare, may refuse to pay hospital or physician charges in case of patients with certain preventable critical care complications. Health care consumers can readily obtain ICU complication rates for their health care institutions from a variety of media. The need to reduce preventable complications of critical care has resulted in guidelines released by professional and regulatory organizations and local hospitals.

Critical Illness Polyneuropathy and Myopathy

Prolonged neuromuscular weakness associated with critical illness was reported as early as the 1950s. Found to be associated with sepsis, hypotension, or multiple organ dysfunction, critical illness polyneuropathy (CIP) may prolong weaning from mechanical ventilation, delay return to ambulation, and significantly affect overall recovery from posttraumatic critical illness. The syndrome is characterized by the development of diffuse neurogenic muscle weakness over a several-week course of severe critical illness. The neurologic manifestations may include unexplained failure to wean from mechanical ventilation, decreased/absent deep tendon reflexes, tetraparesis, muscle atrophy, decreased fibrillations, compound muscle action potentials, and axonal damage on electrophysiologic testing. Nerve conduction velocities are near normal, and histologic evaluation of peripheral nerves has shown acute diffuse neurogenic atrophy in muscles and axonal degeneration in nerve tissue. CIP may be far more common than is currently recognized and may frequently affect ventilator weaning and recovery.[91] It should be considered as a cause of weaning failures or generalized weakness in the setting of critical illness. Electrophysiologic evaluation of muscle and nerve function is important for the diagnosis. Although not conclusive, available data suggest that the avoidance of long-term use of neuromuscular blocking agents (eg, pancuronium and vecuronium), particularly in combination with corticosteroids or aminoglycoside antibiotics, may be an important preventative measure. Recovery from CIP, although prolonged, may be nearly complete from a clinical standpoint. Follow-up electromyographic studies have shown changes with chronic neurogenic damage.

The Geriatric Trauma Patient in the Intensive Care Unit

Mortality in elderly trauma patients is significantly higher than that of their younger counterparts and has been associated with cardiovascular and septic complications.[105]

TABLE 57-14: Pharmacology of Antipsychotics Commonly Used in Intensive Care Unit (ICU) Delirium

						Adverse effects (incidence)				
Antipsychotic agent	Dosage form	Metabolism	Metabolizing enzyme	Equiv. dosages (approx) (mg)	Max dose (mg/d)	QT prolongation potential[a,b]	Sedation	Dopaminergic affinity/ extrapyramidal effects[b]	Anticholinergic effects	Orthostatic hypotension
Haloperidol (Haldol)[c]	Tab, IV injection	T½:: 21 h hepatic	CYP3A4, 2D6	2	20	Low	Low	High	Low	Low[d]
Quetiapine[e] (Seroquel)[c]	Tab	T½:: 6 h hepatic	CYP3A4	125	400	Moderate	Moderate	Low	Moderate	High
Risperidone (Risperdal)[c]	Tab, ODT tab, soln (1 mg/mL)	T½:: 3 h hepatic	CYP2D6, 3A4	1	4	Moderate	Low	High	Low	Moderate
Aripiprazole (Abilify)[c]	Tab, soln (5 mg/mL), IM injection	T½:: 75 h hepatic	CYP2D6, 3A4	5	10–30 mg	Low	Low	Low	Low	Low

[a]Low: 3–10 ms, medium: 10–15 ms, and high: >15 ms.
[b]Dose-related effect.
[c]Note the following FDA Black Box Warning applies to haloperidol and all atypical antipsychotics: "Increased mortality seen when used in elderly patients with dementia-related psychosis due to cardiovascular or infectious complications." The use of these agents for prevention of delirium in ICU patients has not been tested in high-quality trials.
[d]Increased with IV formulation.
[e]Caution: Bone marrow suppression; blood dyscrasias.

FDA, US Food and Drug Administration; IM, intramuscular; IV, intravenous; ODT, orally dissolving tablet; $T_{1/2}$, half-life.

Therefore, aggressive monitoring is warranted as it may help in diagnosing physiologic deterioration and in assessing the effectiveness of various therapies deployed in an attempt to improve outcomes. End-of-life and goals-of-care discussions are particularly important in this patient population.

Sepsis and subsequent multiple organ system failure cause most late deaths following trauma in the elderly. Urosepsis and pneumonia are common in elderly trauma patients, and what would be otherwise a relatively simple problem to treat in the young healthy individual may be the trigger to a cascade of events in the elderly patient, which may culminate with multiple organ dysfunction and death. For these reasons, aggressive and early treatment of these infections, initially with broad-spectrum antibiotics followed by culture-based de-escalation or adjustment of therapy, is a critical determinant of good outcome.

One of the most common causes of death in the geriatric trauma population is pneumonia following blunt chest trauma and rib fractures. Due to decreased pulmonary reserve and associated comorbidities, the elderly trauma patient is generally more susceptible to the development of pneumonia due to an inability to effectively clear secretions and take deep breaths. Two aspects in the early initial care in the ICU in these patients are important: avoidance of fluid overload and adequate analgesia. To this end, patient-controlled narcotic analgesia and/or epidural administration of opiate analgesics or local anesthetics (rib blocks or chest wall pain catheters) may be helpful in appropriately selected trauma patients. Another option is surgical stabilization of rib fractures, but indications are not agreed upon, and data to date have not been able to demonstrate a consistent outcomes benefit.[93]

Geriatric patients are also at increased risk for thromboembolic complications following trauma. Patients in the high-risk group for thromboembolic events (TBI, spinal cord injury, complex pelvic fractures, bilateral lower extremity fractures, prolonged immobilization, or a previous history of deep venous thrombosis or pulmonary embolism) should receive pharmacologic prophylaxis with low-molecular-weight heparin as soon as possible.

Reversal of Oral Anticoagulation in Acute Hemorrhage

Trauma centers in the United States have recently experienced an epidemic of elderly falls. The main clinical trials on anticoagulant therapies rarely include the frail elderly; however, many such patients arrive after taking these drugs. Common agents such as aspirin, clopidogrel, and warfarin have been joined by direct oral anticoagulants (DOACs) such as dabigatran, rivaroxaban, and apixaban. DOACs may require specific antidotes, if available, or use of concentrated clotting factors such a prothrombin complex concentrates (PCCs). Even patients with mild to moderate TBI are at a much higher risk of developing fatal intracranial hemorrhage due to the use of these drugs and because of "increased space" for hematoma expansion due to brain atrophy. Rapidly obtaining a brain CT scan and quickly assessing coagulation parameters for reversal of anticoagulation are critical in early management. Patients with active hemorrhage should undergo rapid reversal with PCC and specific DOAC reversal agents, including idarucizumab for dabigatran and andexanet alfa (approved by FDA in May 2018) for rivaroxaban and apixaban. In a life-threatening or critical site bleed or in situations in which bleeding cannot be controlled, reversal of oral anticoagulants is required with national evidence-based recommendations from the 2017 ACC Expert Consensus Decision Pathway on Management of Bleeding in Patients on Oral Anticoagulants (Table 57-15).[106]

TABLE 57-15: Recommendations for Reversal of Oral Anticoagulants

Vitamin K antagonist (warfarin)	Direct thrombin inhibitor (dabigatran)	Factor Xa inhibitor (rivaroxaban, apixaban, edoxaban)

• Administer 4-factor PCC IV based on INR
  • INR 2–4, 25 units/kg
  • INR 4–6, 35 units/kg
  • INR > 6, 50 units/kg
• Or 4-factor PCC low fixed-dose option
  • 1000 units for any major bleed
  • 1500 units for intracranial hemorrhage
• If 4-factor PCC not available, use plasma 10–15 mL/kg
	• Administer 5 g idarucizumab IV
	• If idarucizumab is not available, administer 4-factor PCC or aPCC 50 units/kg IV
	• Consider activated charcoal for known recent ingestion (within 2–4 h)
		• Administer 4-factor PCC IV, 50 units/kg IV
		• If 4-factor PCC not available, consider aPCC 50 units/kg IV
		• Andexanet alfa (FDA approved for reversal of apixaban or rivaroxaban for life-threatening bleeding), bolus (400 or 800 mg) and infusion (4 vs 8 mg/min for up to 120 min)
		• Consider activated charcoal for known recent ingestion (within 2–4 h)

aPCC, activated prothrombin complex concentrate; FDA, US Food and Drug Administration; INR, international normalized ratio; IV, intravenous; PCC, prothrombin complex concentrate.

Missed Injuries

The initial evaluation of the trauma patient centers on recognizing abnormal physiology and the pattern of injury. Missed injuries are the most common cause of preventable death; however, the true incidence of missed injury is difficult to determine. Surgical intensivists caring for trauma patients must recognize potential injuries likely to occur given a particular mechanism of injury. The challenge becomes the rapid identification of occult injuries before the clinical condition of the patient deteriorates. Missed injury is a major pitfall in the care of trauma, and an unexpected deterioration in the condition of the patient in the ICU should prompt a reexamination for possible missed injury, among other causes. Trauma patients in the ICU should undergo a tertiary survey and careful review of imaging results to reduce the risk of missed injury.[107]

Postresuscitation Hypotension in the Intensive Care Unit

Any patient developing hypotension postresuscitation is bleeding until proven otherwise, and aggressive investigation of the etiology is mandatory. Such episodes should prompt a reevaluation of the patient's workup and raise the specter of a missed intra-abdominal injury or solid organ injury rebleeding due to overresuscitation and dislodgment of the initial hemostatic clot. It is a common pitfall to ignore such an episode and assume that resuscitation has been completed and hypotension is due to other causes such as TBI or bleeding due to long bone fractures.

There are certain injuries that may require ongoing resuscitation with blood products, most prominent among them a vertical shear-type posterior element pelvic fracture. However, in the absence of any such known injury, a diligent attempt must be made to exclude a missed injury in the abdomen or perhaps an injury whose magnitude was underestimated.

The traditional end points of resuscitation include an adequate urinary output, the trend of the base deficit on the arterial blood gas, and normalization of arterial lactate levels. There are situations in which the urinary output may be misleading. The intoxicated patient will have good urinary output even in the face of hypovolemia, because alcohol inhibits the release of antidiuretic hormone from the posterior pituitary; in addition, it is hypertonic and leads to peripheral arterial vasodilation. Another situation in which the urinary output will be misleadingly elevated is in the setting of hyperglycemia. Whether the patient is a diabetic or he or she has received high-dose steroids for a spinal cord injury, the resultant hyperglycemia will cause a misleadingly comforting urinary output. A serum blood sugar over approximately 180 to 190 mg/dL results in glycosuria, and this pitfall must be recognized.

Similarly, the base deficit can also be misinterpreted. The etiology of metabolic acidosis in the injured patient is, until proven otherwise, due to hypoperfusion from hemorrhagic shock; it must be understood, however, that the base deficit can be due to ketosis, non–anion gap acidosis including hyperchloremia due to excess saline infusion, renal dysfunction, and sepsis.

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME, SEPSIS, AND SEPTIC SHOCK

Injury leads to the activation of the inflammatory response, which may be aggravated by the severity of shock, degree of tissue injury, and secondary insults. Severely injured patients commonly develop systemic inflammatory response syndrome (SIRS). SIRS is defined by manifestation of two or more of the following conditions: (1) temperature greater than 38°C or less than 36°C, (2) heart rate greater than 90 bpm, (3) respiratory rate greater than 20 breaths/min or $Paco_2$ less than 32 mm Hg, and (4) white blood cell count greater than 12,000/mm^3, less than 4000/mm^3, or greater than 10% immature forms. The treatment of SIRS is supportive, and the condition resolves over time.

Sepsis was previously defined as the presence of a presumed infection in a patient with SIRS. Severe sepsis included sepsis and organ failure, while septic shock was previously defined as sepsis-induced hypotension and hypoperfusion, refractory to volume replacement and requiring vasopressors. The new Sepsis-3 definitions include only sepsis and septic shock[108] and are listed in Fig. 57-13. The 2016 Surviving Sepsis Campaign Guidelines use the new sepsis definitions.[109]

The source of sepsis in the injured patient relates to the type of injuries. It is extremely rare for a patient to have septic shock early, unless there is an obvious infection, such as an aspiration pneumonia or perforated viscus. The patient who has leukocytosis with bandemia, fever, and clinical deterioration must be investigated closely for a source of infection. The diagnosis of an infection following major trauma is the biggest pitfall since the cardinal signs of infection such as fever, leukocytosis, and hyperdynamic hemodynamic state can be, and frequently are, the result of the inflammatory cascade in response to tissue trauma. The pitfall lies in the differentiation between sepsis and SIRS. The consequences of liberal use of antibiotics to broadly cover for presumptive sepsis are real, including drug resistance, antibiotic-related colitis, and fungemia. The consequences of not treating a patient with fever, hyperdynamic state, and signs and symptoms of infection, in the absence of positive cultures or a clear source, are equally daunting, as the patient may indeed be harboring an infection, but the yield of blood cultures and the other surveillance tests are poor.

Unfortunately, there is no reliable method to distinguish between SIRS and sepsis until a definitive infectious source is identified. The usual sources of infection in the ICU are the lungs, indwelling vascular catheters, the urinary tract, and wounds. Each of these sites must be examined meticulously for infection.

The optimal management of sepsis is compliance with the Surviving Sepsis Campaign bundle (Table 57-16) to improve

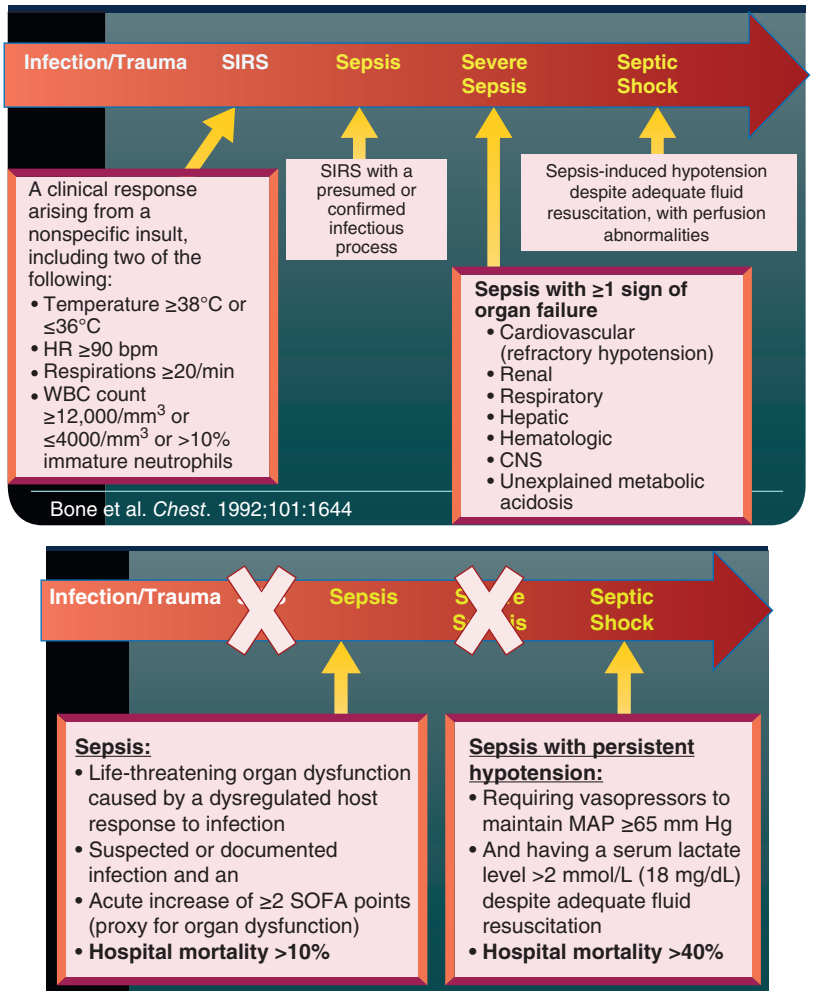

FIGURE 57-13 Sepsis-3 new definitions (2016) compared to prior sepsis definitions. CNS, central nervous system; HR, heart rate; MAP, mean arterial pressure; SIRS, systemic inflammatory response syndrome; SOFA, Sequential Organ Failure Assessment; WBC, white blood cell.

TABLE 57-16: Hour-1 Surviving Sepsis Campaign (SSC) Bundle

- Measure lactate level. Remeasure if initial lactate is >2 mmol/L.
- Obtain blood cultures prior to administration of antibiotics.
- Administer broad-spectrum antibiotics.
- Begin rapid administration of 30ml/kg crystalloid for hypotension or lactate ≥4 mmol/L.
- Apply vasopressors if patient is hypotensive during or after fluid resuscitation to maintain MAP ≥65 mm Hg.

* *"Time zero" or "time of presentation" is defined as the time of triage in the Emergency Department or, if presenting from another care venue, from the earliest chart annotation consistent with all elements of sepsis (formerly severe sepsis) or septic shock ascertained through chart review.*

Note. The most important change in the revision of the SSC bundles is that the 3-hour and 6-hour bundles have been combined into a single "hour-1 bundle" with the explicit intention of beginning resuscitation and management immediately.

MAP, mean arterial pressure.

Source: Reproduced with permission from Levy MM, Evans LE, Rhodes A. The Surviving Sepsis Campaign Bundle: 2018 update. *Crit Care Med.* 2018;46(6):997-1000.

outcomes.[15,110] Lower mortality was observed in high (29.0%) versus low (38.6%) resuscitation bundle compliance sites (P <.001) and between high (33.4%) and low (32.3%) management bundle compliance sites (P = .039).[111] Additional evidence-based recommendations from the recent Surviving Sepsis Campaign Guidelines differ from the prior guidelines (Table 57-17) and include more recommendations labeled as "Strong" (Table 57-18).

ETHICAL ISSUES IN THE INTENSIVE CARE UNIT

Ethics may be regarded, in part, as a series of societal formulations predicated on moral values designed to produce a theoretical "optimal good." With the ability of modern ICUs to maintain physiologic support and homeostasis well beyond the bounds of reasonable sentient existence, physicians are increasingly called on to participate in sometimes difficult live-or-die, withdraw/withhold support decisions. While ICU ethics also include other considerations, such as consent

TABLE 57-17: Surviving Sepsis Campaign Guideline Changes Comparing 2012 and 2016 Recommendations

	2012	2016
Sepsis definition	Systemic manifestation of infection + suspected infection; severe sepsis: sepsis + organ dysfunction.	Life-threatening organ dysfunction caused by dysregulated response to infection. No severe sepsis definition.
Initial resuscitation	At least 30 mL/kg in the first 3 hours; crystalloid fluid (no specific recommendation for fluid type). Albumin if patients require substantial fluids.	
	Early goal-directed therapy protocolized care including CVP, $ScvO_2$.	Use dynamic resuscitation markers (passive leg raise, TTE). Target MAP 65 mm Hg.
	Normalize lactate.	Reassess hemodynamic status to guide resuscitation. Normalize lactate.
Vasopressors	Target MAP 65 mm Hg.	
	Norepinephrine vasopressor of choice; epinephrine if not at target MAP or vasopressin to reduce norepinephrine requirement. Avoid dopamine in most patients.	
Steroids	Only indicated in septic shock refractory to adequate fluids and vasopressors.	
Antibiotics	Administration of effective IV antimicrobials within the first hour of recognition of septic shock and severe sepsis without septic shock.	We recommend that administration of IV antimicrobials be initiated as soon as possible after recognition and within 1 hour for both sepsis and septic shock.
	Initial empiric anti-infective therapy of one or more drugs that have activity against all likely pathogens. Combination empirical therapy for neutropenic patients with severe sepsis and for patients with difficult-to-treat, multidrug-resistant bacterial pathogens such as *Acinetobacter* and *Pseudomonas* spp.	Initial IV broad-spectrum antibiotics to cover all potential pathogens. The addition of a second gram-negative agent to the empiric regimen is recommended for critically ill septic patients at high risk of infection with multidrug-resistant pathogens (eg, *Pseudomonas, Acinetobacter*) to increase the probability of at least one active agent being administered.
	Antimicrobial regimen should be reassessed daily for potential deescalation. Use of low procalcitonin levels or similar biomarkers to assist the clinician in the discontinuation of empiric antibiotics in patients who initially appeared septic but have no subsequent evidence of infection.	May use procalcitonin to guide deescalation of antibiotic therapy.
Source control	Achieve within 12 hours, if feasible.	Achieve as soon as medically and logically feasible.

CVP, central venous pressure; IV, intravenous; MAP, mean arterial pressure; $ScvO_2$, central venous oxygen saturation; TTE, transthoracic echocardiography.

issues and donor organ procurement, this section focuses on the withdrawal/withholding of physiologic support including the application of do not resuscitate (DNR) orders in the surgical ICU.

Ethical Principles Applicable to Medical Decision Making

Ethical decision making should involve the careful application of established principles. The temptation to apply one's individual value system to the decision-making process is strong, but the personal values of the patient are paramount, and the personal judgments of both family members and physicians must be considered in the context of the ethical principles involved. With the possible exception of the principle of distributive justice, each of the following principles should be applied in any given decision-making process:

- Beneficence: The principle of "doing good" as applies to a particular patient, individual, or situation.
- Nonmaleficence: The principle of avoiding harm or wrongdoing, as applied to a particular situation or individual.
- Autonomy: Perhaps the most important operative principle in critical care ethics is the right of self-determination—the inherent right of individuals to make decisions regarding their own treatment options (or withholding thereof) and ultimately make decisions that will impact their survival.
- Full disclosure: The principle of accurate communication of information that will allow individuals (or their surrogates) to exercise autonomy or surrogate decision making.
- Social (distributive) justice: The principle whereby benefits to an individual, if associated with burdens to another individual or individuals, must be weighed in terms of the most "good" done to the society or group as a whole. This last principle typically involves decisions regarding the distribution of scarce resources to allow the "optimum" treatment of not a single individual, but a population of individuals (society). Such a principle may apply during wartime casualty triage or civilian mass-casualty triage.

TABLE 57-18: Strong Recommendations from the Surviving Sepsis Campaign 2016 Guidelines

- 30 mL/kg crystalloid fluid resuscitation within the first 3 hours
- Crystalloids as fluid of choice for initial resuscitation
- Against the use of hydroxyethyl starches for intravascular volume replacement
- Initial target mean arterial pressure of 65 mm Hg in septic shock requiring vasopressors
- Norepinephrine as first-line vasopressor
- Administer antibiotics within 1 hour of recognition
- Empiric broad-spectrum antimicrobial therapy to cover all likely pathogens
- Red blood cell transfusion only when hemoglobin <7 unless extenuating circumstances (myocardial infarction, severe hypoxemia, acute hemorrhage)
- Target tidal volume 6 mL/kg for ARDS, plateau pressure upper limit 30 cm H_2O
- Conservative fluid strategy in ARDS in patients without hypoperfusion
- Against the use of pulmonary artery catheter for patients with sepsis-induced ARDS
- Prone position for sepsis-induced ARDS with Pao_2/Fio_2 ratio <150
- Against use of β_2-agonists for patients with sepsis-induced ARDS without bronchospasm
- Against use of HFOV in adult patients with sepsis-induced ARDS
- Raise head of bed 30–45° in mechanically ventilated patients, spontaneous breathing trials, and a weaning protocol
- Blood glucose control via protocol targeting blood glucose <180 g/dL
- Pharmacologic VTE prophylaxis, unfractionated or low-molecular-weight heparin
- Stress ulcer prophylaxis for patients with risk factors for gastrointestinal bleeding
- Early enteral nutrition, against parenteral nutrition in the first 7 days
- Against use of omega-3 fatty acids as an immune supplement
- Incorporate goals of care into treatment planning using palliative care principles where appropriate

ARDS, acute respiratory distress syndrome; HFOV, high-frequency oscillatory ventilation; VTE, venous thromboembolism.

Withdraw/Withhold Support Decisions

Modern ICUs have developed the increasing technical capability to support homeostasis, even in the face of what would otherwise be overwhelming disease. Increasingly in the trauma population of ICU patients, patient demise is the result of a decision to withdraw or withhold life support. The consequences and irreversibility of such withdraw/withhold decisions in the ICU mandate that they be considered very carefully and predicated on the careful application of ethical and legal principles.

The importance and impact of withdraw/withhold decisions are considerable. In a review of such decision, Smedira et al[112] found that in a mixed population of surgical and medical ICU patients, support was withheld in 1% and withdrawn in 5%. The resultant deaths accounted for 45% of all ICU deaths in the two institutions under study. The general setting under which withdraw/withhold decisions are made is poor prognosis, which would include a low chance of survival and high likelihood of poor cognitive function. Specific criteria that may allow withdrawal/withholding include the following:

- Provision of further treatment is considered medically futile with respect to achieving well-defined therapeutic goals.
- The patient with decision-making capacity (DMC), in exercising his or her autonomy, chooses to have support withdrawn/withheld.
- A legal surrogate decision maker (legal guardian or durable power of attorney) chooses to have support withdrawn/withheld under medically appropriate circumstances.
- The decision is made based on a prior written medical directive stipulating circumstances under which support may be withdrawn/withheld.
- The physician, acting as a surrogate decision maker in conjunction with next of kin, other consultants, and possibly an ethics committee, elects to withdraw/withhold support. The decision should be based on the following considerations:
  - Information regarding the patient's wishes: What the patient would be likely to decide if he or she had DMC. This may be obtained from family, friends, or other providers with a history of relevant contact with the patient.
  - The benefits/burdens test: The benefits of continued treatment are outweighed by the burdens to the patient of such treatment in accomplishing the defined therapeutic goals.
  - Substituted judgment: The "reasonable person test." In the absence of other available information regarding a patient's wishes, a withdraw/withhold decision should be regarded as one likely to be made by any "reasonable person."
  - Best interests test: The decision to withdraw/withhold must be medically appropriate and should not significantly diminish opportunity for recovery within the bounds of benefits/burdens.

Futility

The concept of futility refers to the inability to accomplish a therapeutic goal through medical interventions regardless of the duration of such interventions or the frequency with

which they are repeated. The concept of futility is central to initial withdraw/withhold support decisions. Determination of futility requires two elements: (1) the establishment of an agreed-upon therapeutic goal and (2) determination of the probability, given the application of medical therapy, of reaching these therapeutic goals. Therapeutic goals should be outlined as specifically as possible and may incorporate elements of both physical and cognitive functions. Patients with DMC must be allowed to define their own therapeutic goals, regardless of how "unreasonable" or stringent these goals may seem. The determination of the probability of medical therapy in achieving those goals should be left to the team of treating physicians. Once a given treatment or treatments are deemed to be futile, based on established therapeutic goals, the physician is under no legal or ethical obligation to provide such treatment. Current writing in medical ethics, public policy, and more recently by case law has supported this perspective, although some ethicists do not support this medical prerogative. Individual circumstances, however, particularly in regard to family considerations and consistent with the principle of beneficence, may occasionally be indications for short-term delivery of what otherwise would be considered medically futile care.

During the early ICU phase of care, determination of futility often is achieved in patients with severe nonsurvivable brain injuries (transaxial gunshot injuries or open skull fractures with loss of brain tissue and GCS of 3).

Patients with significant comorbidities, particularly those with end-stage liver or renal disease, and those with malignancies are not candidates for extreme resuscitation efforts or massive transfusion. To the same extent, blunt trauma victims with significant intra-abdominal bleeding and associated nonsurvivable brain injury, greater than 60% total body surface area burns, and cervical spinal cord transactions should not be aggressively resuscitated. Even if some of these patients survive, they will do so with a very poor quality of life, and it is the trauma surgeon's responsibility to provide the family with such information.

Patients who received massive blood transfusions in the operating room without complete hemostasis usually present to the ICU as hypothermic, acidotic, and coagulopathic (see Chapter 13). Although difficult to estimate, the rapidity of bleeding and transfusion requirements greater than two blood volumes have traditionally been used as markers of irreversibility, and most surgeons would agree that in these circumstances, if bleeding is nonmechanical and hypothermia and coagulopathy have not improved over a period of 6 to 8 hours, further resuscitation efforts are probably futile and will serve only to consume precious resources.[113]

Late in the course of ICU care, defining futility in patients with neurologic injury is difficult, as it is almost impossible to predict those who will not achieve a meaningful recovery. Age and comorbidities should be considered when presenting the facts to family members, and they may facilitate the family's decision to withdraw care.

In patients with multiple organ dysfunction, determination of futility is often achieved in those with three or more organ failures as mortality in these circumstances approaches 100%.

Decision-Making Capacity and Autonomy

DMC, which has different implications than the legal term *competent*, requires the following:

- The patient must be able to comprehend and communicate information relevant to making a decision.
- The patient must be able to comprehend his or her alternatives and the benefits and burdens (risks) associated with each.
- The patient must be able to reason and deliberate about these alternatives against a background of stable personal values.

The determination of DMC may generally be made by the primary physician or team, but occasionally, particularly in the presence of underlying psychiatric illness, psychiatric consultation may be of benefit in making this determination. The exercise of autonomy is best accomplished by allowing any patient with DMC to participate in withdraw/withhold or DNR decisions. In many cases, a patient's specific wishes may not be known and legal surrogates or medical directives may be unavailable. With careful adjustment (lightening to the extent possible) of any conscious sedation and directed efforts made in communicating the alternatives (full disclosure), many patients can make decisions or at least provide valuable information allowing surrogates to do so.

The written medical directive provides an alternative means by which a patient may exercise autonomy. Medical directives may be structured in a variety of ways—depending on known medical conditions, age of the patient, and so forth—but they typically contain language stipulating preferences (or not) for life-sustaining treatment as a function of expected physical and cognitive outcomes.[114]

Decision Making in the Absence of Decision-Making Capacity

In situations where the patient does not have DMC and no specific medical directive is available, a surrogate decision-making process is used. Participants in the surrogate decision-making process may include family members, friends, other health care providers, clergy, and members of the institutional ethics committee. Family members invested with durable power of attorney may make clinically appropriate decisions independently on behalf of the patient. Surrogate decision making should involve close collaboration and extensive documented communication between health care providers and the family to the extent possible. The specific role of the family, however, in the absence of durable power, is not to actually make withdraw/withhold decisions but to provide information allowing providers to best formulate decisions consistent with what the patient's desires would be. This information

may include knowledge of the patient's values, goals, religious or philosophical beliefs, or previously expressed wishes with respect to medical care. The importance of this information should not be underestimated; in the absence of durable power of attorney, family members have no recognized legal authority to dictate care or to make decisions that are medically or ethically inappropriate. Health care professionals also have a primary responsibility to act in what they perceive to be the best interests of the patient, which may occasionally be in conflict with wishes expressed by the family or, on rare occasions, the wishes expressed by a durable power agent.

In the absence of any information pertaining to the presumptive wishes of the patient, substituted judgment may be applied based on several considerations:

- What would a "reasonable" person want under similar circumstances? Physicians should rarely be making this judgment independently, and the involvement of colleagues or a formal ethics committee consultation may be appropriate.
- What would the likely benefits of continued treatment be (treatment outcome), weighed against the burdens imposed by both the treatment and the treatment outcome? The anticipated degree of functional recovery and resultant quality of life are important factors in this consideration. Therapeutic intervention designed to prolong life in a setting in which the quality of that life—because of severity of pain, lack of cognitive function, and so forth—is regarded as being excessively burdensome to an individual may not be medically appropriate.

In many cases, the outcome from a critical illness and specific degree of disability, at a given point in time, cannot be predicted with any degree of certainty. The best interests test prevents premature withdraw/withhold decisions from being made that might deprive a patient of an opportunity for satisfactory recovery. Additional professional consultation, including the institutional ethics committee, may help resolve the more difficult cases.

Conflict Resolution

With good ongoing communication, full disclosure of relevant information and prognosis, and sensitivity to patient/family dynamics, withdraw/withhold support decisions can generally be made smoothly. The liberal use of consultants, particularly those involving the neurosciences, may be a valuable adjunct under such circumstances. Ethics consultation services have also been shown to affect management outcome when they are made available. Conflicts may arise, however, over issues of futility, therapeutic goals, and the conduct of surrogate decision making. These conflicts are often based on misunderstanding or mistrust and exacerbated by the lack of good communication.

In situations in which conflict between care providers and family members appears to be irreconcilable, even with ethics committee and institutional risk management/legal consultation, a number of alternatives should be offered to the family. These alternatives may include the following: (1) procurement of additional intramural or extramural medical, religious, or ethical consultations; (2) transferring the care of the patient to another provider within the institution; (3) transfer of the patient to another institution, under the care of another provider; and (4) procurement of a court order mandating a course of treatment.

Do Not Resuscitate Orders

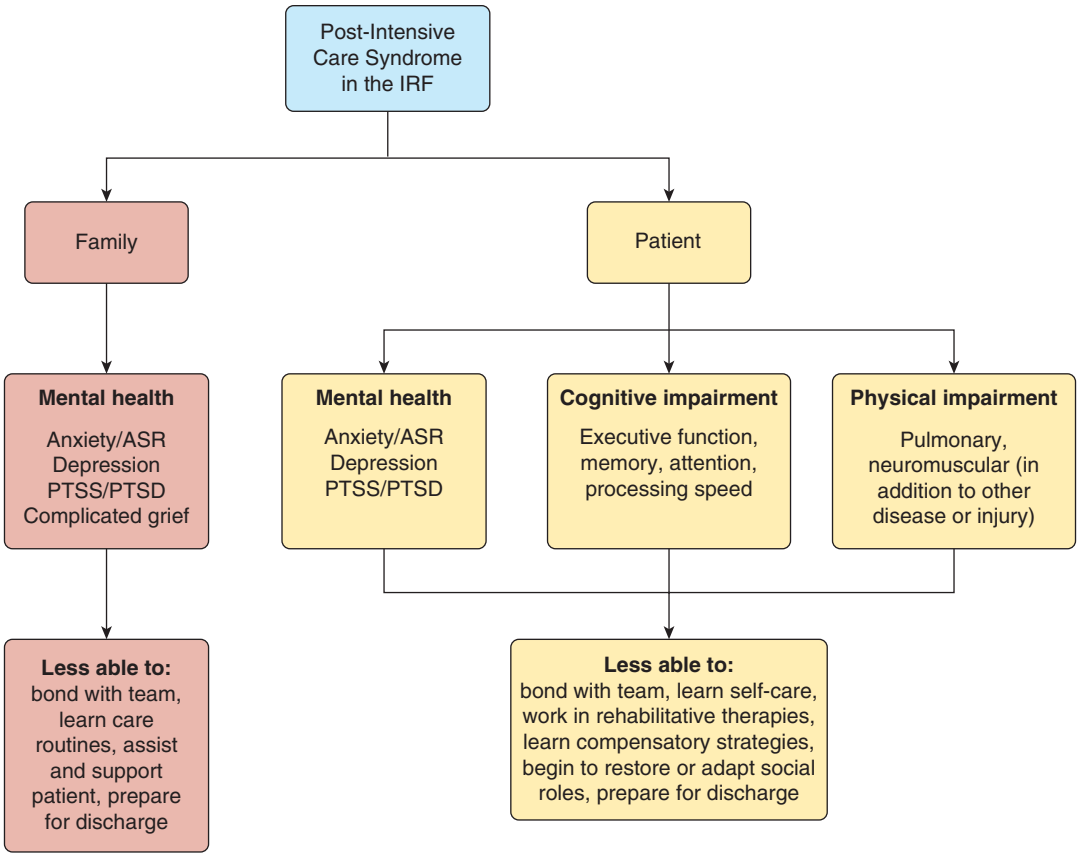
The institution of DNR medical directives has been primarily based on the desire to avoid the indignity of futile cardiopulmonary resuscitation in the setting of inexorable progression of underlying known disease processes. Such orders are frequently applied to patients with long-standing terminal disease (eg, cancer, end-stage AIDS, and irreversible multiple organ failure). DNR orders are implicitly coupled to futility judgments about the benefit of cardiopulmonary resuscitation to achieve prospectively defined therapeutic goals. Under such circumstances, these orders are entirely appropriate and desirable in the variety of clinical disease states. The intensity of critical care interventions with mechanical ventilators and the use of complex drug regimens, including vasoactive drugs, may lead to unexpected (iatrogenic) complications unrelated directly to the underlying disease process for which a DNR order may have been originally placed. In addition, the critical illness being treated in the surgical ICU, particularly for trauma patients, results from a discrete event (surgery or injury) as opposed to complications or exacerbations of chronic disease, as is often the case for medical patients. The presumed reversibility of the physiologic sequelae constitutes a basis for ICU treatment of the trauma patient. As such, DNR for the trauma patient should be applied very carefully to expected complications, or physiologic changes due to inexorable progression of known underlying disease, as opposed to unexpected, very reversible iatrogenic complications.

DNR orders for trauma patients may be more appropriately linked to withdraw/withhold support conditions than more generally to patients with a poor but potentially reversible prognosis. The variability with which DNR orders are interpreted and the "message" such orders send to providers also raise concerns about their applicability for trauma patients. In addition to the potential for the inappropriate application of DNR orders in an ICU, application may result in less aggressive care on the part of ancillary providers.[115,116]

DNR orders constitute the prospective application of a specific "withhold support" decision and should be made with the same care and consideration, as described in the earlier section, as any decision involving the limitation of critical care.

POST–INTENSIVE CARE SYNDROME (PICS)

Millions of trauma survivors experience de novo suffering and disability called the post–intensive care syndrome (PICS). Patients with PICS are robbed of their normal cognitive,



This model, adapted from a model developed in 2010 by the Long-Term Consequences Task Force of the Society of Critical Care Medicine (SCCM), shows the physical, cognitive, and mental health problems affecting inpatient rehabilitation in patients PICS.

FIGURE 57-14 Post–intensive care syndrome (PICS). ASR, acute stress reaction; IRF, inpatient rehabilitation facility; PTSD, posttraumatic stress disorder; PTSS, posttraumatic stress symptoms.

emotional, and physical capacity and cannot resume their previous life (Fig. 57-14). Muscle weakness, memory problems, depression, insomnia, physical pain, and nightmares are just a few examples of the problems that patients may experience following critical illness. Symptoms such as these, which affect emotional, physical, and cognitive health, are now being recognized as PICS. Efforts to educate health care providers, patients, and families about PICS are underway. Some studies have documented that a multidisciplinary, complex, 5-week, peer-supported rehabilitation program, including pharmacy, physiotherapy, nursing, medical, and psychology input, was associated with improved patient outcomes.[117] Additional studies are required to identify optimal treatment for ICU survivors with PICS, but it is our responsibility as intensivists to first identify the symptoms of PICS in our ICU survivors.

Cardiovascular Failure

Nori L. Bradley • Bryan A. Cotton

KEY POINTS

- Cardiac output (heart rate × stroke volume) is determined by rate, preload, afterload, and contractility.
- Ventricular filling determines left ventricular end-diastolic volume, which in turn determines the force of ventricular contraction.
- Hemodynamic transesophageal echocardiography (TEE) is performed with a miniaturized two-dimensional monoplane disposable TEE probe that can be left in place for up to 72 hours.
- Right heart failure is characterized by increased right ventricular (RV) afterload (increased pulmonary resistance), which decreases the ability of the RV to pump blood forward to the left heart, thus decreasing left ventricular preload.
- In valvular aortic stenosis, symptoms of left heart failure include dyspnea on exertion, angina, lightheadedness, and syncope.
- Management of myocardial dysfunction includes vasopressors (eg, norepinephrine, vasopressin, phenylephrine), inotropes (eg, epinephrine, dobutamine, milrinone, dopamine, digoxin), and intra-aortic balloon pump counterpulsation.
- A low mixed venous oxygen saturation occurs with decreased oxygen delivery (decreased hemoglobin, oxygen saturation, or flow) or increased oxygen demand (hyperthermia, pain, seizure, or shivering).
- In the management of acute heart failure, nitroprusside reduces afterload by acting on arteriolar smooth muscle and has a rapid onset of action, and its effects cease within minutes of stopping the infusion.
- In diastolic dysfunction, β-adrenergic blockade or calcium channel blockade reduces heart rate and increases left ventricular filling, which reduce mortality.
- Cardiac death or a myocardial infarction occurs in 1% to 5% of unselected patients undergoing noncardiac surgery, and this concern is the most common indication for a preoperative cardiac evaluation.

INTRODUCTION

Cardiovascular failure is deterioration of cardiac function or vascular tone that results in impaired end-organ perfusion. In the acute phase of trauma, most shock is due to hemorrhage. Hemorrhagic shock causes decreased preload and thus decreased heart filling volumes, which are compensated by tachycardia. Without appropriate volume resuscitation and control of bleeding, hemorrhagic shock may progress to hypotension and end-organ hypoperfusion. In contrast, cardiogenic shock is due to impaired myocardial contractility with elevated cardiac filling pressures and low cardiac output that progresses to end-organ hypoperfusion.[1] Unlike hemorrhagic shock, cardiogenic shock often does not respond simply to volume/blood product resuscitation and control of hemorrhage, and may often worsen as the patient is "driven off" the Starling curve.[2,3] Cardiogenic shock solely from impaired contractility is most often due to an acute myocardial infarction or acute-on-chronic heart failure.[4] Therapy to support the failing cardiovascular system is directed at the etiology of the shock state and includes fluid management (optimize preload) as well as pharmacologic modulation of vascular tone (optimize afterload), contractility (with inotropes), and heart rate (with chronotropes). This chapter will explain the physiologic components of cardiovascular failure and the evaluation, treatment, and monitoring of patients with cardiovascular failure (Fig. 58-1).[5]

DETERMINANTS OF CARDIAC OUTPUT

Cardiac output (CO) is defined as the quantity of blood ejected into the aorta by the heart each minute and is calculated as heart rate multiplied by stroke volume (CO = heart

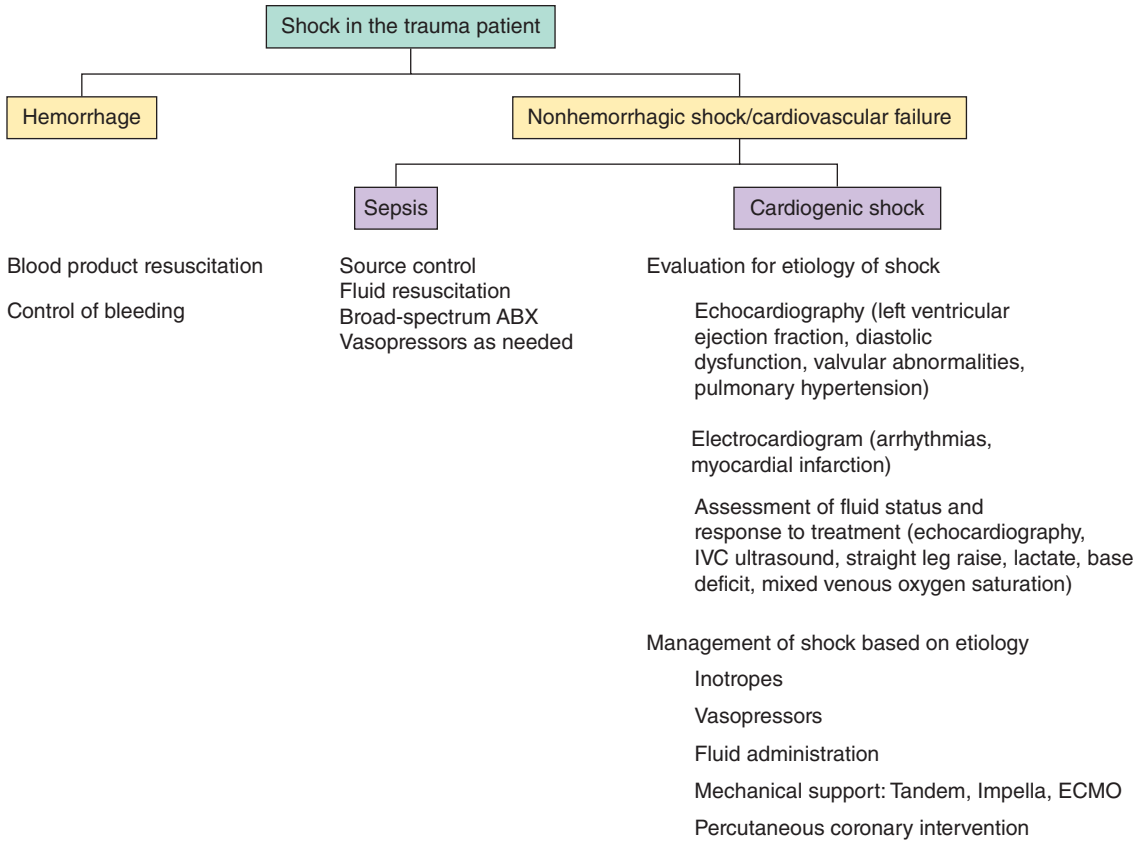

FIGURE 58-1 Algorithm for the approach to the patient in the surgical intensive care unit (SICU) with cardiovascular failure. ABX, antibiotics; ECMO, extracorporeal membrane oxygenation; IVC, inferior vena cava.

rate × stroke volume). This is the quantity of blood that flows through the circulation and is responsible for oxygen and nutrient transport to the tissues. The primary determinants of CO are listed in the box below. Accordingly, the majority of therapies for augmenting CO aim to (1) control heart rate, (2) restore filling pressures, and (3) optimize the ability of heart to contract.[5]

Determinants of Cardiac Output (CO)

CO = heart rate × stroke volume

- Preload
- Afterload
- Contractility

Heart rate = number of beats per minute
Preload = ventricular filling
Afterload = the forces opposing ventricular contraction
Contractility = force with which myocardium contracts

The average CO for adults is approximated as 5 L/min. However, CO varies with activity and is influenced by level of metabolism, exercise state, age, size of the individual, and other factors. CO in women is generally stated as being 10% to 20% lower than in men. CO increases in proportion to increasing body surface area. Therefore, to standardize CO measurements between individuals, cardiac index (defined as CO divided by body surface area in meters squared) is employed.[6]

Preload

Preload is the degree of myocardial stretch prior to contraction and most commonly is volume dependent. The Frank-Starling relationship shows that as cardiac sarcomere length increases, the force of contraction increases. However, when the sarcomere is stretched beyond its maximal length (overfilling), the force of contraction decreases. The Frank-Starling relationship provides a paradigm by which the cardiovascular system and its derangements can be approached. Ventricular filling determines left ventricular end-diastolic volume (LVEDV), which in turn determines the force of ventricular contraction. Factors influencing ventricular filling include intravascular volume status, intrathoracic pressure, intra-abdominal pressure, ventricular compliance, valvular disease, atrial kick, pericardial compliance, and ventricular wall thickness[5] (Table 58-1).

LVEDV can be directly measured with echocardiography. However, it is most frequently estimated via the left ventricular end-diastolic pressure (LVEDP). Assuming unaltered ventricular compliance, LVEDP theoretically approximates

TABLE 58-1: Factors Influencing Ventricular Filling

Factor	Clinical example	Effect on preload	Effect on CVP	Effect on PAWP
Intravascular volume	Hemorrhage	↓	↓	↓
	Sepsis[a]	↓←→	↓←→	↓←→
Intrathoracic pressure	Positive-pressure ventilation	↓	↓	←→ or ↑
	Tension PTX			
Intra-abdominal pressure	Abdominal compartment syndrome	↓	↑	↑
	Pregnancy			
Ventricular compliance	Diastolic dysfunction (↓)	↓	↑	↑
Ventricular hypertrophy	HTN → LVH	↓	←→ or ↑	←→↑ or ↓
	PHTN → RVH	↓	↑	
Valvular disease	MR	↓	←→ or ↑	↑
	AS?	↑		
Atrial kick	Atrial fibrillation	←→ or ↓	↑ (?)	←→ or ↓
Pericardial compliance	Tamponade	↓	↑	↓
	Constrictive pericarditis		↑	

[a]Sepsis can present as intravascular hypovolemia with decreased preload, CVP, and PAWP. However, once resuscitated, if septic cardiomyopathy ensues, ventricular volume may increase but with accompanying ventricular dilation and increased compliance that decreases filling pressures.

AS, aortic stenosis; CVP, central venous pressure; HTN, hypertension; LVH, left ventricular hypertrophy; MR, mitral regurgitation; PAWP, pulmonary artery wedge pressure; PHTN, pulmonary hypertension; PTX, pneumothorax; RVH, right ventricular hypertrophy.

the LVEDV. Traditionally, a pulmonary artery catheter (PAC) was used to measure the pulmonary arterial wedge pressure (PAWP), which approximates LVEDP. Alternatively, measuring central venous pressure (CVP) with a central venous catheter at the cavoatrial junction reflects right ventricle end-diastolic pressure (RVEDP). Again, assuming unaltered ventricular compliance, RVEDP theoretically approximates right ventricle end-diastolic volume (RVEDV). With normal pulmonary compliance and cardiac valves, RVEDV approximates LVEDV. Unfortunately, in the setting of critically ill patients, factors such as myocardial ischemia, heart failure, and myocardial edema can decrease ventricular compliance, rendering measurement of PAWP and/or CVP as surrogates for end-diastolic volume unreliable. In addition, valvulopathy and poor pulmonary compliance can influence right- and left-sided filling volumes differentially. In any of these situations, normal or elevated PAWP and/or CVP does not rule out inadequate preload as a cause of low CO. Therefore, multiple measurements of cardiovascular function, including the pulmonary artery pressure, CVP, and inferior vena cava filling, straight leg raise, response to fluid challenge, and the clinical scenario should be integrated to gauge preload when caring for these complex patients.[7] See later section, "Evaluation of Volume Status and Cardiac Function."

Afterload

Afterload is the force that opposes ventricular contraction. It is primarily dependent on vascular tone, arterial compliance, and ventricular transmural systolic pressure. Resistance is the primary determinant of vascular tone, and afterload is often estimated using systemic vascular resistance (SVR). SVR is calculated using the hemodynamic equivalent of Ohm's law (see the following box).[7]

Determinants of Systemic Vascular Resistance (SVR)

$$SVR = (MAP - CVP)/CO$$

MAP = mean arterial pressure
CVP = central venous pressure
CO = cardiac output

This equation provides an approximation of vascular impedance. However, there are several limitations in using SVR to estimate afterload. SVR values from a PAC are calculated, not directly measured. The calculation assumes nonpulsatile blood flow and does not account for blood viscosity, arterial elastic properties, or microvascular resistance. Despite these limitations, in a critically ill trauma patient, knowledge of SVR may help differentiate between different or overlapping types of shock and guide management (Table 58-2).[7]

Ventricular transmural systolic pressure is the intrathoracic pressure that the ventricular cavity must overcome to achieve ejection. This is notable for the trauma patient undergoing positive-pressure ventilation. Positive end-expiratory pressure (PEEP) decreases the intrathoracic pressure and thus decreases afterload for the left ventricle. For the patient in cardiovascular failure with adequate preload, increasing positive pressure may improve CO. Similarly, removing positive pressure (eg, extubation) increases afterload. For the failing (or recovering) heart, this increased afterload may contribute to end-organ hypoperfusion or extubation failure.[8]

TABLE 58-2: Differentiating Between Overlapping Types of Shock

	Hypovolemic	Distributive	Cardiogenic
Preload (CVP/PCWP)	↓↓	↓↓	↑↑
Cardiac output	↑↑	↑↑	↓↓
Afterload (SVR)	↑↑	↓↓	↑↑
Clinical example	Hemorrhage	Sepsis, spinal cord injury	Heart failure, myocardial infarction

CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.

Cardiovascular failure due to a reduction in afterload is referred to as distributive shock. Etiologies include sepsis, neurologic deficit, and anaphylaxis. In the absence of a PAC, clinical history and physical exam of peripheries and pulse pressure can help assess afterload; warm peripheries and wide pulse pressure would support the diagnosis of distributive shock.[9] In trauma patients, distributive shock in the immediate posttrauma period should raise the suspicion of severe central nervous system injury. Later in the hospital course, sepsis is highest on the differential diagnosis, and the source should be identified and treated accordingly.

Contractility

Contractility, also known as inotropy, is the force with which the myocardium contracts. The inotropic state of the myocardium can be visualized by the construction of a left ventricular pressure–volume loop (Fig. 58-2). This loop is bounded by the four phases of the cardiac cycle: isovolemic relaxation, diastolic filling, isovolemic contraction, and systolic ejection. The difference between end-diastolic volume and end-systolic volume is the stroke volume. The area bounded by this loop is the stroke work, or the external work done by the ventricles to eject the stroke volume. The maximal pressure that can be developed by the ventricle at any given left ventricular volume represents the end-systolic pressure–volume relationship (ie, inotropy). The slope created by this relationship varies directly with inotropic state of the ventricle.[7]

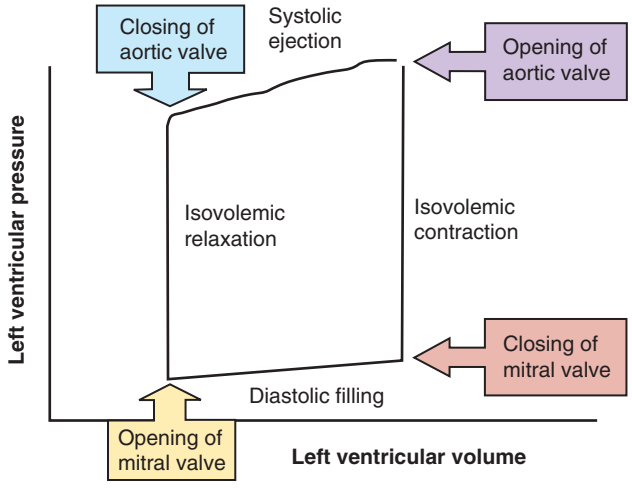

FIGURE 58-2 The relationship between left ventricular pressure and left ventricular volume during a stylized cardiac cycle.

The main factors determining contractility are autonomic nervous system activity, disease, and drugs, mainly by influencing intracellular calcium stores. Sympathetic nerves regulate inotropy and are augmented by epinephrine release during times of stress, such as trauma. Conversely, cardiac disease such as systolic heart failure is associated with reduced peak and sarcoplasmic reticulum calcium uptake. Myocardial ischemia and hypoxia lead to decreased adenosine triphosphate (ATP) production and decreased sarcoplasmic reticulum calcium function. Drugs such as digoxin, β-adrenoceptor agonists, and phosphodiesterase inhibitors influence intracellular calcium by a variety of pathways in order to increase inotropy. However, excessive inotropic stimulation can overwhelm the capacity of myocytes to participate in aerobic metabolism, which can ultimately result in aerobic lactate production, acidosis, and further impairment of sarcoplasmic reticulum function.[7] Clinically, this points toward manipulation of contractility to balance myocardial oxygen supply, demand, and delivery.

Heart Rate

Heart rate is a key determinant of CO. In the setting of constant stroke volume, increasing the number of cardiac ejections per unit time results in increased CO. In addition, increasing heart rate can overwhelm the Na/K-ATPase, allowing intracellular calcium to accumulate via the sodium–calcium exchanger, further increasing inotropy. However, ventricular filling occurs during diastole. In the setting of myocardial failure, high heart rates can shorten the diastolic interval, decrease ventricular filling (ie, preload), and result in decreased CO.[7] High heart rates can also overwhelm myocyte aerobic metabolism, further worsening contractility and CO, as described in the previous section. Therefore, appropriate rate control becomes paramount in ensuring matched oxygen delivery and utilization in patients with cardiovascular failure. Rate control is best initially managed by addressing the underlying cause, such as hypovolemia, anemia, control of pain or agitation, or pulmonary embolism (PE), before initiating rate or rhythm control agents.

EVALUATION OF VOLUME STATUS AND CARDIAC FUNCTION

Because ventricular filling is a key determinant of CO and because knowing the degree of ventricular filling can help rule in or rule out specific causes of shock, assessment of volume status is essential to understand cardiac function in real time. Multiple measurements and tools are available to determine volume status.

Central Venous Pressure

CVP monitoring has been used for many years as a surrogate measurement of preload; however, recent reviews have showed low positive predictive value for CVP as a measure of fluid responsiveness.[10,11] In the young trauma patient with normal cardiac function and ventricular compliance, the CVP monitor provides an assessment of right-sided filling pressure (or preload) that should be used in conjunction with other measures to guide fluid resuscitation.[10] A CVP monitor is usually placed percutaneously as a central venous catheter into the superior vena cava via the subclavian or internal jugular vein. Normal CVP in a nonventilated patient is between 0 and 4 mm Hg; however, response to fluid is more useful than an absolute number. A CVP less than 8 mm Hg has a moderate likelihood of fluid responsiveness.[11] Conversely, an elevated CVP is less likely to respond to fluid or suggests an alternate shock state, such as cardiogenic or obstructive. However, CVP is a static measurement and is affected by multiple variables, which may contribute to its limitation in assessing volume status. Malposition of the catheter, right- or left-sided congestive heart failure (CHF), pneumothorax, lung recruitment techniques or high PEEP, PE, cardiac tamponade, increased intrathoracic pressure, and/or increased intra-abdominal pressure may all lead to increases in CVP measurements, which do not reflect the true overall volume status (Table 58-1).[11] With the current availability of other techniques, CVP should be interpreted in conjunction with measurements such as ultrasound/echocardiography, pulse pressure variation, and passive leg raise in order to assess volume status and cardiac function.[10,11] These are discussed later in this chapter.

Pulmonary Artery Catheters

PACs, first introduced for human use in 1970, have been widely accepted as the standard for invasive monitoring of not only volume status, but also cardiac function by measurement and approximation of left-sided cardiac pressures. Measurement of the PAWP is used as an indirect measurement of LVEDP and LVEDV; however, these measurements often show poor correlation and can be altered by myocardial ischemia, ventricular outflow obstruction, mitral regurgitation, vasodilator therapy, or severe heart failure.[12] Similar to CVP, PAWP can be affected by decreased pulmonary compliance and high PEEP (as seen in lung recruitment strategies). Commercially available PACs currently incorporate multiple calculations to derive other indices of cardiac function and tissue perfusion such as mixed venous oxygen saturation (Svo_2), SVR, oxygen delivery (Do_2), and oxygen consumption (Vo_2).[13] However, a large randomized clinical trial reported that PAC-guided treatment was not superior to that of central venous catheter–guided treatment; mortality and intensive care unit (ICU) length of stay were similar, but the PAC group had a higher rate of complications.[14] A 2013 Cochrane Review analyzing 13 studies found no difference in mortality or hospital or ICU length of stay with the routine use of PAC and found that PAC use was associated with higher costs.[15] Although routine use of PAC may not be indicated in trauma patients, its use should be considered in certain situations, such as in patients with ongoing hemodynamic instability of unclear etiology, patients with a history of CHF or pulmonary hypertension who are not responding as expected to traditional therapy, and patients with suspected hemodynamic changes from blunt cardiac injury.

Echocardiography

Echocardiography, either transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE), has gained wide acceptance in the monitoring of cardiac function and has emerged as an effective tool in the ICU as a guide to resuscitation and monitoring fluid responsiveness. In addition, information about structural abnormalities of the heart, aorta, and main pulmonary arteries can be obtained, as well as assessment of ventricular dysfunction (eg, ejection fraction), ventricular filling, valvular abnormalities, ventricular hypertrophy, and PE. For the critically ill patient in shock, TEE may be able to help differentiate hypovolemic shock (eg, empty/underfilled ventricle) from cardiogenic shock (eg, new wall motion abnormality), obstructive shock (eg, D-shaped septum), and distributive shock (eg, global hypokinesis). Continuous TEE can give accurate measurements of both right- and left-sided filling volumes of the heart and may provide a better assessment of myocardial preload when compared to CVP or PAC measurements.[16] Placed in the esophagus, Doppler probes can accurately predict CO using the diameter of the aorta and measurements of blood flow velocity. The finding of short mitral deceleration time (≤140 ms) is highly predictive of pulmonary capillary wedge pressure of ≥20 mm Hg, which is consistent with cardiogenic shock.[17] A prospective, multicentered study in 2013 demonstrated that the performance of at least 31 supervised examinations over a 6-month period was required to achieve competence in TEE-driven hemodynamic evaluation of a critically ill patient.[18] TEE has been found to be a safe procedure that can be done at the bedside by intensivists and has been found to affect management of the critically ill patient in up to 80% of patients.[19]

Hemodynamic Transesophageal Echocardiography

Hemodynamic TEE (hTEE) is essentially point-of-care echocardiography that has become available for assessment of cardiac structure and function for the intensivist. As with conventional echocardiography (TEE or TTE), hTEE provides information regarding both the overall structure and function of the myocardium, although on a limited scale. Recently developed devices, such as the miniaturized two-dimensional monoplane disposable TEE probe (ClariTEE, ImaCor-USA, Uniondale, NY), allow for continuous less invasive hemodynamic and cardiac monitoring that can be

left in place for up to 72 hours. These devices use a miniature TEE probe (mTEE) with an associated ultrasound system to obtain three cross-sectional views of the heart (midesophageal four-chamber view, transgastric short axis) as well as visualization of the superior vena cava. Two-dimensional transverse, 0-degree images with associated ante- and retroflexion can be viewed.[20]

When compared to TTE or TEE, hTEE/mTEE provides several benefits. Whereas TEE and TTE require extensive training, are more invasive, pose a small risk of complications, and are limited in duration of use, mTEE devices are smaller in size (approximately 5.5 mm in diameter) and can be left in position for intermittent and continuous evaluation for up to 72 hours.[21,22] Multiple studies have demonstrated the learning curve for adequate operator proficiency in both performing and interpreting TEE and TTE. Whereas Charron's group[23] reported that 31 completed and supervised TEEs were adequate for competency in the ICU, the National Board of Echocardiography requires a minimum of 150 exams and interpretation of 300 studies, and the British Society of Echocardiography requires 250 cases over 24 months before accreditation can be sought.[24] Cioccari et al[21] proceeded to demonstrate that proficiency with hTEE/mTEE by ICU practitioners without any prior TEE experience could be obtained after a short training course. Furthermore, the rates of interrater agreement (kappa) between novice TEE practitioners and cardiologists for the three views in hemodynamically unstable patients were all statistically significant (all three views, P <.0001). Associated clinical implications of hTEE use in the ICU and trauma population are present, although limited in the reported literature. hTEE has been used to guide clinical decision making in the care of extracorporeal membrane oxygenation (ECMO) patients, cardiac surgery patients, and trauma patients. The use of hTEE has been shown to aid diagnostic and therapeutic decision making 50% to 66% of the time with respect to critically ill patients, and when compared to standard hemodynamic monitoring, hTEE is able to identify critical issues 66% of the time.[25-28] Unfortunately, only one study has described the use of hTEE in the trauma population to date. Griffin et al[29] demonstrated that the use of hTEE in posttrauma ICU care reduced use of continuous renal replacement therapy (CRRT) as well as days of CRRT use. Although this was a well-powered study, the conclusions drawn regarding hTEE are not easily extrapolated to the posttrauma ICU patient, and further studies involving the trauma population and hTEE are needed.

Ultrasound of the Inferior Vena Cava

Ultrasound evaluation of the inferior vena cava (IVC) can give an estimate of the volume status of the patient and help predict a beneficial response to fluid. The IVC should be identified in a transverse plane with the cardiac probe, and then rotated 90° to the longitudinal plane. IVC diameter should be measured 1 to 2 cm caudad from the hepatic vein–IVC junction (3–4 cm from the caval atrial junction).[30] Static measurements of IVC diameter have been compared to CVP. In a spontaneously breathing patient, an IVC diameter of less than 2 cm is associated with a CVP of less than 10 mm Hg, whereas a diameter of greater than 2 cm is associated with elevated CVP. However, static IVC measurements fail to predict fluid responsiveness.[30] Conversely, dynamic measurements of IVC diameter during the respiratory cycle have been validated to predict fluid responsiveness in both fully ventilated and spontaneously breathing patients. Once the IVC is identified in the manner described earlier, the time-motion (M-mode) feature is used to measure changes in IVC diameter during the respiratory cycle at end expiration and early inspiration. An average of three measurements should be taken. In ventilated patients, positive pressure causes IVC dilation during respiration. An increase of IVC diameter of 12% to 18% during the respiratory cycle of fully ventilated patients indicates fluid responsiveness. In spontaneously breathing, nonventilated patients, negative pressure causes the IVC collapse during respiration. A decrease in IVC diameter greater than 40% is predictive of fluid responsiveness.[30] Multiple studies have demonstrated that ultrasound of the IVC can be a useful noninvasive technique for volume status measurement and fluid responsiveness.[31,32] Serial measurements can also assess response to interventions. However, at this time, the use of IVC ultrasound to predict volume responsiveness in ventilated but spontaneously breathing patients has not been reliably validated.

Pulse Pressure Variation and Stroke Volume Variation

An arterial catheter can be a useful adjunct in the evaluation of a trauma patient's fluid status and heart function (eg, FloTrac Monitor, Edwards Lifesciences, Irvine, CA). Specialized devices can monitor trends in CO and cardiac index, but even simple arterial catheters can provide information regarding a patient's volume responsiveness, via monitoring of the pulse pressure variation (PPV) and stroke volume variation (SVV). Excessive variations in arterial blood pressure caused by the specific interactions of the heart and lungs under positive-pressure ventilation are a clinically well-known sign of hypovolemia.[33] Variations in PPV are exaggerated when the left ventricle (LV) is on the steep portion of the Frank-Starling curve; small preload changes cause large stroke volume changes (see the following box).

Calculation of Pulse Pressure Variation

Pulse pressure variation (PPV):

$$PPV\ (\%) = (PP_{max} - PP_{min})/[(PP_{max} + PP_{min})/2] \times 100$$

where PP_{max} is the largest pulse pressure during inspiration and PP_{min} is the smallest pulse pressure during expiration

This variation is also influenced by ventilator tidal volumes.[11] PPV greater than 8% in low tidal volume patients

(<7 mL/kg) and 11% in high tidal volume patients (≥7 mL/kg) is indicative of fluid responsiveness.[11] PPV is a surrogate of SVV; however, there are limitations in measuring PPV.[34] Pulse pressure can vary independently of the true cardiorespiratory physiology during nonsinus rhythms and may be falsely increased with bradycardia or right ventricular failure. PPV is proportional to stroke volume and inversely related to aortic compliance. Therefore, PPV may vary highly even if SVV is small when aortic compliance is decreased. Finally, spontaneous respiration influences variability and makes PPV difficult to interpret.

In contrast, stroke volume is a volume, not a pressure, measurement. Therefore, SVV may be more accurate than PPV. Multiple studies of SVV have shown improved prediction of fluid responsiveness over CVP and PAWP and have validated SVV and PPV as helpful adjuncts used to improve CO.[35,36] Despite the promise of encouraging initial results in intraoperative patients, the use of SVV has its limitations due to questions of validity at high respiratory rates, with tachycardia, in the presence of β-adrenergic blockade, and in the presence of an over- or underdampened arterial curve.[37]

Arterial pulse contour analysis has also been clinically validated for continuous CO measurement and is now available for the real-time quantification of LV SVV and CO.

Passive Leg Raise

An additional noninvasive method of measuring response to changes in preload is the passive leg raise (PLR) test. The appropriate (and validated) method has the following five steps: (1) Position the patient semi-recumbent with the trunk at 45°. (2) Use the bed controls to both flatten the trunk supine and raise the legs to 45°. (3) Assess the change in CO or pulse pressure and heart rate over 60 seconds. (4) Return the patient to semi-recumbent position with the trunk at 45°. (5) Reassess the hemodynamic status for return to baseline.[38] This method transfers approximately 300 mL of fluid from the lower body to the right heart, and thus PLR simulates the heart's response to a fluid challenge but without adding actual volume. In a recent meta-analysis, a 10% increase in CO during PLR had the highest positive predictive value and lowest negative predictive value for likelihood of fluid responsiveness. Similarly, a 10% increase in PP during PLR had moderate predictive value for fluid responsiveness. These results were fairly robust during both spontaneous and controlled ventilation.[11]

PLR results, however, can be falsely elevated by sympathetic stimulation, the shock state, or vasomotor tone. If the test induces pain, cough, or awakening, an increase in CO or pulse pressure may not be due to the fluid bolus; this is suggested by an elevated heart rate during the PLR.[38] Failure of the CO or pulse pressure to return to baseline after the PLR may indicate the hemodynamic change is influenced by the disease state rather than increased preload with leg raise. Changes in pulse pressure specifically are affected by arterial compliance (increased PPV seen with decreased compliance), as described in the previous section.[38]

MYOCARDIAL DYSFUNCTION AND SHOCK

Myocardial dysfunction can be defined on the basis of perturbed preload, afterload, contractility, or heart rate, as described earlier. Systemic hypovolemia causing inadequate preload, due to hemorrhage or third-space losses, is the most common etiology in the postsurgical or trauma patient. Other causes of decreased CO may arise from acute heart failure or decreased contractile function of the heart. Impaired contractility can be due to the evolution of direct muscle ischemia or from any insult that results in intrinsic metabolic derangements at the cellular level. The latter typically occurs in the settings of sepsis, post–cardiac arrest, post–cardiopulmonary bypass, or traumatic brain injury.[39] Direct physical injury to the myocardium, as occurs following blunt chest injury, may produce contused cardiac muscle, which can lead to contractile dysfunction and decreased CO.

Right Heart Failure

One of the more difficult scenarios to diagnose and manage is dysfunction of the right ventricle (RV) following inferior wall myocardial infarction (MI). Although cardiogenic shock results from RV infarction infrequently, mortality from RV infarction is high (23%–53%).[40] In addition, patients with inferior MI have much higher rates of arrhythmias including atrial fibrillation, ventricular fibrillation and tachycardia, and second- or third-degree atrioventricular block.[41]

The pathophysiology of right heart failure can be explained in terms of end-diastolic pressure. Increased RV afterload (increased pulmonary resistance) decreases the ability of the RV to pump blood forward to the left heart, thus decreasing LV preload. Decreased LV preload results in decreased LVEDP. Increased blood volume in the RV eventually leads to RV dilatation and increases RV preload. Increased RV preload results in increased RVEDP. When RVEDP is greater than LVEDP, the ventricular septum bows from right to left during diastole, further decreasing LV filling volume and LVEDP. This clinical result is decreased CO and, ultimately, cardiogenic shock. In this setting, fluid resuscitation only further increases RVEDP and exacerbates the already decreased LV filling.[7] In critical illness, right heart failure is mainly due to excessive preload, excessive afterload, or insufficient myocardial contractility. These factors can cause increased pressure load or increased volume load on the right heart. For trauma patients, common causes of pressure overload are chronic left heart failure that worsens in the ICU or PE. Volume overload can be caused by excessive fluid resuscitation or right-sided valvular abnormalities. Both overload states can lead to ischemia, but the right heart tolerates pressure overload very poorly. Increased pressure impairs RV wall perfusion and exacerbates ischemia. Impaired contractility, either as a primary cause or physiologic sequela, further reduces CO.[7] Diagnosis requires a multimodality assessment to determine preload, afterload, and contractility. RV preload can be determined by volume status assessments, as described

previously; echocardiography; and clinical resuscitation details. Afterload can be assessed directly by elevated mean pulmonary artery pressure via PAC but is now more often inferred by using chest x-ray, computed tomography (CT) of the chest, and arterial blood gas to identify pathology that induces pulmonary hypoxia (eg, acute respiratory distress syndrome [ARDS]) or obstruction (eg, PE). Contractility can be directly measured using echocardiography, and signs of right heart strain or ischemia can be seen via electrocardiogram (ECG) and troponin. A 15-lead ECG may be necessary to confirm right-sided ischemia. Additional tests, such as ventilation/perfusion scan or abdominal ultrasound, are more often used in the outpatient setting. Once the diagnosis is made, treatment goals are to optimize right-sided filling pressures (preload), reduce right heart afterload, and augment contractility if needed.[42] Details are discussed later in "Management of Specific Cardiac Problems."

Pulmonary hypertension (PH) may develop after significant chest trauma, primarily due to blunt cardiac injury or severe pulmonary contusions and development of ARDS. With blunt cardiac injury, this is most often due to either an acute valvular or papillary disruption, formation of a ventricular septal defect,[43] or myocardial damage to the RV. With contusions/ARDS, the hypoxia-induced vasoconstriction increases RV afterload and can induce the metabolic sequelae leading to elevated pulmonary artery pressures. PH is technically diagnosed with right heart catheterization and mean pulmonary artery pressure of greater than 25 mm Hg at rest; however, formal catheterization is often not feasible in critically ill patients.[42] Therefore, physical examination findings (eg, new and worsening jugular venous distention, a new murmur, unexplained hypotension or hepatic failure, a new arrhythmia) in the proper traumatic setting should prompt further testing with echocardiography. In fact, as many as 27% of major chest trauma patients may have PH suggested on TTE.[44] Signs include a dilated RV and right atrium with normal or small LV, a D-shaped septum, and increased tricuspid regurgitant jet velocity on Doppler measurement (>2.9 m/s suggestive and >3.4 m/s likely).[45] Chest CT scan can help rule out underlying causes such as chronic PE or a preexisting lung pathology.[42] Treatment is based on treating the underlying cause and using the principles described later for management of PH and right heart failure.

Valvular Pathology and Left Heart Failure

Acute traumatic injury to a cardiac valve is rare and is discussed elsewhere (see Chapter 30). Knowledge of common valvular pathology and the impact on trauma resuscitation is important because valve abnormalities can significantly impact the response to fluids, vasopressors, and inotropes. Three of the more common valve disorders (aortic stenosis, mitral regurgitation, and tricuspid regurgitation) will be discussed in this section. In aortic stenosis, narrowing of the aortic valve most often leads to symptoms of left heart failure with patients complaining of dyspnea on exertion, angina, lightheadedness, or syncope. These patients have a fixed CO due to the limited aortic valve area and dilated LV. Thus, persistent and excessive fluid resuscitation or failure of diuresis during recovery may exacerbate the symptoms of aortic stenosis. Similarly, hypotension is poorly tolerated due to decreased LV compliance.[7] Induction of anesthesia or rapid sequence intubation should ensure adequate preload and hemodynamically neutral agents in order to avoid drops in blood pressure that can lead to cardiac arrest. Epidural catheters can similarly cause significant hemodynamic effects that must be anticipated if placement is necessary. Chronic mitral regurgitation may lead to decompensated LV failure. Often, due to left atrial enlargement, these patients suffer from atrial fibrillation or can readily go into atrial fibrillation if the atria are overstretched by volume resuscitation. As with aortic stenosis, responsible fluid management in these patients is necessary. Excessive fluid resuscitation may lead to the development of pulmonary edema and right heart failure. Acute mitral regurgitation can result from either acute MI or, rarely, blunt cardiac injury damaging the mitral valve.[46] Acute mitral regurgitation can lead to the rapid development of cardiogenic shock, pulmonary edema, and hemodynamic instability. Given the failure of the mitral valve, the pressures within the left atrium and ventricle will equalize, impairing ventricular filling. Treatment is generally emergent and includes afterload reduction for hemodynamic stabilization and surgical repair.[47] Tricuspid regurgitation is common and infrequently symptomatic in the general population but is the least common traumatic valvular injury.[48] Tricuspid regurgitation can lead to clinical signs of jugular venous distention and abdominal and ankle edema. Without judicious resuscitation, fluid overload will lead to right heart failure, which can impair CO with deficits in end-organ perfusion.

Unstable Arrhythmias

Critically ill patients are at high risk for developing arrhythmias, due to elevated catecholamines, fluctuations in intravascular volume, electrolyte disturbances, and inflammatory states, such as surgery and sepsis.[49] The development of an arrhythmia in the ICU is associated with increased mortality, with a recent study showing a 17% in-hospital mortality for patients without the development of an arrhythmia, 29% for those who developed a supraventricular arrhythmia, and 73% for those with a ventricular arrhythmia.[50] New onset of an arrhythmia in the ICU also leads to increased length of stay by up to 33%.[51] Identification of any arrhythmia should prompt an evaluation of electrolyte levels, assessment of the rhythm with an ECG, review of medications, and clinical exam for hypotension or signs of impaired perfusion (mental status changes). An echocardiogram may also be indicated if no recent exam exists or the arrhythmia is new. The management of arrhythmias follows the most recent Advanced Cardiac Life Support (ACLS) guidelines.[52]

The most common tachyarrhythmia in the critically ill patient is atrial fibrillation.[53] Given a 25% prevalence of atrial fibrillation in the community and an aging population,

either preexisting or new-onset atrial fibrillation may be seen in up to one-third of critically ill patients. Atrial fibrillation is thought to occur via an arrhythmogenic atrial substrate and an arrhythmogenic trigger that ultimately leads to atrial fibrosis and electrical remodeling. In critical illness, fibrosis and remodeling can be accelerated due to infection and/or inflammation. Risk factors for atrial fibrillation in the ICU include atrial stretch (volume overload), excessive adrenergic stimulation (vasopressors, infection, β-agonists, ventilator dyssynchrony), myocyte trauma/injury (ischemia, contusion), altered intracellular ions (electrolyte abnormalities), inflammation (surgery, sepsis), and increasing injury severity.[53] Thus, clinical assessment should include identifying and modifying risk factors where possible, including an evaluation as described earlier.

The treatment algorithm then depends on whether the patient is hemodynamically stable or unstable. For *hemodynamically stable* patients, medical cardioversion with rate control (calcium channel blockers, β-blockade, or digoxin) or rhythm control agents (magnesium or amiodarone) can be used.[53] In patients with *hemodynamically unstable* presentations, such as hypotension and mental status changes, emergent electrical cardioversion is indicated. While many recommend starting with 100 J, our practice is to proceed directly to 200 J with more immediate resolution of atrial fibrillation. In addition, we recommend premedicating the patient with intravenous midazolam (2–4 mg) to provide perievent amnesia; however, in postoperative patients requiring cardioversion, successful conversion to sinus rhythm occurred in 71%, and only 43% and 23% of patients remained in sinus rhythm at 1 and 2 hours after cardioversion, respectively.[54] Therefore, concurrent rate or rhythm control therapy should be considered to reduce the risk of recurrence.

Bradyarrhythmias in the critically ill patient can be life threatening. Most commonly, bradyarrhythmias are caused by elevated intracranial pressure, exaggerated vagal activity, hypothermia, electrolyte abnormalities, and medications (β-blockers, calcium channel blockers, clonidine, opioids, and dexmedetomidine).[55] Assessment, as described earlier, should be initiated. Management includes removing the offending agent, if possible. Otherwise, atropine or urgent transcutaneous pacing should be emergently organized if there is evidence of hypoperfusion.

Septic Myocardiopathy and Neurogenic Stunned Myocardium Syndrome

In the subacute phase of severe trauma, patients are subject to septic complications related to injury, surgery, or their ICU stay. In some patients with severe sepsis or septic shock, inflammatory cytokines can trigger a nitric oxide cascade and mitochondrial dysfunction that ultimately causes depressed cardiac contractility. This septic cardiomyopathy has three distinct features: LV dilatation (with normal or low filling pressures), depressed ejection fraction, and recovery in 7 to 10 days. Treatment is generally supportive by treating the underlying infection, using targeted volume resuscitation, and using vasopressor support when needed.[56]

Patients with traumatic brain injury and subarachnoid hemorrhage have a systemic catecholamine "storm" triggered by the central nervous system axis. The subsequent massive sympathetic outflow can cause a complex cascade of autonomic and inflammatory responses that can ultimately result in adverse cardiac effects. The neurogenic stunned myocardium syndrome (NSM) is a neurologically mediated cardiac injury characterized by ECG changes, arrhythmias, LV dysfunction, and elevated cardiac biomarkers. It is caused by excessive norepinephrine release from myocardial sympathetic nerve terminals, independent of circulating catecholamine levels. The severity of NSM and cardiac insult is related to the severity of the underlying brain injury. There is a spectrum of cardiac injury, from ECG changes to cardiogenic shock and pulmonary edema. NSM is more common after subarachnoid hemorrhage but should be on the differential diagnosis for traumatic brain injury patients showing signs of cardiac abnormalities with low suspicion of baseline coronary artery disease.[39]

ECG changes include ST-segment changes, flat or inverted T waves, U waves, and QTc prolongation and are most common the first few days after injury. Electrical changes generally do not follow a vascular ischemic territory. Arrhythmias, including sinus tachycardia, atrial fibrillation, premature atrial and ventricular contractions, and atrioventricular dissociation, often occur within the first week after injury. Most are benign, but careful attention to electrolyte levels and QTc-prolonging medications is important. Elevations of cardiac troponin I can be seen early after brain injury, and troponin I usually peaks below the level consistent with MI.[39] Ventricular dysfunction can be detected echocardiographically; includes impaired LV contractility, hypokinesia, and decreased ejection fraction; and often occurs within 3 days of brain injury. The key feature that differentiates NSM from a primary cardiac event is the pattern of regional wall motion abnormalities (RWMAs), which involve the basal and middle portions of the anteroseptal and anterior ventricular walls with apical sparing. The RWMAs follow the sympathetic nerves instead of the vascular territories and resolve spontaneously within days.[39]

Cytopathic Hypoxia

During the acute resuscitative phase of care, cardiovascular failure in trauma patients is the result of hemorrhage, and reversal of this failure occurs only with control of hemorrhage and transfusion of blood products. However, some patients remain in cardiovascular failure despite hemorrhage control and adequate blood product resuscitation. These patients often remain acidotic with large base deficits. The underlying derangement in this circumstance may be cytopathic hypoxia.[57,58] Although an infrequent cause of cardiovascular failure, it should be considered in the adequately resuscitated but hypotensive and acidotic patient. In fact, cytopathic hypoxia may manifest as profound vasoplegia

(see later in chapter) with potential etiologies being mitochondrial dysfunction, problems with nitric oxide metabolism, and alterations in hypoxia-induced pathways. Although no specific therapy is available, treatment must be systemic and target all cells (eg, methylene blue, ubiquitin, therapeutic hypothermia).

MANAGEMENT OF MYOCARDIAL DYSFUNCTION

As described previously, myocardial dysfunction should be managed based on optimizing preload, afterload, contractility, and heart rate. However, sometimes vasopressors, inotropes, and mechanical support are necessary to augment the failing heart until recovery or necessary interventions can occur.

Vasopressors

The use of vasopressors during acute resuscitation after severe injury should be avoided if possible because hemorrhage is the source of almost all shock in the immediate postinjury period (Table 58-3).

NOREPINEPHRINE

Norepinephrine is an endogenous sympathetic neurotransmitter with α- and β-adrenergic effects. α-Receptors are primarily in vascular smooth muscle, and activation leads to vasoconstriction. In cardiac myocytes, β_1-receptor stimulation leads to increased inotropy and chronotropy, whereas in vascular smooth muscle, β_2-receptor stimulation results in vasodilation. At high doses, α-adrenergic effects predominate, with less β_1 effects and even less β_2 effects. Thus, increased SVR and increased blood pressure result. Specifically, in the setting of RV failure, low-dose norepinephrine improves cardiac function without adversely affecting visceral perfusion.[59] Norepinephrine is typically the vasopressor of first choice during or after fluid resuscitation[5] and in the setting of sepsis.[9] In cardiogenic shock, norepinephrine, when compared to dopamine, is associated with decreased mortality and rates of arrhythmia.[60] The latter is likely due to lower β_1 effects than dopamine.[61] Norepinephrine is widely used in the care of the head-injured patient in shock because its vasoconstrictive effects do not extend to the cerebral vasculature, making it an ideal agent for maintaining cerebral perfusion pressure. However, norepinephrine's β effects can worsen hypoxic pulmonary vasoconstriction and thus should be spared in the patient with concomitant hypoxemia, respiratory failure, or PH.[62]

VASOPRESSIN

Vasopressin is a natural hormone produced by the posterior pituitary that acts as a potent vasoconstrictor, acting on V1 receptors in vascular smooth muscle.[61] Vasopressin is recommended as the second vasopressor during septic shock that is refractory to norepinephrine according to the Surviving Sepsis Campaign.[9] When vasopressin is combined with norepinephrine, outcomes in the treatment of catecholamine-resistant cardiovascular failure in septic shock are superior to therapy with norepinephrine alone. In the postoperative cardiotomy patient, vasopressin significantly reduces the need for both pressor and inotropic support and the development of arrhythmias.[63]

Vasopressin also has pulmonary vasodilatory properties, likely mediated via a nitric oxide pathway. The clinical effects are thought to be a reduced pulmonary vascular resistance (PVR)/SVR ratio. In contrast, norepinephrine has been found to increase the PVR/SVR ratio. Thus, vasopressin should be considered early in patients with hypotension and significant hypoxia or pulmonary hypotension.[62]

PHENYLEPHRINE

Phenylephrine is a pure α-agonist and has no β activity. Phenylephrine is often administered in the bolus form for acute hypotension but may also be infused in patients with hypotension and serious arrhythmias that may be triggered

TABLE 58-3: Dosage, Mechanism, and Actions of Pharmacologic Agents Commonly Used in the Treatment of Cardiovascular Failure

Agent	Typical dosage	HR	MAP	CO	SVR	α_+	β_1	β_2
Vasopressors								
Norepinephrine	0.5–30 mcg/min	+	++	+	++	++	+	
Vasopressin	0.04 U/min		++	–	++			
Phenylephrine	0.5–1 mcg/kg/min		++		++	++		
Inotropes								
Dobutamine	2–20 mcg/kg/min	+	±	++	–		++	+
Epinephrine	0.5–10 mcg/min	++	++	+	++	++	++	++
Milrinone	0.125–0.75 mcg/kg/min			+++	–			
Dopamine	3–5 mcg/kg/min	+	+	++			++	
	10–20 mcg/kg/min	++	++	+	+++	++	+	

CO, cardiac output; HR, heart rate; MAP, mean arterial blood pressure; SVR, systemic vascular resistance.

by other vasopressors with β activity.[57] It is also favored to correct hypotension in patients with aortic stenosis, hypertrophic obstructive cardiomyopathy, or vagally mediated reactions.[61] Phenylephrine has a duration of action of up to 20 minutes, making it a useful agent for periprocedural hypotension.[64] At high doses, phenylephrine administration may lead to reflex bradycardia[65] and visceral hypoperfusion.

METHYLENE BLUE FOR PROFOUND VASOPLEGIA

Profound vasoplegia occurs when hypotension and inadequate end-organ perfusion persist despite adequate fluid resuscitation, high CO, and the use of multiple vasopressors.[66] The exact physiologic mechanism of profound vasoplegia is poorly understood but is most commonly encountered in cardiac surgery patients, especially those who have required cardiopulmonary bypass. Mortality rates, wound infections, days on mechanical ventilation, and lengths of stay are all increased in cardiac patients who have profound vasoplegia.[30] Profound vasoplegia may occur in the trauma and postoperative surgical patient as well. Unfortunately, additional treatment modalities for profound vasoplegia are limited. Methylene blue has been used with some success to help to reverse profound vasoplegia. Methylene blue inhibits nitric oxide–mediated vasodilation and can be administered as a slow infusion (2 mg/kg over 20 minutes) for this purpose. Outside of cardiac surgery, methylene blue has been used to reverse vasoplegia in burn patients,[67] following liver transplant,[68] and for septic shock.[69] It is also first-line treatment for symptomatic methemoglobinemia, or methemoglobin levels greater than 20%. Although it should not be considered standard of care, methylene blue may be used in a trauma patient with profound shock unresponsive to fluids or vasopressors as a last resort.

Inotropes

EPINEPHRINE

Epinephrine is an endogenous catecholamine with significant α- and β-adrenergic activity on cardiac and vascular smooth muscle. At high doses, epinephrine has more α-adrenergic effect, causing intense vasoconstriction. At low doses, it exerts primarily β-adrenergic effects, increasing contractility and reducing SVR. Despite this, there is little evidence that epinephrine is superior to dobutamine in the treatment of low-output states. However, it is the first-line agent when managing cardiac arrest, as it rapidly increases diastolic blood pressure to help resume organized myocardial contraction.[61] In patients with septic shock who have been adequately fluid resuscitated, epinephrine increases heart rate and stroke volume (and therefore CO) and systemic oxygen delivery without altering vascular tone. Care must be taken when using epinephrine because renal vasoconstriction, cardiac arrhythmias, reduced splanchnic blood flow,[59] and increased myocardial oxygen consumption and demand may result.[70] Additionally, metabolic abnormalities are common, including dyskalemias, hyperglycemia, and ketoacidosis.[71]

DOBUTAMINE

Dobutamine is a synthetic catecholamine with primarily β-adrenergic effects, although it does possess some α_1-adrenergic properties. Its predominant β_1 effects make it a strong inotrope, increasing contractility, with weaker chronotropic effects. Dobutamine also has β_2-adrenoreceptor activity, producing peripheral vasodilatation. This combination of increased contractility and reduced afterload results in improved CO. However, the increase in CO occurs with an increase in myocardial oxygen consumption (as seen with its exercise-mimicking effects). Thus, dobutamine utility may be limited in settings of cardiac ischemia, and malignant arrhythmias can occur at any dose.[61] Because of the vasodilatory effects, dobutamine is ideally suited for use in low-output cardiac states. For these reasons, dobutamine should be considered the first-choice inotrope for patients with low CO once adequate preload has been confirmed.[9] Its short half-life also makes it easily titratable. In addition, dobutamine may be added in the setting of septic shock if cardiac dysfunction is considered to be a contributor to the shock state.

MILRINONE

Milrinone selectively inhibits phosphodiesterase-3, which leads to increased cyclic adenosine monophosphate (cAMP) and increased calcium intracellularly to promote more efficient contractility. Overall, milrinone administration leads to pulmonary and systemic vasodilation with increased inotropy. The pulmonary vasodilation effects make it a useful agent in PH or high RV afterload states. Milrinone is also used more frequently in the patient with well-established cardiac failure because the half-life is long (2.5 hours) and it is not a rapidly titratable medication, unlike dobutamine or epinephrine. As with dobutamine, hypotension may result from either bolus or excessive milrinone use, especially in patients who are hypovolemic. Although there is increased risk of arrhythmia with milrinone, it is slightly less intense than with dobutamine due to less significant chronotropic effects.[61]

DOPAMINE

Dopamine is an endogenous catecholamine that has several cardiovascular effects, including increased heart rate, increased contractility, and peripheral vasoconstriction. It has historically been used primarily for inotropic support, although it is no longer a first-line (or second-line) agent. Dopamine acts on α- and β-adrenoreceptors as well as DA1 and DA2 dopamine receptors, and its actions can be classified based on dose. At doses of 1 to 3 mcg/kg/min, dopamine acts at primarily DA1 receptors in renal, mesenteric, coronary, and cerebral vascular beds, resulting in vasodilation. At moderate doses (3–5 mcg/kg/min), dopamine stimulates primarily cardiac β-adrenoreceptor, increasing contractility and thus CO. At higher doses of dopamine (10 mcg/kg/min), peripheral vasoconstrictive effects from stimulation of α-adrenergic receptors predominate. This can result in significant coronary vasoconstriction resulting in angina, vasospasm, and increased PAWP. Additionally, increasing afterload from

vasoconstriction coupled with an increased heart rate seen at this dose result in increased myocardial oxygen consumption and demand. Individual variation in the pharmacokinetics of dopamine due to weight-based dosing typically results in poor correlation between blood levels and administered dose. Tachycardia can occur with any dose of dopamine, particularly in the hypovolemic patient. Due to the variable effects of dopamine, the dosage ranges used to define which receptors it affects are to be used as broad guidelines only, with the awareness that low-dose dopamine may have the unwanted effects of medium- or high-dose dopamine on an individual patient. Low-dose dopamine is no longer used for renal protection.[72]

DIGOXIN

Digoxin is a cardiac glycoside that is traditionally used as an oral agent in the outpatient setting. However, it can have several uses in the critically ill patient. In myocardial cells, digoxin binds to the α-subunit of Na/K-ATPase and inhibits the Na/K pump, ultimately increasing intracellular calcium and contractility. Thus, it can work as an inotrope to improve cardiac contractility in the patient with systolic heart failure. It is in this setting that our group has found digoxin to be most useful in weaning other cardiovascular therapeutics and chemical agents. Digoxin also increases vagal tone and thus can be used to decrease ventricular rates in patients with supraventricular tachycardias, including atrial fibrillation. While other agents are more commonly used to manage atrial fibrillation in the critical care setting, digoxin should be considered if patients have contraindications to other agents or have refractory atrial fibrillation. Note that digoxin is contraindicated in the atrial fibrillation secondary to Wolf-Parkinson-White syndrome or in hypertrophic cardiomyopathies. Due to risk of toxicity and a narrow therapeutic window, digoxin levels should be monitored closely in the critically ill, and dosing adjustments should be considered in the setting of geriatric patients or those with renal insufficiency.[61]

Mechanical

INTRA-AORTIC BALLOON PUMP COUNTERPULSATION AND MECHANICAL SUPPORT

Until recently, when myocardial failure had an underlying, surgically correctable, anatomic cause and pharmacologic methods were ineffective in augmenting CO, the use of intra-aortic balloon counterpulsation (IABP) was quite common.[73] However, recent studies, including the IABP-SHOCK II trial, showed no benefit in mortality for IABP use in patients in cardiogenic shock.[74] The 2013 American College of Cardiology Foundation and American Heart Association guidelines on post–ST-segment elevation myocardial infarction (STEMI) care downgraded the recommendation for use of IABP.[75] However, there are still some cases where this type of mechanical support is used, and surgeons managing these patients should be familiar with its use and function. IABP involves placement of a balloon catheter into the proximal descending aorta (distal to the origin of the left subclavian artery) via the femoral artery. The balloon catheter is connected to a pumping device that, in synchrony with the ECG, inflates the balloon during cardiac diastole and deflates it during systole. By filling during diastole, the balloon displaces approximately 40 mL of blood retrograde into the coronary arterial circulation and antegrade into the descending aorta. The balloon is abruptly deflated at the beginning of systole, decreasing LV afterload and facilitating the LV to eject its stroke volume. These dual functions of augmenting coronary arterial flow while decreasing afterload thereby reduce myocardial oxygen consumption and increase systemic blood pressure. Use of IABP is considered a bridge until there is myocardial recovery or a different type of treatment can be obtained. It also requires anticoagulation to prevent clot burden on the balloon.[76]

Other methods of providing direct inotropic support to the acutely failing heart include the Impella and Tandem Heart devices. These devices are inserted percutaneously and deposited into the left heart to provide circulatory support for a failing LV.[77] Like the IABP, both of these devices are used to bridge the patient until more appropriate, longer-term therapy is available and require systemic anticoagulation, which may limit use in the trauma patient.

EXTRACORPOREAL MEMBRANE OXYGENATION

ECMO can provide temporary respiratory support (venovenous [V-V]) or cardiorespiratory support (venoarterial [V-A]) as the last step in resuscitation.[78] Essentially, ECMO can provide the necessary blood flow to maintain oxygen delivery to the brain and end organs (eg, large RV infarct) while also oxygenating and removing carbon dioxide from the blood if the lungs are unable to adequately do so (eg, severe ARDS). Traditionally, ECMO is run with an anticoagulant as the ECMO circuit is thrombogenic and common complications of ECMO are intracranial, surgical, gastrointestinal, or pulmonary bleeding.[46] Given the need for anticoagulation, the use of ECMO in trauma patients who often have injuries that prevent anticoagulation has been limited. However, with newer circuits that have anticoagulant coatings, recent reports have shown that ECMO with or without anticoagulation[47] can safely and successfully be performed in trauma patients.[79,80] With this in mind, though, the use of ECMO in trauma patients should be reserved for centers well experienced in the delivery of ECMO.

OPTIMAL END POINTS OF RESUSCITATION

Mixed Venous Oxygen Saturation

Mixed venous oxygen saturation (Svo_2) is a measurement of the oxygen saturation in the venous return to the heart. It is an indirect measurement of oxygen utilization by the end

organs, as the Svo_2 reflects the amount of oxygen "left over" after tissue extraction. A true Svo_2 is taken from the distal tip of a PAC. This reflects oxygen utilization from the upper body (superior vena cava), lower body (IVC), and the coronary veins (coronary sinus). It becomes "mixed" by the time it reaches the pulmonary artery and thus reflects global oxygen consumption. Normal values are approximately 65% to 80% and are calculated by using a derivation of the Fick equation to determine the difference between measured oxygen delivery and calculated oxygen consumption. Central venous oxygen saturation measurements ($Scvo_2$) are obtained from internal jugular or subclavian central catheters. $Scvo_2$ reflects oxygenation from the head and upper limbs; thus, normal values are slightly higher than mixed venous oxygenation (>70%).[81]

Determinants of Mixed Venous Oxygen Consumption

Variables determining mixed venous oxygen consumption

$$VO_2 = CO \times Hb \times (Sao_2 - Svo_2)$$

VO_2 = oxygen consumption
CO = cardiac output
Hb = hemoglobin
Sao_2 = oxygen saturation
Svo_2 = mixed venous oxygen saturation

As expected by the equation, changes in the above variables may increase or decrease Svo_2.

High Svo_2 can occur with:

- Increased oxygen delivery (increased Fio_2, hyperoxia, hyperbaric oxygen)
- Decreased oxygen demand (hypothermia, anesthesia, paralytic)
- High-flow states (sepsis, hyperthyroidism, severe liver disease)

Low Svo_2 can occur with:

- Decreased oxygen delivery
  - Decreased hemoglobin (anemia, hemorrhage, dilution)
  - Decreased oxygen saturation (hypoxemia)
  - Decreased flow (shock, arrhythmia)
- Increased oxygen demand (hyperthermia, shivering, pain, seizure)

However, Svo_2 can be falsely high despite end-organ hypoxia. In the trauma ICU, this can occur acutely with burn patients subjected to cyanide poisoning or subacutely with sepsis and significant microvascular shunting. Even though the cell may have inadequate perfusion, the inability to use oxygen can result in a normal or elevated Svo_2.[81]

Lactate and Base Deficit

Elevated serum lactate, or lactic acidosis, can be an indicator of cellular hypoxia or shock. When cells can no longer function normally due to hypoxia or decreased blood flow, the normal mechanism of ATP generation by aerobic metabolism is shifted to anaerobic metabolism. This inefficient method of ATP production yields increased amounts of pyruvate, which is converted to lactate. Therefore, increased levels of lactate may be a reflection of ongoing tissue hypoxia. The use of serum lactate measurements as a guide to resuscitation is limited due to the time necessary for laboratory results to return if point-of-care tests are not available. However, in critically ill patients past the acute resuscitation phase of treatment, serum lactate levels may be useful in determining the onset of organ dysfunction.[82] In clinical practice, multiple other factors may also affect lactate levels. Following severe injury, increased circulating epinephrine may cause an increase in lactate production by aerobic glycolysis in response to increased activity of the Na^+/K^{1+}-ATPase, despite adequate tissue perfusion.[83] Hepatic dysfunction may increase serum lactate levels due to inability of the liver to metabolize lactate to carbon dioxide. Seizures, such as after traumatic brain injury, may cause an acute elevation in lactate that then clears quickly. An undiagnosed bowel injury or ischemia may also cloud the picture in the setting of a rising or persistently elevated lactate.

The base deficit is the difference between the standard value of 24 mEq/L and the serum bicarbonate level. This value is typically negative in hypovolemic shock, and therefore, the term *base deficit* is widely used. The magnitude of the base deficit has been used to quantify the magnitude of acidosis, with mild acidosis having a base deficit of –3 to –5 mEq/L; moderate acidosis, –6 to –10 mEq/L; and severe acidosis, less than 10 mEq/L. As the magnitude of the base deficit increases, the resuscitation volumes of both blood and fluid increase, as does mortality.[82] Patients who are able to clear their base deficits in less than 48 hours have decreased mortality when compared to patients whose base deficits persist beyond this time frame. Persistent base deficits despite normal vital signs may be a signal of compensated shock requiring further resuscitation. If left untreated, it may lead to multiorgan dysfunction and increased morbidity and mortality. New-onset lactic acidosis and increasing base deficit in the critically ill patient may be early signs of a low-flow state, cellular hypoxia, and/or end-organ injury; therefore, every effort should be made to find the cause and address it as quickly as possible.

Capnography

Defined as the measurement of carbon dioxide (CO_2), capnography is most commonly used during endotracheal intubation to ensure proper placement of the endotracheal tube. Other studies have reported its use to predict prognosis following cardiopulmonary arrest, to assess resuscitation efforts, to detect alveolar dead space changes, and to monitor sedation and paralytic therapy.[81,82] Under normal conditions, exhaled CO_2 closely correlates with arterial blood CO_2 levels. Due to unmatched areas of ventilation and perfusion in the lungs, the arterial $Paco_2$ will usually be slightly higher than the exhaled CO_2.

End-tidal CO_2 ($EtCO_2$) has been shown to predict resuscitation efforts during cardiopulmonary arrest.[82] Higher $EtCO_2$ levels correlate with increased survival after cardiac arrest. Original research found that nonsurvivors with prehospital arrests after 20 minutes of ACLS were found to have an average $EtCO_2$ of 3.9 mm Hg, whereas survivors had $EtCO_2$ values of 31 mm Hg.[84] An $EtCO_2$ value of 10 mm Hg has been determined to provide a 100% sensitivity to predict return of spontaneous circulation (ROSC).[85] However, subsequent guidelines have advocated thresholds of 10 to 20 mm Hg to improve delivery of chest compressions. A more recent meta-analysis found that an $EtCO_2$ of 25 mm Hg better predicted ROSC and that further research is needed to optimize $EtCO_2$ targets and improve outcomes following ROSC after cardiorespiratory arrest.[86]

MANAGEMENT OF SPECIFIC CARDIAC PROBLEMS

Management of Acute Heart Failure

The shock state precludes vasodilation; however, in acute heart failure without shock, afterload reduction with vasodilators may be advantageous to global perfusion while a rapid reduction in preload should help with a heart that cannot handle whole-body fluid demands. The most commonly used intravenous agents in the critically ill include nitroprusside and nitroglycerin.[2]

Nitroprusside acts primarily on arteriolar smooth muscle, reducing afterload. The onset of action of nitroprusside is rapid, and its effects cease within minutes once the infusion is discontinued. When titrating the dose of nitroprusside, SVR should be decreased with a concomitant increase in CO, thereby maintaining a relatively constant systemic arterial pressure. Although the effects of nitroprusside favor arterial dilatation, it does have mild venous dilatory effects that can lead to an increase in venous capacitance and decreased preload. Care must be taken when using nitroprusside because cyanide toxicity is a known side effect. This is generally seen with infusion rates in excess of 10 mcg/kg/min, with prolonged therapy (several days), or in the setting of renal or hepatic dysfunction. Treatment is with sodium nitrite and is aimed at providing an alternate substrate for the cyanide ion. Sodium nitrite also converts hemoglobin to methemoglobin, producing a ferric ion that competes with the ferric ion in the cytochrome system for the cyanide ion. Methylene blue can be administered to treat the methemoglobinemia that results from sodium nitrite treatment.[87]

Nitroglycerin, a potent arteriolar and venous smooth muscle dilator, is a useful agent when both preload and afterload are elevated. The cardiovascular effects are dose dependent, with low doses (5–20 mcg/min) primarily increasing venous capacitance and higher doses (>20 mcg/min) relaxing arterial tone. Side effects are generally the result of an overly rapid reduction in venous or arterial tone and are readily reversed by cessation of the medication.[2,88]

Management of Acute-on-Chronic Heart Failure

As our population ages, the number of elderly patients in the ICU will increase. In fact, the number of elderly patients (>65 years old) is expected to double in the next three decades. With an aging population, there are age-related changes in physiology, exacerbations of chronic illnesses, and effects of therapeutic drugs, which need to be taken into consideration when caring for the traumatically injured patient. Often, these patients will present with chronic CHF. Acute-on-chronic heart failure in the geriatric patient, which may develop in the posttrauma period, needs to be considered in the setting of low urine output despite fluid resuscitation or worsening pulmonary edema. In this case, fluid status and medication administration need to address both the traumatic injury and heart failure. This is a difficult balancing act that requires a combination of the cardiac monitoring and multiple volume status assessments, as previously discussed in this chapter. In addition, the 2017 American College of Cardiology (ACC)/American Heart Association (AHA) guidelines for heart failure recommend obtaining admission levels of B-type natriuretic peptide (BNP) or N-terminal pro-BNP (NT-pro-BNP) to assist in prognostication of acutely decompensated heart failure. Higher admission levels of natriuretic peptide are associated with greater risk for morbidity and mortality (all-cause and cardiovascular).[89]

From a chronic heart failure perspective, many patients will present on an angiotensin-converting enzyme inhibitor (ACE-I), angiotensin receptor blocker (ARB), or angiotensin receptor–neprilysin inhibitor (ARNI). However, these agents can be nephrotoxic and should be held in the setting of acute kidney injury, which is common in critically ill patients. A second-line approach that can be used in the patient with heart failure but without shock is hydralazine and nitrates (isosorbide dinitrate).[89] In addition, these patients often present on diuretics, including mineralocorticoid antagonists. For the trauma patient immediately post hemorrhagic shock, diuresis is counterintuitive (and potentially dangerous), and risk of hyperkalemia with acute kidney injury is a real concern. Thus, frequent assessments of volume status and consideration for early, goal-directed diuresis must be part of the clinical care plan, with resumption of heart failure medications as soon as appropriate.

Management of Diastolic Dysfunction

The syndrome of CHF typically brings to mind an enlarged heart and decreased systolic function; however, systolic function is normal, or near-normal, in nearly 50% of patients diagnosed with CHF. The presence of other clinical manifestations of CHF, such as orthopnea, dyspnea, increased jugular venous pressure, and abnormal heart sounds on auscultation, leads to the diagnosis of diastolic dysfunction (DD). DD is one of the underlying causes of heart failure with preserved ejection fraction (HFpEF). DD is associated with hypertension, diabetes mellitus, female gender, coronary artery

disease, and chronic atrial fibrillation. Aging itself has been associated with reductions in elastic properties of the great vessels, decreased ventricular filling, diminished relaxation and compliance, and decreased β-adrenergic receptor density. The diagnosis of DD or HFpEF is generally made clinically and is often one of exclusion. Objective testing should include echocardiography or cardiac catheterization. Because the normal ejection fraction is not a standardized number and given that systolic dysfunction often accompanies DD, the diagnosis of DD is often not clear-cut. Therefore, the diagnostic "gold standard" for DD is cardiac catheterization demonstrating increased ventricular diastolic pressure with normal systolic function and volumes. Echocardiography, being noninvasive and practical, can be used to exclude systolic dysfunction. The majority of clinical studies have been geared toward management of systolic dysfunction, with a relative paucity of information regarding the specific management of DD.[90]

In general, the treatment principles for patients diagnosed with DD include antihypertensive therapy, reduction of volume overload, decreasing heart rate, maintenance of sinus rhythm, and the reduction of ischemia. With hypertension being the primary predisposing factor for CHF, neurohormonal regulation has been shown to play a role in CHF and DD. The renin–angiotensin system influences CHF indirectly by causing hypertension and LV hypertrophy (LVH) and directly by both angiotensin II and endothelin contributing to LVH and impaired myocardial relaxation. Blockade of the renin–angiotensin system improves diastolic distensibility in both human and animal studies. Volume overload can be reduced with diuretics or renal replacement therapy in patients with renal failure. In DD, the use of β-adrenergic blockade or calcium channel blockade to reduce heart rate and increase LV filling time reduces mortality. Digoxin decreases hospitalization of patients with CHF with and without systolic dysfunction; however, because digoxin is a negative chronotrope, the benefit may be due to the rate-lowering effect of the drug rather than to its other hemodynamic properties. Although ACE-I therapy is beneficial in patients with hypertensive disease and in patients with mixed systolic and diastolic dysfunction, there is no direct evidence that ACE-Is reduce mortality or morbidity in patients with DD.[90] However, hypertension control is important for treatment; thus, use of β-blockers, ACE-Is, and ARBs are part of the ACC/AHA 2017 guidelines for management of HFpEF.[89] If a patient has both DD and rate-altering arrhythmias, such as atrial flutter or atrial fibrillation, rate control will lead to increased filling times once normal sinus rhythm is restored. Myocardial ischemia can also contribute to DD; thus, patients with drug-resistant ischemic DD may benefit from percutaneous coronary intervention (PCI) or coronary artery bypass grafting. Aldosterone has also been shown to contribute to CHF with detrimental effects on endothelial function as well as inducing a vasculopathy. The latest guidelines suggest that patients with ejection fraction greater than 45%, elevated BNP levels on admission, and adequate renal function be considered for aldosterone receptor antagonists in order to reduce hospitalizations.[89]

Management of Right Heart Failure and Pulmonary Hypertension

As described earlier, right heart dysfunction may progress from underlying pathology or acquired injury in the setting of trauma and critical illness. Management is based on targeting areas of dysfunction with respect to preload, afterload, and contractility.

OPTIMIZING RV PRELOAD

The right heart needs to be full enough, but not too full as to impair LV filling (as described earlier). Judicious fluid resuscitation and objective measures of volume status to assess ventricular filling are advised. Ventilator PEEP can also drop venous return and reduce RVEDP and may need to be reduced. If the heart is overfull, aggressive diuresis or CRRT may be required to remove adequate volume.[7]

OPTIMIZING RV AFTERLOAD

Reversing conditions that increase pulmonary vascular tone can improve RV output. Alveolar hypoxia, hypercapnia, and acidemia should be normalized. Limit vasopressors with pulmonary vasoconstriction (eg, norepinephrine). Add selective pulmonary vasodilators, such as inhaled nitric oxide. Treat underlying lung pathology, such as appropriate antibiotics for pneumonia or anticoagulation for PE. Of note, empiric anticoagulation is no longer first-line management for PH in the absence of PE.[91]

OPTIMIZING RV CONTRACTILITY

Overstretched myocytes are at a mechanical disadvantage, deranged myocardial metabolism can decrease myocardial contractile force, and impaired coronary perfusion impairs myocyte oxygen delivery, especially during the increased demand of critical illness. It is important to keep systemic arterial pressure close to, but greater than, RV systolic pressure in order to maintain RV perfusion. Adequate RV coronary perfusion requires systemic pressures greater than the RV free wall tension. If vasopressors are required to support adequate systemic pressure, an agent with minimal pulmonary vasoconstricting properties, such as vasopressin, is preferred. The RV is dependent on atrial kick because it generally cannot change its stroke volume. Thus, maintaining sinus rhythm at a rate of at least 80 bpm is key for RV contractility. Cardioversion may be required if sequential pacing is not in place to ensure sinus rhythm. If all the above interventions fail to improve RV contractility, inotropes, such as milrinone or dobutamine, can then be added. The increased contractility and chronotropy can be arrhythmogenic and/or worsen myocyte metabolism and ischemia (especially with dobutamine), and thus, inotropes should be used judiciously. Epinephrine will obviously also increase contractility and heart rate but significantly increases cardiac work and is more recommended in the setting of shock and bradycardia with right heart failure. The final method to treat ongoing cardiogenic shock from right heart failure that fails to respond to

these interventions is mechanical support with venoarterial ECMO.[7]

More advanced therapies also exist in the treatment of PH. Phosphodiesterase type 5 inhibitors, such as sildenafil, prolong the vasodilatory effect of nitric oxide and can be helpful in the treatment of PAH. The typical dose of sildenafil used for treatment of PH is 20 mg orally (or 10 mg intravenously) three times daily. Its onset of action is rapid, with effects seen within 1 hour; the half-life is approximately 3 to 4 hours. In stable patients, when it is used alone or in combination with inhaled nitric oxide, the CO will increase. It is contraindicated in patients receiving systemic nitrates because of the potential for severe hypotension, and its use should be closely monitored in patients with liver dysfunction (since it undergoes hepatic metabolism). Although use of calcium channel blockers in the management of chronic PH is effective for control of heart rate, there are no studies of their use in the critically ill patient with PH. Because of their negative inotropic effects, they may precipitate fatal worsening of RV failure. Other therapies, used in isolation or combination, include endothelin receptor antagonists (eg, bosentan), prostanoids (eg, epoprostenol), and guanylate cyclase stimulants. Initiation of these agents should follow diagnosis of a clear underlying etiology of PH, and they should be initiated in concert with a heart failure team.[91]

Perioperative Risk

Patients at high risk for cardiac events during noncardiac surgery have increased mortality from perioperative arrhythmias and MI. Cardiac death or MI occurs in 1% to 5% of unselected patients undergoing noncardiac surgery and is the most common reason for a preoperative cardiac evaluation. The pathophysiology of MI in the perioperative setting differs from that seen in nonsurgical patients. In the latter, MI usually follows rupture of atherosclerotic plaques in the coronary arteries, leading to platelet aggregation and thrombus formation. MI in the perioperative setting is due to plaque rupture approximately 50% of the time; the remainder of MIs are triggered by myocardial ischemia from decreased myocardial oxygen supply and increased demand in the presence of atherosclerotic coronary artery disease. These demands are often exacerbated by anemia, hypotension, hypoxia, hypertension, and tachycardia. Perioperative shifts in intravascular volume, withdrawal of anesthesia, and postoperative pain are all factors that may contribute to the increased demand of oxygen in the perioperative setting. Postoperative tachycardia, arrhythmias, and MI most commonly occur 3 days after an operation, when fluid shifts are at their greatest.

Until recently, reducing cardiac events has centered on preoperative risk assessment with clinical recommendations and often cancellation or postponement of procedures. Perioperative ischemia has been linked to postoperative MI with a 21-fold increase in risk and, thus, has been a target of medical strategies. Mixed results have been obtained in studies using intraoperative calcium channel blockers and nitroglycerin. However, strong evidence has accumulated regarding β-blockers. Two randomized controlled trials (RCTs) have shown that β-blocker therapy reduces perioperative cardiac complications. Mangano et al[92] performed a randomized, double-blinded, placebo-controlled trial using atenolol in 200 patients with known coronary artery disease and/or risk factors for atherosclerosis who underwent noncardiac surgery. Although acute perioperative mortality did not differ between the two groups at 6 months, eight deaths occurred in the placebo group and none in the atenolol group (P <.001), with the difference being sustained at the 2-year follow-up period.[92] In a landmark 1999 study, patients with clinical risk factors and ischemia demonstrated by dobutamine stress echocardiography who were to undergo major vascular procedures were randomly assigned to bisoprolol or placebo.[93] The study was terminated early when investigators noted that bisoprolol markedly reduced perioperative mortality (17% vs 3.4%; P = .02) and MI (17% vs 0%; P <.001). A 2002 meta-analysis of RCTs concluded that β-blockade may be beneficial in preventing perioperative cardiac morbidity despite the heterogeneity of the trials.[94] Subsequent studies have shown that withdrawal of β-blockers increases the risk of morbidity and mortality and that initiation of β-blockers in the preoperative setting requires titration to blood pressure and heart rate control. Although perioperative β-blockade has been demonstrated to decrease perioperative cardiac morbidity, there also is an increased risk of stroke, bradycardia, hypotension, and (potentially) all causes of death. Furthermore, perioperative metoprolol has been demonstrated in multiple studies to have worse outcomes than those associated with more selective agents, such as bisoprolol or atenolol.[95] Therefore, the 2014 ACC/AHA recommendations are aimed at continuation of β-blocker therapy in the perioperative period for those patients already taking a β-blocker. The initiation of selective β-blockade should be strongly considered in patients who are undergoing high-risk surgery and have a history of coronary artery disease or evidence on stress test of reversible ischemia.[96]

Current Treatment of Acute Myocardial Infarction

The definition of acute MI encompasses a spectrum of clinical entities ranging from non-STEMI (also known as acute coronary syndrome [ACS] or unstable angina) to acute STEMI. The pathophysiology for ACS differs from that of STEMI, as does the treatment. Whereas ACS in nonsurgical patients is commonly due to a partial occlusion of the coronary arteries or transient ischemia (due to plaque rupture with platelet aggregation), in the surgical patient, ACS is more commonly secondary to decreased oxygen supply or increased demand due to anemia, tachycardia, intravascular fluid shifts, hypotension, or arrhythmias. Acute STEMI refers to complete occlusion of the coronary arteries with myocardial injury.[96]

During workup of suspected MI, the interpretation of elevated troponins can be confounded by a variety of factors, including recent chest trauma, chest compressions, and/or demand ischemia, all of which can cause mild elevations in

troponin levels. Significant troponin elevations in the presence of ECG changes should prompt evaluation by a cardiologist. Mild troponin elevation in the absence of ECG changes, especially in the presence of suspected demand ischemia, should be trended with levels checked every 6 hours.[96] However, keep in mind that troponin clearance will be prolonged in patients with renal insufficiency.

Despite marked advances in diagnosis and treatment, there is still an approximately 6.3% in-hospital mortality associated with acute MI. Reduced mortality has been shown to result from adherence to three basic tenets of treatment for acute MI: (1) prompt diagnosis, (2) immediate aspirin and oxygen therapy, and (3) rapid restitution of blood flow to the infarcted myocardium. Whereas prompt diagnosis and institution of aspirin and oxygen therapy are relatively straightforward, the reestablishment of blood flow to the affected myocardium has evolved into two primary therapies: pharmacologic therapy with thrombolytic agents and interventional therapy with PCI.[97] With its ease of administration, early studies on the use of thrombolytic therapy consistently showed decreased mortality and improved myocardial performance compared with placebo; however, thrombolytic therapy has well-documented limitations and contraindications.[98] Intracranial bleeding resulting in death or stroke occurs in 0.6% to 1.4% of patients who receive thrombolytic therapy. Thrombolytic therapy is also associated with a reocclusion rate of 30%, resulting in reinfarction of the affected area within 3 months.[98] In the multiply-injured patient with an increased risk of bleeding, head injury, or multivessel disease, thrombolytic therapy is contraindicated.

PCI has been shown to result in better clinical outcomes when compared to thrombolysis.[99] In addition to improved outcomes, PCI offers direct visualization of the affected anatomy and also provides specific hemodynamic and functional data that can be used to guide further therapy. It can also quickly identify patients who should not undergo reperfusion therapy, which include patients with minimal residual stenosis, spontaneous reperfusion, coronary vasospasm, myocarditis, and aortic dissection involving the ostia.[100] The 2015 ACC Foundation/AHA updated guideline for the management of STEMI still recommends PCI for any patient with an acute STEMI, provided that the procedure can be performed in a timely fashion; this is defined as within 90 minutes at a PCI-capable hospital or within 120 minutes for patients transferred from a non–PCI-capable hospital to a PCI-capable hospital.[96] Unfortunately, PCI is not available in all medical centers, and there is wide variability in the use of PCI even in those centers that are PCI capable.[101] Complications from PCI include major bleeding (7%), vascular complications that require surgical repair (2%), and renal failure (13%). The incidence of renal failure rises with increasing age, volume of contrast material, decreased baseline renal function, and hypovolemia. When comparing thrombolytic therapy to PCI, primary PCI had been found to be more effective in reducing both short- and long-term outcomes, including death. The use of platelet glycoprotein (GP) IIb/IIIa inhibitors (eg, abciximab) or platelet adenosine diphosphate chemoreceptor inhibitors (eg, clopidogrel bisulfate) at the time of PCI reduces the rates of subacute thrombosis and recurrent ischemia and the need for repeat revascularization procedures during the first month after PCI with or without stents. However, clinical outcomes do not differ at 6-month follow-up. Despite the heterogeneity of these trials, including whether or not stents were used and the use of platelet inhibitors versus the various thrombolytic agents, the accumulated data appear to favor primary PCI in the treatment of acute STEMI.[96] The addition of platelet inhibitors should be based on clinical judgment in the multiply-injured trauma patient with ACS. A recent meta-analysis compared immediate versus delayed stent placement after STEMI. Although "delayed" varied from hours to 7 days, outcomes were similar for major cardiac events, bleeding, and target vessel revascularization and improved for delayed stenting in long-term LV ejection fraction. Given the risk of bleeding after major trauma or surgery (especially intracranial or spinal injury), these data may provide increased flexibility in timing of PCI for trauma patients when antiplatelet and GP IIb/IIIa inhibitors are contraindicated.[102]

For patients with non-STEMI, treatment is based on the presence or absence of hemodynamic instability. Hemodynamically unstable patients require treatment with aspirin (ASA) and vasopressors and cardiac catheterization with or without PCI. In patients with no hemodynamic instability and minimal risk factors for recurrence, medical management with ASA, β-blockers, ACE-Is, and statins is first-line therapy. Low-dose anticoagulation may also be considered in patients for whom anticoagulation is not contraindicated.[103] Although the initial results from studies regarding the initiation of statin therapy following ACS were encouraging, a 2014 Cochrane Review of 18 RCTs comparing statins to placebo demonstrated no significant reduction in death or MI after 4 months. There was, however, a reduction in unstable angina with statin administration.[104] For patients with multiple risk factors, cardiac catheterization may be indicated when the patient is able to be systemically anticoagulated.[96]

Respiratory Failure

Ben E. Biesterveld • Aaron M. Williams • Hasan B. Alam

KEY POINTS

- The Lung Injury Score (LIS) is based on the chest x-ray, hypoxemia, positive end-expiratory pressure (PEEP), and respiratory compliance, and each component is scored from 0 to 4.
- The Berlin definition of acute respiratory distress syndrome (ARDS) (2012) includes timing (within 1 week of a known clinical insult), bilateral opacities on chest x-ray, respiratory failure not explained by cardiac failure or fluid overload, and mild, moderate, or severe hypoxemia.
- A consistent histopathologic feature of ARDS is neutrophil infiltration of the pulmonary microvasculature, interstitium, and alveoli.
- With ARDS, it is not unusual to see greatly diminished lung compliance on the order of 10 to 30 mL/cm H_2O.
- The current standard of care for ARDS is lower tidal volume ventilation and the use of incremental inspired oxygen–PEEP combinations to achieve oxygenation goals.
- PEEP is used in ARDS to allow for adequate oxygen delivery to tissues while reducing the concentration of inspired oxygen to nontoxic (below 0.6) levels.
- The most common type of extracorporeal life support ([ECLS]; or extracorporeal membrane oxygenation [ECMO]) is venovenous, where blood is withdrawn from and returned to the venous system.
- Inhaled nitric oxide (iNO) is a selective pulmonary vasodilator with no systemic side effects.
- Any use of "rescue" steroids for late ARDS must be individualized and, optimally, delivered before disease day 14.
- The mortality of ARDS in several randomized controlled trials over the past two decades has decreased to 20% to 25%.

INTRODUCTION

The maintenance of gas exchange may be tenuous in the injured patient because of dysfunction in three key elements of the respiratory system. First, the central nervous system (CNS) may be impaired, resulting in inadequate respiratory drive, or inability to maintain patent proximal airways. Second, injury to the torso can produce changes in compliance, ineffective respiratory effort, and pain that impact the patient's ability to complete the work of breathing. Third, primary and secondary insults to the lung result in ineffective gas exchange. In practice, it is common for patients to suffer simultaneous insults affecting all three elements. Respiratory failure that relates primarily to injury to the CNS is discussed at length in other chapters and will not be extensively covered here. This chapter will focus on insults that affect work of breathing and gas exchange. The syndrome of acute respiratory distress syndrome (ARDS) and current management are the major focus.

HYPERCAPNIC PULMONARY FAILURE

The neurohormonal response to injury (see Chapter 63) results in a remarkable increase in cellular metabolism. This creates a substantial increase in carbon dioxide (CO_2) production that must be matched by increased elimination from the lungs. While a resting adult eliminates 200 $cm^3/kg/min$ of CO_2, postinjury hypermetabolism results in CO_2 production in the range of 425 $cm^3/kg/min$.[1] Thus, the minute ventilation required to maintain eucapnia may rise from a resting rate of approximately 5 L/min to more than 10 L/min. This represents a 100% increase in the work of breathing simply to meet the metabolic demands.

Additionally, injured patients typically have an increase in physiologic and anatomic dead space regions that do not participate in gas exchange. In a normal adult, the proportion of each breath that is dead space (V_d/V_t) is approximately 0.35. In the intubated, ventilated patient, the V_d/V_t can be accurately determined using Fowler's nitrogen washout technique[2]

or more commonly calculated by a number of techniques including the Bohr-Enghoff method (V_d/V_t = [{$Paco_2$ – mean expired CO_2}/$Paco_2$]).[3] For practical purposes (since mean expired CO_2 is not commonly measured), this is a reflection of the minute volume required to achieve a given $Paco_2$. In ventilated patients with pulmonary failure, the V_d/V_t often exceeds 0.6. This extra dead space is a burden because each breath is less effective at eliminating CO_2, and therefore, minute ventilation requirements in the 12 to 20 L/min range are not uncommon in the postinjury setting.

The above increase in respiratory demand might be met by a healthy adult; however, the injured patient faces several challenges in completing this additional work. CNS dysfunction from injury impairs respiratory drive, as do many medications routinely used for sedation and analgesia. Decreased thoracic compliance from abdominal distension (eg, as part of the abdominal compartment syndrome), chest wall edema, and recumbent positioning increase the energy required to complete a respiratory cycle. Decreased pulmonary compliance from an increase in extravascular lung water and pleural collections (effusions/hemothorax) also contributes. Muscular weakness from impaired energetics (hypothermia, acidosis, coagulopathy, cardiovascular failure, mitochondrial dysfunction, and oxidant stress) or fatigue may be an insurmountable challenge. Finally, pain from torso injuries or operative interventions makes the increased ventilatory demand a substantial burden to the patient.

The net effect of increased demand and diminished capacity to execute the work of breathing is hypercapnic respiratory failure. In the early postinjury period, patients most commonly present with a mixed acid-base disorder where ventilation is inadequate to maintain physiologic pH in the face of a metabolic acidosis. This frequently occurs in the absence of major hypoxia, and therefore, caution is warranted in relying on oximetry alone to assess adequacy of pulmonary function. Particularly in patients with tachypnea, blood gas analysis is the best method to quickly identify patients who are not meeting their ventilatory demands. While efforts to diminish the work of breathing should be routine, most patients with hypercapnic failure require some form of mechanical ventilation to meet their demands.

Two injury patterns that precipitate hypercapnic respiratory failure are worthy of special mention, including spinal cord injury and flail chest/pulmonary contusion. In spinal cord injury, conventional wisdom asserts that lesions below C5 should not result in pulmonary failure, because innervation to the diaphragm remains intact. In practice, however, most complete cord lesions in the cervical and upper thoracic regions frequently result in failure, requiring mechanical ventilation.[4] The genesis is multifactorial, including loss of vital capacity, ineffective cough with retention of secretions due to loss of innervation of intercostal and abdominal musculature (important accessory muscles of respiration), pneumonia in the setting of multiple injuries, associated pulmonary contusion, and aspiration at the time of the initial insult. Furthermore, vagal nerve autonomic dysfunction results in increased secretions, bronchospasm, and pulmonary edema. This patient population requires aggressive mobilization and pulmonary care, because recurrent lobar collapse and pneumonia are certain and lethal if not aggressively prevented.

Early operative stabilization of the spine is advocated because it has been shown to decrease the need for mechanical ventilation and length of stay in the intensive care unit (ICU).[5] Other adjuncts such as noninvasive ventilation, bronchodilators, mucolytics, and percussion should be considered. Flail chest and pulmonary contusion can be thought of as a single entity. This is a challenging injury pattern, because it impacts both the patient's ability to execute the work of breathing (from pain and mechanical instability of the thoracic) and gas exchange (from the pulmonary contusion). Isolated pulmonary contusion rarely requires mechanical ventilation. Since minor contusions are frequently identified by computed tomography (CT), it is important to realize that this tends to take a relatively benign course (see Chapter 28). It is clear that the number of rib fractures is strongly associated with the development of pulmonary failure, ARDS, and mortality, which profoundly impact the elderly population.[6] Early pain control, preferably beginning in the emergency department with regional anesthesia, has been shown to be effective in reducing the impact of multiple rib fractures and should be routinely applied, especially in patients over the age of 65 who have more than three continuous ribs fractured.[7] Admission to a high-volume trauma center, use of patient-controlled analgesia, epidural- or paravertebral catheter–administered analgesia, routine tracheostomy, and an algorithm-driven approach are associated with improved survival.[8,9]

HYPOXIC PULMONARY FAILURE, INCLUDING ACUTE RESPIRATORY DISTRESS SYNDROME

Hypoxic pulmonary failure is a substantial contributor to respiratory failure in the trauma setting. The etiologies are diverse, including aspiration pneumonitis, pneumonia, pulmonary embolism, congestive heart failure, blunt thoracic trauma, and ARDS. Most of these entities are discussed elsewhere; however, ARDS will be the focus of this chapter. Indeed, the mechanisms at work in ARDS share many common features with these other processes that affect the alveolar–capillary interface.

ARDS is a clinical syndrome of inflammatory lung injury that can be thought of as the final common pathway of diverse systemic processes. In the past two decades, major progress has been achieved in defining the underlying ARDS pathophysiology and optimal supportive care. Specific therapies that address the underlying mechanisms responsible for ARDS development remain elusive at present.

DEFINITIONS OF ACUTE RESPIRATORY DISTRESS SYNDROME AND THEIR LIMITATIONS

The recognition of ARDS as a distinct clinical entity resulted from the description by Ashbaugh et al[10] in 1967. Subsequent descriptions include five principal criteria: (1) hypoxemia

TABLE 59-1: Lung Injury Score[a]

Chest radiograph score	
No alveolar consolidation	0
Alveolar consolidation confined to one quadrant	1
Alveolar consolidation confined to two quadrants	2
Alveolar consolidation confined to three quadrants	3
Alveolar consolidation confined to four quadrants	4
Hypoxemia score	
Pao_2/Fio_2 ≥300	0
Pao_2/Fio_2 225–299	1
Pao_2/Fio_2 175–224	2
Pao_2/Fio_2 100–174	3
Pao_2/Fio_2 <100	4
Positive end-expiratory pressure (PEEP) score (when ventilated)	
PEEP ≤5 cm H_2O	0
PEEP 6–8 cm H_2O	1
PEEP 9–11 cm H_2O	2
PEEP 12–14 cm H_2O	3
PEEP ≥15 cm H_2O	4
Respiratory system compliance score (when available)	
Compliance ≥80 mL/cm H_2O	0
Compliance 60–79 mL/cm H_2O	1
Compliance 40–59 mL/cm H_2O	2
Compliance 20–39 mL/cm H_2O	3
Compliance ≤19 mL/cm H_2O	4

[a]The final value is obtained by dividing the aggregate sum by the number of components that were used: no lung injury, 0; mild to moderate lung injury, 0.1–2.5; severe lung injury (acute respiratory distress syndrome), 2.5.

refractory to oxygen administration; (2) diffuse, bilateral infiltrates on chest radiograph; (3) low static lung compliance; (4) absence of congestive heart failure; and (5) presence of an appropriate at-risk diagnosis.

Since the initial description of ARDS 50 years ago, the optimal definition of ARDS remains a controversial subject. The Lung Injury Score (LIS), proposed by Murray et al[11] in 1988, has been a commonly used measure of lung injury severity in previous clinical studies. The LIS is based on four components: chest radiograph, hypoxemia, positive end-expiratory pressure (PEEP), and respiratory compliance (Table 59-1).[11] Each component is scored from 0 to 4. The LIS is calculated by summing the scores of the available components and dividing by the number of components used. ARDS (or severe lung injury) is defined as an LIS greater than 2.5. Zero represents no lung injury, and 0.1 to 2.5 represents mild to moderate lung injury.

The first standard definitions were developed in 1994 by the Consensus Conference of American and European Investigators (AECC). Acute lung injury (ALI) was defined as respiratory failure of acute onset with a Pao_2:Fio_2 (P:F) ratio

TABLE 59-2: American–European Consensus Conference (AECC) Definitions of Acute Lung Injury and Acute Respiratory Distress Syndrome

Acute lung injury criteria

Timing: acute onset

Oxygenation: Pao_2/Fio_2 ≤300 mm Hg (regardless of positive end-expiratory pressure)

Chest radiograph: bilateral infiltrates on anteroposterior chest radiograph

Pulmonary artery occlusion pressure ≤18 mm Hg or no clinical evidence of left atrial hypertension

Acute respiratory distress syndrome criteria

Same as acute lung injury except:

Oxygenation: Pao_2/Fio_2 ≤200 mm Hg (regardless of positive end-expiratory pressure)

of less than or equal to 300 mm Hg (regardless of the level of PEEP), bilateral infiltrates on frontal chest radiograph, and a pulmonary capillary wedge pressure less than or equal to 18 mm Hg (if measured) or no evidence of left atrial hypertension. ARDS was defined identically except for a lower limiting value of less than 200 mm Hg for P:F (Table 59-2).[12] The AECC definition of ALI/ARDS has been used in many of the ARDS Network clinical trials; however, debate still exists as to the usefulness of the AECC diagnostic criteria. Criticism of the AECC definition includes lack of including criteria about timing of ARDS development from injury, not including how ventilator settings could affect Pao_2/Fio_2, subjectivity of reading chest radiographs, and challenges to exclude volume overload as the cause for respiratory failure.[13]

An alternative definition of ARDS developed by a consensus panel of senior investigators using the Delphi method appears to be more specific than AECC criteria.[14] Briefly, the authors include PEEP in the consideration of hypoxia and require either the absence of congestive heart failure or the presence of a recognized risk factor for ARDS. The degree of hypoxia required is a P:F less than 200 mm Hg with PEEP greater than or equal to 10 cm H_2O; therefore, it excludes patients who are hypoxic purely because of derecruitment or suboptimal PEEP (Table 59-3). By allowing patients with high filling pressures in the presence of a recognized ARDS risk factor, the definition recognizes the prevalence of high left atrial pressure during the course of ARDS and includes patients with concomitant congestive heart failure and ARDS.

TABLE 59-3: The Delphi Definition of Acute Respiratory Distress Syndrome (ARDS)

Timing: acute onset

Oxygenation: Pao_2/Fio_2 ≤200 mm Hg with PEEP ≥10 cm H_2O

Chest radiograph: bilateral infiltrates

Absence of CHF or presence of recognized risk factor for ARDS

CHF, congestive heart failure; PEEP, positive end-expiratory pressure.

TABLE 59-4: The Berlin Definition of Acute Respiratory Distress Syndrome

Timing: Within 1 week of a known clinical insult or new or worsening respiratory symptoms

Chest imaging: Bilateral opacities—not fully explained by effusions, lobar/lung collapse, or nodules

Origin of edema: Respiratory failure not fully explained by cardiac failure or fluid overload

Oxygenation

Mild: 200 mm Hg < Pao_2/Fio_2 ≤ 300 mm Hg with PEEP or CPAP ≥5 cm H_2O

Moderate: 100 mm Hg < Pao_2/Fio_2 ≤ 200 mm Hg with PEEP or CPAP ≥5 cm H_2O

Severe: Pao_2/Fio_2 <100 mm Hg with PEEP or CPAP ≥5 cm H_2O

CPAP, continuous positive airway pressure; PEEP, positive end-expiratory pressure.

TABLE 59-5: Risk Factors for Acute Respiratory Distress Syndrome (ARDS)

Risk factor	Frequency of ARDS (%)
Direct	
Aspiration	12–36
Pneumonia	12–31
Pulmonary contusion	5–22
Toxic inhalation	2–17
Indirect	
Sepsis syndrome	11–80
Multiple transfusions	5–36
Multiple fractures	2–21
Pancreatitis	7–18
Disseminated intravascular coagulation	23

The definition of ARDS was most recently revised by a panel of specialists in a joint effort of the European Society of Intensive Care Medicine, the American Thoracic Society, and the Society of Critical Care Medicine. Their collective aim was to address the current limitations of the AECC definition and explore other defining ARDS variables. The panel agreed to maintain the previous conceptual model, which defined ARDS as a syndrome of acute, diffuse lung inflammation, with edema because of increased permeability of the alveolar-capillary membrane, and clinically characterized by decreased oxygenation because of increased venous admixture, decreased lung compliance, increased physiologic dead space, and bilateral radiographic opacities. The newest and most widely accepted ARDS criteria, also referred to as the Berlin definition of ARDS, are provided in Table 59-4.[15]

EPIDEMIOLOGY OF ACUTE RESPIRATORY DISTRESS SYNDROME

The estimated incidence of ARDS in population-based studies is on the order of 40 cases per 100,000 person-years.[16-18] In the United States, this represents about 200,000 cases per year, and about 15% of ICU admissions. The LUNG SAFE international trial in 50 countries found that ARDS occurred in 10% of ICU admissions and mortality was 35%, 40%, and 46% for patients with mild, moderate, and severe ARDS.[19]

RISK FACTORS FOR ACUTE RESPIRATORY DISTRESS SYNDROME

Clinical Risk Factors

Clinical risk factors for ARDS can be broadly categorized into direct and indirect pulmonary factors (Table 59-5). Direct pulmonary factors are those primarily associated with local pulmonary parenchymal injury and include inhalation injury, pulmonary contusion, aspiration, and pulmonary infection. Indirect pulmonary factors are those thought to be associated with systemic inflammation and resultant lung injury. These include trauma, shock, burn injury, extrapulmonary sepsis, transfusion of blood products, multiple long bone fractures, pancreatitis, and others.[16,20]

The King County Lung Injury Project (KCLIP) identified pulmonary and extrapulmonary sepsis as the most common risk factors, with 46% and 33% of ARDS cases, respectively. Following sepsis in descending order of frequency were aspiration (11%), trauma (7%), transfusion (3%), drug overdose (3%), and pancreatitis (3%). The highest mortality rates were noted in aspiration-associated (44%) and pulmonary sepsis–associated lung injury groups (41%), with the lowest rate in trauma-associated lung injury (24%).[18]

Demographic Risk Factors

Several demographic factors have been identified as risk modifiers for development of ARDS. The incidence of ARDS increases with age, and older patients have consistently higher mortality rates, although it is unclear whether this simply represents diminished physiologic reserve in older patients.[21,22] Alcohol abuse, active cigarette smoking, and exposure to secondhand smoke have also been linked to ARDS incidence.[23,24] Higher body mass index has been associated with increased incidence of ARDS,[25] with data suggesting a decrease in mortality.[26]

Treatment Risk Factors

It is well established that high tidal volume ventilation increases mortality for patients with established ARDS.[27] Several studies have shown that increased tidal volume is an independent risk factor for the subsequent development of ARDS in a dose-responsive manner.[28,29] This phenomenon, termed *ventilator-induced lung injury* (VILI), has been a target to decrease the development of ARDS.

TABLE 59-6: National Heart, Lung, and Blood Institute Consensus Conference Definition of Transfusion-Related Acute Lung Injury (ALI)

Onset of signs or symptoms ≤6 h after transfusion.
No ALI may be present prior to transfusion.
Alternative ALI risk factors may be present, but the patients' clinical course should determine whether the ALI is mechanistically related to the transfusion.

Transfusion of blood products is a major iatrogenic risk factor for ARDS. Multiple studies have shown increased risk of ARDS in ICU patients receiving packed red blood cells, fresh frozen plasma, and/or platelet transfusions,[25,30] a phenomenon termed *transfusion-related acute lung injury* (TRALI). In addition to ARDS, the National Heart, Lung, and Blood Institute definition of TRALI requires additional criteria (Table 59-6): (1) A patient must develop ARDS during or within 6 hours of transfusion, and (2) no ARDS may be present before transfusion. (3) Alternative ARDS risk factors may be present, but the patient's clinical course should determine whether the ARDS is mechanistically related to the transfusion.[31]

PATHOLOGY OF ACUTE RESPIRATORY DISTRESS SYNDROME

The current paradigm of systemic inflammation leading to ARDS posits that a variety of insults, both infectious and noninfectious, can result in an unbridled hyperinflammatory response. This leads to organ injury from indiscriminate activation of effector cells that subsequently release oxidants, proteinases, and other potentially injuring compounds. If the initial insult is severe enough, early organ dysfunction results ("one-hit" or single-insult model). More often, a less severe insult results in a systemic inflammatory response that is not by itself injurious. These patients appear, however, to be primed such that they have an exaggerated response to a second insult, which leads to an augmented/amplified systemic inflammatory response and multiple organ dysfunction ("two-hit" or sequential insult model; see Chapter 63).[32]

Inflammatory models provide a unifying hypothesis for ARDS and multiorgan failure (MOF); however, the precise relationship between ARDS and MOF remains to be further refined. MOF is a frequent occurrence and the most common cause of mortality in patients with ARDS.[33] It is also now clear that ventilator strategies that inadvertently promote lung injury may produce systemic inflammation, perhaps leading to other organ failures.[34]

Inflammatory lung injury leads to the pathologic lesion of diffuse alveolar damage. This prototypic lesion of ARDS is at the alveolar–capillary interface, which results in epithelial and endothelial damage as well as high-permeability pulmonary edema. The histologic appearance of this lesion can be divided into three overlapping phases as follows: (1) the exudative phase, with edema and hemorrhage; (2) the proliferative phase, with organization and repair; and (3) the fibrotic phase.[35]

The exudative phase generally encompasses the first 3 to 5 days but may last up to a week. The initial histologic changes include interstitial edema, proteinaceous alveolar edema, and intra-alveolar hemorrhage. The exudative phase is characterized by the appearance of hyaline membranes, which are composed of fibrin, immunoglobulin, and complement. Electron microscopy reveals endothelial injury with cell swelling, widening intercellular junctions, and increased pinocytotic vesicles. In addition, there is disruption of the basement membrane.

The alveolar epithelium usually exhibits extensive loss of type I cells, which slough and leave a denuded basement membrane. While some loss may be from necrosis, it appears that apoptosis contributes substantially. Activation of matrix metalloproteinases, toll-like receptors, and oxidative stress pathways initiates programmed cell death in these cells. Demonstration of soluble Fas ligand in bronchoalveolar lavage (BAL) fluid early in ARDS supports this concept.[36] Loss of the alveolar epithelial barrier results in alveolar edema, as the remaining cells are unable to drive sodium from the alveolar into the interstitial compartment.

During the proliferative phase, typically occupying the second 2 weeks after the onset of respiratory failure, type II cells divide and cover the denuded basement membrane along the alveolar wall. This process may be seen as early as 3 days after the onset of clinical ARDS. Type II cells are also capable of differentiating into type I epithelial cells. Fibroblasts and myofibroblasts proliferate and migrate into the alveolar space in the third phase. Fibroblasts change the alveolar exudate into granulation tissue, which subsequently organizes and forms dense fibrous tissue. Eventually, epithelial cells cover the granulation tissue. This whole process is called fibrosis by accretion and is important in lung remodeling. Septal collagen deposition by fibroblasts and "collapse induration" also contribute to fibrous remodeling of the lung in ARDS.

Many patients with ARDS recover lung function 3 to 4 weeks after initial injury; however, some enter a fibrotic phase characterized by thickened, collagenous connective tissue in the alveolar septa and walls. Pulmonary vascular changes occur as well, with intimal thickening and medial hypertrophy of the pulmonary arterioles. Complete obliteration of portions of the pulmonary vascular bed is the end result. Clinical sequelae include an increased risk of pneumothorax, decreased lung compliance, and increased pulmonary dead space. This may lead to increased long-term support on mechanical ventilators and/or need for supplemental oxygen.

PATHOGENESIS OF ACUTE RESPIRATORY DISTRESS SYNDROME

Lung injury in ARDS involves components of inflammation, coagulation, vasomotor tone, and other systems (see Chapter 63). The pivotal cellular mediators appear to be

leukocytes, with both local and humoral mediators orchestrating their function. Activation of these leukocytes results in release or activation of multiple cytokines, chemokines, oxidants, and proteases that result in the final common pathway of tissue injury in ARDS.

Neutrophils

A consistent histopathologic feature of ARDS is neutrophil infiltration of the pulmonary microvasculature, interstitium, and alveoli. Neutrophil infiltration may result in lung injury due to neutrophil-mediated release of reactive oxidant species (ROS) and resulting oxidant stress.[37] Furthermore, neutrophils are an important source of proinflammatory cytokines. Persistence of neutrophils in serial BAL fluid samples from patients with ARDS suggests unbridled inflammation and portends poor prognosis. In animal models, neutrophil depletion prior to an insult markedly attenuates resulting lung injury.[38] Evidence from clinical studies supporting excess ROS in ARDS include findings of increased hydrogen peroxide in exhaled breath,[39] decreased levels of glutathione in lung lavage fluids,[40] and increased lipid peroxidation products in plasma.[41] Neutrophils obtained from trauma patients with ARDS also are able to more effectively break down the endothelial layer.[42]

Macrophages

The lung contains large numbers of fixed tissue macrophages that are a critical component of the inflammatory response in ALI. Activated macrophages can cause tissue injury by releasing the same toxic mediators as neutrophils (ROS and proteases). Probably more important is the macrophage capability to synthesize multiple proinflammatory mediators, such as complement fragments, cytokines, and chemokines, leading to neutrophil and monocyte recruitment. Thus, macrophages are thought to have a major role in amplifying and perpetuating the inflammatory response.[43]

Endothelium

The pulmonary endothelium is not a passive bystander in the pathogenesis of ARDS, but actively participates in initiating and perpetuating the inflammatory response. Endothelial cells increase the expression of adhesion molecules (ICAM-1, ICAM-3, and E-selectin) following exposure to an activating stimulus. These ligands serve as tethering and signaling molecules by binding to their associated leukocyte membrane proteins. Thus, the endothelial cell actively coordinates trafficking, firm adhesion, and transmigration. In the setting of systemic inflammation, inappropriate endothelial cell activation may lead to indiscriminate leukocyte recruitment and parenchymal inflammation. Moreover, endothelial cells produce and release vasoactive substances, such as prostacyclin, nitric oxide (NO), and endothelins. These substances may mediate much of the pulmonary vascular dysfunction characteristic of ARDS. The activated endothelium expresses procoagulant activity, which also contributes to intravascular coagulation and microvascular dysfunction.[35] Thrombin, in turn, has proinflammatory effects on leukocytes. Endothelial injury, then, may be both a proximate cause and a marker for ALI.

Mediators and Markers of Acute Respiratory Distress Syndrome

COMPLEMENT

Systemic complement activation secondary to trauma or sepsis is considered a major early factor in ARDS.[44] C5a, a product of complement activation, is a powerful neutrophil chemoattractant. Moreover, C5a induces neutrophil aggregation and activation, leading to pulmonary neutrophil sequestration and lung injury. Clinically, BAL proteomic analysis reveals markedly differential expression of the complement pathway in ARDS survivors versus nonsurvivors.[45]

ENDOTHELIAL INJURY

The pulmonary endothelium is recognized as an active participant in the development of ALI. As such, markers of endothelial activation or injury have been investigated as predictors of the development of ARDS.[35] von Willebrand factor antigen (vWF:Ag) has been studied fairly extensively as a marker of endothelial dysfunction. vWF:Ag is synthesized largely by vascular endothelial cells and has been shown to be a sensitive marker of endothelial injury or activation and predictive for the development of ALI in injured burn patients.[46]

Following activation, endothelial expression of adhesion molecules, including ICAM-1, VCAM-1, E-selectin, P-selectin, and Ang-2, is upregulated. These compounds are susceptible to proteolytic cleavage and may exist in the circulation in a soluble form. Therefore, these molecules represent a measure of endothelial activation or damage. Ang-2 is released by activated endothelial cells, increases vascular permeability and sensitizes the cell to inflammatory stimuli, and has been shown to be predictive of ARDS mortality.[47] Elevated ICAM-1 levels have been found in severely injured patients who subsequently developed MOF.[48] In contrast, plasma levels of soluble E- and P-selectins measured at admission were not useful in predicting lung injury, and levels of L-selectin were downregulated in those who would go on to develop ARDS.[47]

Markers of leukocyte activation have also been measured in plasma and BAL fluid of patients in an attempt to predict development of ARDS. Gordon et al[49] noted markedly elevated plasma elastase levels very early after multisystem trauma. Subsequent studies supported a causative role for neutrophil elastase in ARDS and have led to the clinical development of human elastase inhibitor (see the section "Pharmacologic Therapy of Acute Respiratory Distress Syndrome").[50]

CYTOKINES

Circulating and BAL fluid levels of cytokines are also inherently attractive as predictors of ARDS; whether they are markers or mediators remains an important question. Direct measurement of BAL or pulmonary edema fluid in ARDS patients has shown that both fluids consistently contain elevated levels of tumor necrosis factor (TNF)-α and interleukin (IL)-1; additionally, high levels of TNF-α and IL-1 in plasma and in BAL have been associated with an increased risk of death in patients with ALI and ARDS.[35] Persistently elevated IL-6 levels have also been associated with an increased risk of death in ARDS patients. In the ARDS Network (ARDSNet) trial, there was a significantly steeper fall in IL-6 levels over the initial 72 hours in the lung-protective treatment group with decreased mortality compared to the higher-tidal-volume treatment group. Of all the inflammatory cytokines, IL-8 in lavage fluid has been shown to be the strongest predictor of ARDS mortality. IL-10 is a potent inhibitor of proinflammatory molecules including TNF-α and IL-1. Lower levels of IL-10 in blood and lung lavage fluid have been associated with development of ARDS.[51]

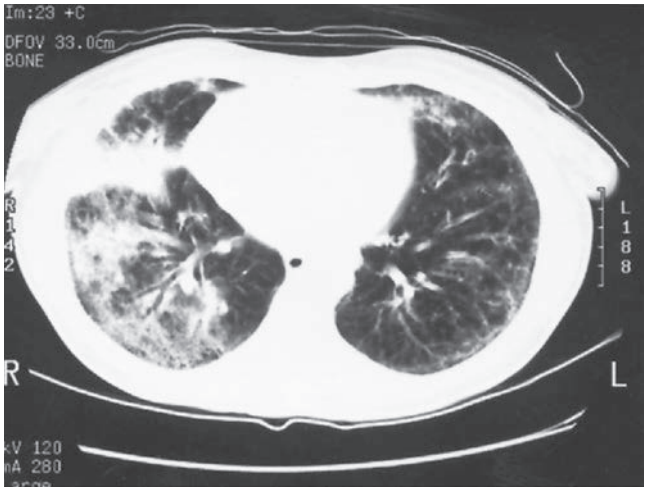

FIGURE 59-2 Chest computed tomography scan of a patient with acute respiratory distress syndrome shows marked inhomogeneity of the process with areas of dense consolidation and essentially normal intervening pulmonary parenchyma.

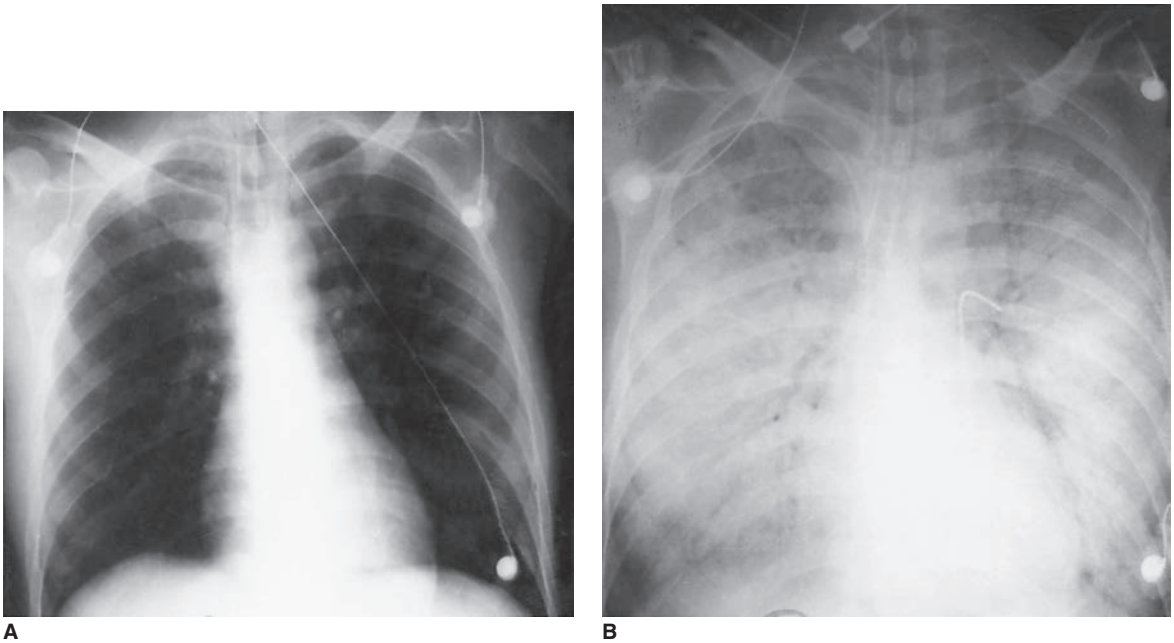
PATHOPHYSIOLOGY OF ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is characterized by diffuse, patchy, panlobular pulmonary infiltrates on plain chest radiograph (Fig. 59-1). CT of the chest will demonstrate that the parenchymal changes are heterogenous with the dependent lung regions most affected (Fig. 59-2). The inhomogeneous distribution of parenchymal densities led to the concept of a three-compartment model of the lung in ARDS.[52] One compartment is substantially normal (healthy zone), one is fully diseased without any possibility of recruitment (diseased zone), and, finally, the third compartment is composed of collapsed alveoli potentially recruitable with increasing pressure (recruitable zone). Increased airway pressure is necessary to recruit collapsed alveoli. In the 1990s, however, it was already recognized that in the heterogeneously injured lung, VILI may be damaging



A B

FIGURE 59-1 **(A)** Normal admission chest x-ray in a 27-year-old trauma patient with multiple lower extremity fractures. **(B)** Chest x-ray from the same patient following onset of respiratory insufficiency. Note the bilateral, dense pulmonary infiltrates consistent with severe acute respiratory distress syndrome.

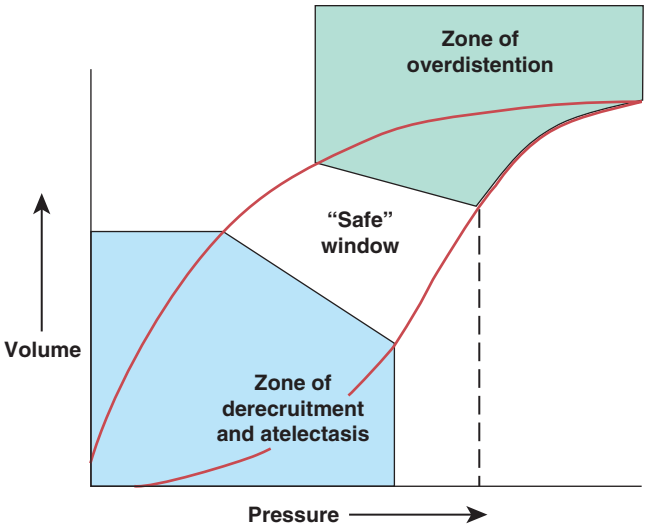


FIGURE 59-3 Idealized static pressure–volume curve of the lungs in acute respiratory distress syndrome. At low pressures and volumes, derecruitment, atelectasis, and lung injury from repetitive opening and closing of gas exchange units are a concern. At high pressures and volumes, overdistention, increased shunt, and lung injury from excessive stretch predominate. In between these two extremes is the optimal zone, where lung stays recruited but is not overstretched.

to the healthy zone. This injury is thought to be responsible for severe protracted ARDS, as well as perpetuation of systemic inflammation and MOF.[53]

A standard method used to describe the mechanical properties of the lung is to determine the static pressure–volume (PV) curve during inflation and deflation (Fig. 59-3). In early ARDS, the lower inflection point represents the airway pressure at which considerable alveolar recruitment occurs. The upper inflection point is where near-maximal inflation occurs such that further increases in airway pressure result in alveolar overdistension and little change in volume. In practice, however, inflection points in individual patients have been difficult to consistently measure.

Pulmonary Edema

Increased pulmonary capillary permeability is a consistent feature. Increased permeability promotes alveolar flooding with protein-rich edema fluid, as well as release of proteins generally confined to the lung into the systemic circulation. In ARDS, the pulmonary epithelium is injured, leading to altered fluid transport. Multiple studies have documented elevated total protein concentrations in BAL fluid from patients with established ARDS.[54] One study observed higher BAL fluid protein concentrations in those who died, suggesting that more severe lung injury is associated with greater endothelial and epithelial permeability.[52]

Gas Exchange

Hypoxemia in ARDS results from ventilation/perfusion mismatching and intrapulmonary shunting of blood flow. Shunting results from blood that passes through the systemic venous to pulmonary arterial system without going through the normal gas exchange units in the lung (ie, right–left shunt). Normally, the shunt fraction is less than 5%; however, in ARDS, it may exceed 25%. Because blood flowing through a shunt is not exposed to alveoli participating in gas exchange, supplemental oxygen is ineffective in increasing arterial oxygen concentration. Other techniques designed to restore ventilation to diseased lung regions, such as PEEP or continuous positive airway pressure (CPAP), are thus necessary to improve oxygenation. Hypoxic pulmonary vasoconstriction is a protective mechanism that limits perfusion to poorly ventilated alveoli and minimizes shunting. In ARDS, hypoxic pulmonary constriction is impaired, resulting in greater intrapulmonary shunt. Multiple factors may contribute to loss of hypoxic pulmonary vasoconstriction in lung injury, including local prostaglandin or NO production.[55]

In early ARDS, most patients are tachypneic from hypoxemia and are secondarily hypocapneic. With disease progression, hypercapnia may become a prominent feature because of physiologic dead space and CO_2 production. Increased dead space ventilation is invariably present. As discussed earlier, the normal dead space–to–tidal volume ratio is approximately 35%, but in ARDS, it can approach 60%. Exacerbating the ability to ventilate is the surfactant dysfunction and terminal bronchiolar spasm contribution to loss of ventilated alveoli.

Pulmonary Mechanics

Lung compliance is defined as the change in lung volume per change in transpulmonary pressure. Normal lung compliance in a mechanically ventilated patient ranges from 60 to 80 mL/cm H_2O. With ARDS, it is not unusual to see greatly diminished lung compliance on the order of 10 to 30 mL/cm H_2O. Initially, reduced compliance is the result of interstitial and alveolar edema with alveolar flooding. In later ARDS, interstitial fibrosis and parenchymal loss further reduce pulmonary compliance.

Hemodynamics

Pulmonary hypertension is a frequent finding in patients with ARDS and can lead to increased interstitial pulmonary edema, right ventricular dysfunction, and impaired cardiac output. When severe, pulmonary hypertension has been observed to be a marker of poor outcome. The etiology of pulmonary hypertension in ARDS is multifactorial. Early in ARDS, the predominant mechanism is most likely impaired vasorelaxation related to hypoxemia, acidosis, and vasoactive mediators, in concert with obstruction from microvascular coagulation. In late ARDS, fibrosis and obliteration of the pulmonary vascular bed are most likely responsible. Wiedemann et al[56] noted markedly depressed right ventricular function in nonsurvivors of ARDS. The authors related this to reduced myocardial contractility and not to pulmonary hypertension.

They also noted that oxygen delivery was more related to cardiac performance than to pulmonary gas exchange.

PRESENTATION OF ACUTE RESPIRATORY DISTRESS SYNDROME

The diagnosis of ARDS is based on the criteria used to define the syndrome and has historically been divided into four clinical phases with radiographic, clinical, physiologic, and pathologic correlates. In the initial phase, dyspnea and tachypnea are evident, with a remarkably normal chest examination (radiographically and clinically). Arterial oxygen saturation is preserved, and hypocapnia from hyperventilation is frequently noted.

The second phase quickly follows (12–24 hours), with physiologic and pathologic evidence of lung injury. The chest x-ray now shows bilateral patchy alveolar infiltrates with hypoxemia evident on arterial blood gas determination. If ARDS persists and progresses, the third clinical phase becomes evident. Acute respiratory failure necessitates mechanical ventilation with increasing inspired oxygen concentrations. There is an increase in physiologic dead space and rising minute ventilation. Patients at this point may develop sepsis syndrome with a hyperdynamic hemodynamic pattern. The radiographic picture worsens with more diffuse infiltrates, consolidation, and air bronchograms.

Without resolution, progressive pulmonary failure and fibrosis characterize the fourth phase. Hypercapnia may worsen and become more difficult to control. MOF commonly develops and is the most common cause of death.

MANAGEMENT OF ACUTE RESPIRATORY DISTRESS SYNDROME

Because there is no proven specific treatment for ARDS, therapy primarily involves supportive measures to maintain life while the lung injury resolves. Such measures include identifying and treating predisposing conditions, mechanical ventilatory support with oxygen, nutritional support, nonpulmonary organ support, and hemodynamic monitoring as necessary. Attention to detail is necessary to avoid nosocomial infection and iatrogenic complications.

Fluid Management and Hemodynamic Support

One of the hallmark pathologic changes in ARDS is increased endothelial and epithelial permeability, resulting in extravasation of fluid and plasma elements, including albumin, in the interstitium and alveolar space. This leads to hypoxemia, atelectasis, decreased lung compliance, and increased pulmonary artery pressures.[55] Fluid management is one of the most important measures shown to impact ARDS. Based on the known pathophysiologic mechanisms, current management is in favor of limiting the forces that favor fluid filtration from the capillaries or augmenting those factors implicated in fluid reabsorption, which can limit fluid accumulation in the lung.

One of the most important trials in the treatment of ARDS has been the Fluid and Catheter Treatment (FACTT) trial.[56] This study randomized 1000 patients to liberal versus conservative fluid management, based on targeted central venous pressure or pulmonary capillary wedge pressure. There was no significant 60-day mortality difference between the groups, but patients in the conservative strategy group had significantly more days alive, days free of mechanical ventilation, and shorter ICU stay. Importantly, there was no increase in organ failures in these patients at 7 and 28 days.

Because ARDS is a common complication in patients with sepsis, proper fluid management is essential for optimal outcomes. However, the correct assessment of fluid status in ICU patients is still a challenge. A tool in estimating lung fluid balance is extravascular lung water (EVLW), which is calculated using the single thermodilution method.[57] Traditionally, EVLW has been indexed to actual body weight (mL/kg); however, a recent observational cohort study of patients with ARDS has shown that baseline EVLW when indexed to predicted body weight is a better prognostic indicator of mortality, after adjusting for severity of illness and other important factors, than EVLW indexed to actual body weight.[58] EVLW may also be a tool to predict those at risk for developing ARDS in postoperative patients.[59]

With respect to colloids, there is no evidence that their use for acute resuscitation improves outcome. A study in hypoproteinemic patients suggests that gas exchange can be improved in late ALI by using colloid in concert with diuretics to mobilize interstitial fluid and promote diuresis.[58] A 2006 randomized controlled trial (RCT) suggested that critically ill patients with profound hypoproteinemia have fewer organ failures (by Sequential Organ Failure Assessment score) when given colloid therapy.[60] Short-term improvement in physiology is not, however, accompanied by an improved outcome in these investigations. The very large Australian SAFE study revealed no difference in mortality and other significant clinical end points for patients resuscitated with albumin, as compared to those resuscitated with normal saline; however, the patient population in this study was heterogeneous.[61] Further large randomized studies of colloid use only in ARDS patients are needed.

Mechanical Ventilation

Most patients with ARDS require endotracheal intubation for mechanical ventilation. This technique reduces shunt physiology and administers high concentrations of oxygen. Emergent intubation is associated with significantly higher morbidity and mortality. Accordingly, early elective intubation should be considered in all patients with deteriorating gas exchange or mental status. Noninvasive positive-pressure mask ventilation should be used very cautiously, if at all, for hypoxemic respiratory failure as several studies have shown a higher mortality and increased risk of intubation-related complications.[62,63]

Respiratory support with a mechanical ventilator is a cornerstone in the supportive management of patients with or at risk for ARDS. The goals of mechanical ventilation in ARDS are to maintain oxygenation while avoiding oxygen toxicity. Typically, this involves maintaining oxygen saturation in the range of 85% to 90% and decreasing F_{IO_2} to less than 65% in the first 24 to 48 hours. It has long been recognized that the ventilator settings can contribute to VILI by worsening lung injury and causing barotrauma (eg, mediastinal emphysema, pneumothorax). This recognition supported many early experimental studies in animals showing that high tidal volume (V_T) ventilation caused injury morphologically similar to ARDS in humans, and even multiorgan system failure in otherwise healthy animals, which was associated with release of inflammatory cells and proinflammatory cytokines.[64,65] Early RCTs examining low V_T strategies were inconclusive with limited sample size and lack of statistical power. The hallmark clinical study by the ARDSNet was the first to conclusively show the benefit of low V_T ventilation compared to traditional strategies.[27] In this trial, volume-controlled, continuous mandatory ventilation was used, and V_T was set based on ideal body weight (IBW). In the group treated with traditional V_T, the target V_T was 12 mL/kg IBW. In the group treated with lower V_T, the target V_T was 6 mL/kg IBW if the plateau pressure did not exceed 30 cm H_2O and 4 mL/kg if plateau pressure was greater than or equal to 30 cm H_2O. For patients with severe dyspnea, the V_T could be increased to 8 mL/kg IBW. The trial was stopped after the enrollment of 861 patients because mortality was significantly lower in the group treated with lower V_T than in the group treated with traditional V_T (31% vs 39.8%). Importantly, plasma IL-6 levels and the number of organ failure–free days were lower among the low V_T group.

Whereas previous studies employing low V_T allowed permissive hypercapnia and acidosis to achieve the protective ventilation goals of low V_T and inspiratory airway pressure, the ARDSNet study allowed increases in respiratory rate as the V_T was decreased and administration of bicarbonate to correct acidosis. This may explain the positive outcome in this study compared to earlier studies that had failed to demonstrate a benefit. However, the ARDSNet trial was criticized for relying on strict ventilator protocols for the higher tidal volume group.

With the results of the ARDSNet trial, the current standard of care now includes a lower tidal volume ventilatory strategy ("ARDSNet lung-protective strategy") and the use of incremental F_{IO_2}-PEEP combinations to achieve oxygenation goals.[53]

Permissive Hypercapnia

Controlled hypoventilation (relative to CO_2 production) with increased P_{aCO_2} is referred to as permissive hypercapnia. The widespread acceptance of the ARDSNet lung-protective strategy has led to a shift in clinical paradigms regarding hypercapnic acidosis (HCA)—from intolerance to acceptance. In fact, not only is it accepted that permissive HCA is well tolerated, there are emerging data regarding the benefits of permissive hypercapnia in experimental models of lung injury.

HCA has multiple physiologic effects on different organs, particularly the pulmonary, cardiovascular, and cerebrovascular systems. Because CO_2 diffuses freely across cell membranes, an increase in extracellular P_{CO_2} will result in intracellular acidosis. Gradual increases in P_{aCO_2} are usually well tolerated, provided renal compensation is adequate (see Chapter 61), and severe acidosis (pH <7.1) usually does not occur. Three mechanisms are responsible for this regulation: (1) physiochemical buffering, mainly due to proteins and phosphates; (2) reduced intracellular generation of protons; and (3) changes in transmembrane ion exchange. Physiochemical buffering is immediate, while the other mechanisms require 1 to 3 hours. These regulatory mechanisms are remarkably powerful and efficient. As a result, normoxic HCA has only limited potential for resulting in intracellular acidosis and is generally well tolerated.

Moderate HCA enhances tissue perfusion and oxygenation through multiple mechanisms. In both normal and diseased lungs, there is evidence that HCA reduces ventilation/perfusion heterogeneity, likely through increasing compliance and directing ventilation to underventilated lung regions with higher alveolar P_{CO_2}. The overall hemodynamic response to acute HCA in human experiments is increased cardiac output, heart rate, and stroke volume, with decreased systemic vascular resistance.[66]

HCA has multiple effects on the CNS. CO_2 is an important regulator of cerebrovascular tone. It has long been recognized that hypercarbia increases cerebral blood flow and intracranial pressure secondary to diminished vascular tone and enlargement of cerebral blood volume.[67] Indeed, traditional management of traumatic brain injury (TBI) historically included hypocapnia to reduce cerebral blood volume and intracranial pressure. Accumulating evidence, however, has shown that sustained hypocapnia reduces cerebral oxygen supply and increases brain ischemia, vasospasm risk, and seizures.[66] Studies have shown that prehospital hypocapnia worsens outcomes after severe TBI.[68,69]

The direct contribution of HCA to the protective effects observed with lung-protective ventilator strategies remains an area of debate. A secondary analysis of ARDSNet data, using multivariate logistic regression and controlling for comorbidities and severity of lung injury, showed that HCA on day 1 was associated with reduced mortality in patients ventilated with 12 mL/kg but not in patients ventilated with 6 mL/kg.[70] Recent studies have introduced the concept of *therapeutic hypercapnia*, whereby deliberately elevated P_{aCO_2} can lessen lung and systemic organ injury. Substantial evidence demonstrates that moderate HCA directly reduces VILI through several mechanisms including prevention of stretch-induced lung inflammation.[71,72] HCA has been shown to directly attenuate indices of ALI in in vivo and ex vivo models of primary and secondary ischemia-reperfusion lung injury.[73,74] In contrast to the observed beneficial effects of HCA described earlier, there are data to suggest that HCA can be deleterious

in prolonged, untreated pneumonia through reduction of neutrophil- and macrophage-mediated bacterial killing.[75] Also, HCA appears to impair pulmonary epithelial wound healing by diminishing cellular migration through inhibition of NF-κB.[76] Despite these concerns, the potential for therapeutic HCA in attenuating lung injury is promising.

A major area of controversy in regard to HCA is the role of buffering with sodium bicarbonate infusion, a common practice in many ICUs. Although bicarbonate may correct arterial pH, it may actually worsen intracellular acidosis because the CO_2 produced from reaction of metabolic acids with bicarbonate diffuses readily across cell membranes.[77] Accumulating evidence also suggests that the protective effects of HCA are attenuated by pH buffering,[77-79] suggesting that these benefits are a function of pH, rather than elevated CO_2.

There has been a lack of human trials to establish guidelines for the use of buffering during therapeutic hypercapnia. In most institutions, sodium bicarbonate would not be administered unless the pH was less than 7.2. With increased experience, however, many centers reserve bicarbonate infusion for pH less than 7.0. A previous alternative was to use tris(hydroxymethyl)aminomethane (THAM), which does not increase CO_2 production but is not specifically labeled for this use.[80] However, the manufacturer of THAM has recently discontinued its production. Sedation is mandatory with permissive hypercapnia in mechanically ventilated patients in order to control respiratory drive and prevent discomfort. Even with heavy sedation, however, respiratory drive may be insufficiently suppressed, resulting in patient–ventilator dyssynchrony. Neuromuscular blockade is often necessary in these patients.

Positive End-Expiratory Pressure

PEEP is one of several methods of increasing mean airway pressure and improving oxygenation. It improves oxygenation by enhancing lung volume and increasing functional residual capacity (FRC) through recruitment of collapsed alveoli. Lung compliance may also be improved. The use of PEEP in patients with ARDS has two primary goals: adequate tissue oxygen delivery and the reduction of F_{IO_2} to nontoxic (generally <0.6) levels. Increasing PEEP above a certain level, however, may have significant adverse effects. By raising intrathoracic pressure, PEEP may significantly reduce venous return and cardiac output.[63] This may result in decreased tissue oxygen delivery despite improvement in arterial oxygen saturation. This effect is accentuated in the hypovolemic patient and can usually be reversed with intravascular volume expansion. Cardiac depression is rarely seen with PEEP levels less than or equal to 10 cm H_2O. If PEEP greater than 10 cm H_2O is required, assessment of intravascular volume status and cardiac function is warranted.

PEEP may also result in alveolar overdistention with compression and obliteration of surrounding pulmonary capillaries. This alveolar overdistention may actually worsen oxygenation by increasing the shunt fraction. Moreover, dead space ventilation may be increased, resulting in a higher minute ventilation requirement. Finally, PEEP may cause a maldistribution of tidal volumes and pressures, creating overdistension of normally aerated lung regions. This hyperinflated form of lung injury may result in barotrauma referred to as *volutrauma*.

The optimal approach to PEEP for ARDS remains a matter of debate. In the ARDSNet study, patients ventilated with lower V_T required higher levels of PEEP (9.4 vs 8.6 cm H_2O) to maintain oxygen saturation greater than 85%, leading some to speculate that the improved survival rates were due to higher levels of PEEP. However, three subsequent RCTs, including the ARDSNet trial of higher versus lower PEEP levels in patients with ARDS, have failed to demonstrate additional benefit of higher PEEP in patient outcomes.[81-83] It is likely, however, that these trials enrolled patients who had both a lower and a greater potential for alveolar recruitment. Gattinoni et al[84] found that in patients with ARDS, the percentage of potentially recruitable lung differs widely. With the use of higher levels of PEEP, there can be an associated increase in plateau pressure in patients who have regions of lung that are nonrecruitable with a higher risk of overdistention of already recruited alveoli. Patients with recruitable lungs have proportionally less increase in plateau pressure when higher levels of PEEP are used and may benefit from PEEP with less risk of overdistention.[85]

In the individual patient, the application of PEEP needs to be balanced between providing a sufficient inspiratory plateau pressure (peak alveolar pressure) to maintain adequate oxygenation and at the same time avoiding derecruitment of the alveoli during exhalation. Today, many centers have adopted the algorithm-driven approach adopted by the ARDSNet investigators where PEEP was individually titrated with combinations of PEEP and F_{IO_2} selected for a target level of arterial oxygenation. The advantage of a ratio approach is that it can be done without measurement of pulmonary compliance curves or invasive hemodynamic monitoring. One disadvantage is that it is not necessarily applicable to an individual patient with individual physiology. Despite this criticism, this approach has been used in all of the trials conducted by ARDSNet and carries validity.

The PV curve has also been used to select optimal PEEP. In this approach, static PV curves are used to select a PEEP level above the lower inflection point to prevent alveolar end-expiratory collapse. Although this approach is intriguing, static PV curves can be difficult to obtain as well as to implement. Measurement of the PV also requires sedation and often paralysis as patient effort may confound measurements of inflection points. Further evidence is needed before the PV curve can used routinely to determine optimal PEEP. Other methods for selecting PEEP include use of the stress index (the shape of the pressure–time curve during constant flow volume-controlled ventilation), use of esophageal pressure monitoring to maintain positive transpulmonary pressure, and use of imaging techniques such as CT, electrical impedance tomography, and ultrasound to evaluate PEEP settings.[85]

Recruitment Maneuvers

A recruitment maneuver is a transient increase in transpulmonary pressure to promote reopening of collapsed alveoli. The use of recruitment maneuvers in ARDS for the symptomatic treatment of hypoxemia is still a matter of debate. Complications secondary to recruitment maneuvers such as desaturation or hypotension are common, but serious complications, such as a new air leak through an existing chest tube, are infrequent.[86] A systematic review and meta-analysis including 10 RCTs reported a decrease in hospital mortality with the use of recruitment maneuvers; however, there is concern about the risk of bias in the included studies and the use of concomitant therapeutic strategies.[87] Some groups advocate use of recruitment maneuvers as rescue therapy in patients with ARDS who have life-threatening hypoxemia.

New light was shed on this debate with the recent results of the Alveolar Recruitment for Acute Respiratory Distress Syndrome Trial (ART). Investigators randomized patients with moderate to severe ARDS to low PEEP and low tidal volume as standard treatment versus an experimental treatment group consisting of incremental high PEEP recruitments up to 45 cm H_2O. After recruitment, PEEP was decreased to what was best respiratory compliance to determine optimal PEEP, then followed by another recruitment maneuver. Thereafter, tidal volume was adjusted to optimal PEEP, low tidal volume (4–6 mL/kg), and plateau pressures below 30 cm H_2O. At 28 days, death was higher in the intervention group (55%) compared to the control group (49%). Death was still higher at 6 months in the intervention group (65%) compared to the control group (60%). Patients being recruited also had a higher incidence of pneumothorax and requirement of pneumothorax drainage.[88] The Sigh Ventilation to Increase Ventilator-Free Days in Victims of Trauma at Risk for Acute Respiratory Distress Syndrome (SiVent) trial is a large ongoing trial that randomizes trauma patients on mechanical ventilation to standard mechanical ventilation or the treatment group of a "sigh" breath every 6 minutes. The sigh breath gives a tidal volume that produces a plateau pressure of 35 cm H_2O (or 40 cm H_2O in morbidly obese patients or those with significant abdominal distention). Notably, the time at higher PEEP for recruitment will be markedly shorter in this trial, although more frequent. The SiVent trial with a different recruitment strategy will give important insights regarding regular recruitment in trauma patients and how it could potentially decrease rates of ARDS.

Equally as important as recruiting new alveoli is maintaining recruitment. Our institution uses a protocol of pressure support and PEEP of 40/20 for 2 minutes as a recruitment maneuver and then will keep the PEEP at 2 cm H_2O above what the previous value PEEP was prior to the recruitment. A common pitfall we have seen leading to significant derecruitment is when ventilator tubing is exchanged, such as when patients are being transported to and from the operating room. We commonly clamp the endotracheal tube prior to disconnecting from the ventilator to prevent the airway pressure drop from an open airway and subsequent derecruitment.

Prone Ventilation

Prone positioning has been used for more than 30 years in patients with acute hypoxemic respiratory failure and ARDS. Initially, prone positioning in ARDS patients was found to be an efficient technique to improve oxygenation as a rescue treatment in case of life-threatening hypoxemia; it is also now evident that prone positioning is able to prevent VILI. Therefore, prone positioning is a strategy that covers the two major goals of ventilator support in ARDS patients: maintaining safe oxygenation, and preventing VILI.

Since the initial description by Bryan[89] of the beneficial effects of the prone position on arterial oxygenation more than 40 years ago, it is remarkable that it took 20 years for the first RCT to be performed. Several early RCTs showed an improvement in survival with prone positioning.[90-93] However, meta-analyses[94,95] have since shown benefit in severe ARDS subgroups. A recently published RCT by the Proning Severe ARDS Patients (PROSEVA) Study Investigators[96] assigned 466 patients with severe ARDS to undergo prone-positioning sessions of at least 16 hours or to be left in the supine position. The 28-day mortality was 16.0% in the prone group and 32.8% in the supine group (P <.001). Furthermore, unadjusted 90-day mortality was 23.6% in the prone group versus 41.0% in the supine group (P <.001), with a hazard ratio of 0.44 (95% confidence interval [CI], 0.29–0.67). Importantly, there was no significant difference in the incidence of complications between the groups, except for the incidence of cardiac arrests, which was higher in the supine group.

The mechanisms by which prone positioning improves survival in patients with severe ARDS are multifactorial.[97] Pappert et al[98] used the multiple inert gas elimination technique and showed that the improvement in oxygenation was the result of decreased intrapulmonary shunt fraction. Albert and coworkers have investigated the mechanism of prone ventilation in a canine oleic acid model of ARDS. The prone position consistently reduced shunt fraction compared with the supine position. The improvement in gas exchange was independent of changes in cardiac output or FRC between the two positions. Subsequently, pulmonary blood flow was shown to be distributed preferentially to dorsal lung regions in the supine and prone positions.[99] In supine animals, pleural pressure increases from nondependent to dependent regions. This may lead to dependent atelectasis in the highly perfused dorsal lung regions, resulting in intrapulmonary shunt and hypoxemia. In the prone position, the pleural pressure gradient is less, and the dorsal (now nondependent) regions are exposed to a lower pleural pressure. This results in opening of previously atelectatic alveoli. Intrapulmonary shunting is reduced because perfusion of the dorsal lung regions is maintained.[100] Using chest CT, Gattinoni et al[90] showed that in the supine position, gasless lung was found predominantly in the dorsal regions. With prone positioning, densities redistributed to the ventral areas and dorsal regions were well aerated. Thus, prone positioning results in recruitment of previously atelectatic dorsal lung regions.

In addition to improvement in oxygenation, there is increasing evidence regarding the effects of prone position on respiratory mechanics and lung volume. In adult humans with ARDS, chest wall elastance, which contributes to set the end-expiratory lung volume (EELV), has consistently been found to be higher in the prone than in the supine position.[97] Pelosi et al[101] found that sighs superimposed on the prone position further increased EELV and oxygenation only in the prone position, suggesting that the prone position extends the potential for recruitment. Lung CT scan studies have also shown that the prone position promotes lung recruitment as compared to the supine position regardless of whether PEEP was low or high in the supine position.[84]

Because vascular dysfunction is a major independent factor associated with ARDS mortality, the beneficial effects of prone positioning on hemodynamics have been shown to be important. These effects include the reduction of the transpulmonary gradient (the difference of mean pulmonary arterial pressure relative to pulmonary artery occlusion pressure).[102] Also, the increase in pulmonary arterial occlusion pressure induced by prone positioning is thought to result in pulmonary vascular recruitment, thus decreasing dead space, another factor independently related to ARDS mortality.[102] There is also evidence that prone positioning unloads the right ventricle in severe ARDS,[103] which may play a role in patient outcome.

Another important benefit of prone positioning appears to be prevention of VILI. Broccard et al[104] showed that prone positioning attenuates and redistributes VILI in dogs. Papazian et al[105] also found lower concentrations of proinflammatory cytokines in BAL fluid in ARDS patients after 12 hours in the prone position compared to supine position in similar settings.

The technical aspects of prone positioning require a coordinated team effort. Prone positioning must be performed with care to avoid inadvertent extubation or loss of intravenous lines or chest tubes. Transient hemodynamic instability and desaturation also may occur during repositioning. Cardiopulmonary resuscitation is difficult, if not impossible, in the prone position. Placement of multifunction electrode pads, which allow defibrillation, cardioversion, and pacing, has been recommended to facilitate cardiopulmonary resuscitation in the prone position. Other areas of concern that accompany prone positioning include facial and eyelid edema, peripheral nerve injury, tongue injuries, and skin necrosis. Multiply injured patients may present unique problems due to the presence of incisions, drainage tubes, extremity fractures, cervical spine fractures, or facial fractures, and the like.

High-Frequency Ventilation

Recognition of the impact of mechanical ventilation on VILI naturally led to an interest in the use of high-frequency oscillatory ventilation (HFOV); after all, this might be considered the ultimate in "low tidal volume ventilation." High-frequency ventilation techniques such as HFOV use very small tidal volumes (1–5 mL/kg) delivered at rates of 60 to 3600 cycles/min. Although peak airway pressures are reduced compared with conventional modes, mean airway pressures, barotrauma, and hemodynamic compromise appear unchanged. The OSCILLATE (OSCillation in ARDS Treated Early) trial[106] showed that HFOV did not reduce, and may increase, in-hospital mortality. HFOV was also associated with higher mean airway pressures and greater use of sedatives, neuromuscular blockers, and vasoactive drugs. The OSCAR (High-Frequency Oscillation in ARDS) trial[107] also showed that HFOV failed to reduce 30-day mortality in patients undergoing mechanical ventilation for ARDS. The disappointing results of these two major trials have cast doubt on the benefits of HFOV in ARDS. A recent meta-analysis again showed increased mortality in patients with mild to moderate ARDS when HFOV was used; however, results are less clear in severe ARDS.[108]

In light of the available evidence and until further trials address the previously discussed issues, HFOV should likely be reserved for a subset of patients with refractory hypoxemia. When using HFOV, monitoring lung recruitment and right ventricular function to ensure achievement of appropriate physiologic goals is crucial.

Extracorporeal Life Support (See Atlas Figures 38 and 39)

Extracorporeal life support (ECLS), also called extracorporeal membrane oxygenation (ECMO), has been in clinical use since 1972. The most common type of ECLS used in ARDS patients is venovenous (V-V) ECLS, where blood is both withdrawn from and returned to the venous system. Blood is withdrawn into an extracorporeal circuit by a mechanical pump before entering an oxygenator. A membrane within the oxygenator provides a blood–gas interface for diffusion of gases. The "flow" of blood to this membrane helps to control oxygenation and can be dialed up or down depending on the support needed. The "sweep" gas at this membrane is typically 100% oxygen or carbogen (5% CO_2, 95% O_2) and blows away CO_2 that has diffused from blood and similarly can be fine-tuned to control patient blood CO_2 levels. The oxygenated extracorporeal blood can be warmed or cooled as needed and then returned to the body.

The results of two early RCTs in patients with ARDS (published in 1997[109] and 1994[110]) did not show a survival benefit with ECLS, including extracorporeal CO_2 removal (a related technique). The old ECLS circuits were difficult to manage and potentially hazardous, with a relatively high complication rate. Recently, technologic advancements in circuitry, including introduction of dual lumen percutaneous catheters and better pumps and oxygenators, have been instrumental in improving patient outcomes and wider adaptation of this therapy. Recent observational studies have suggested a benefit in severe cases of ARDS, with survival rates ranging from 47% to 66%.[111-113] Widespread interest in use of ECLS intensified with the H1N1 influenza epidemic in 2008 to 2009 that resulted in thousands of cases of severe respiratory failure, often with concomitant septic shock generated.

The use of ECLS in these critically ill patients was associated with an impressive 70% survival rate.[114-116]

The Conventional Ventilator Support Versus ECMO for Severe Adult Respiratory Failure (CESAR) trial[117] was the first controlled clinical trial using modern ECMO technology. In this trial, 180 patients were allocated to either continued conventional management or referral to a specialized center with a standardized management protocol that included consideration for treatment with ECLS—75% of those allocated patients eventually received ECLS. Of the patients randomized to ECLS, 63% survived to 6 months without disability compared to 47% of those assigned to conventional management. However, this study was not a randomized trial of ECLS compared with standard lung-protective ventilation. In fact, only 70% of patients in the conventional management group received lung-protective ventilation. Despite these limitations, this trial provides support for transferring patients with severe ARDS to a tertiary care center that is capable of advanced ventilator management techniques and not necessarily the ability to carry out ECMO.

The ECMO to Rescue Lung Injury in Severe ARDS (EOLIA) trial results were just recently published, and the trial attempts to provide clarity on the utility of early ECMO compared to standard ventilation of severe ARDS.[118] As opposed to the CESAR trial, nearly all of the patients randomized to ECMO were in fact cannulated. This trial also did a better job of standardizing treatment for the control group including lung-protective ventilation. The trial was stopped early because it was determined that the preset absolute risk reduction of 20% would not be met, and the authors concluded that early ECMO was not superior to conventional treatment. Because the trial was ended early, it was likely underpowered, but there is still much to learn from it. Before trial termination, mortality at 60 days was 35% in the ECMO group and 46% in controls. Importantly, 28% of patients in the conventional treatment arm were allowed to cross over to ECMO for refractory hypoxemia, which could dilute the ECMO treatment effect. It also showed that complications between the groups were the same, highlighting that ECMO can be used safely.

The CESAR and EOLIA trials highlight the uncertainty regarding which patients with ARDS are the best candidates for this treatment and the optimal timing for initiation of therapy. In general, indications for ECLS in patients with ARDS include one or more of the following: severe hypoxemia, uncompensated hypercapnia, and the presence of excessively high end-inspiratory plateau pressures (Table 59-7).[118] According to the 2017 Extracorporeal Life Support Organization (ELSO) guidelines,[119] the use of ECMO should be considered when the ratio of Pao_2 to Fio_2 is less than 150, and ECMO is indicated when the ratio is less than 80. CO_2 retention despite a plateau pressure greater than 30 cm H_2O is also considered an indication for ECMO in patients with ARDS, as are severe air leak syndromes, need for intubation for patients listed for lung transplant, or acute cardiac or respiratory collapse. There are no absolute contraindications; however, the following should be thoughtfully considered if ECMO is considered because they portend a poorer outcome: mechanical ventilation at high settings for 7 days, major pharmacologic immunosuppression, recent or expanding CNS hemorrhage, nonrecoverable comorbidity, and increasing age.[119]

Obtaining vascular access is done by cannulation of large vessels in the neck or groin. Where and how to place cannulas depends on the status of the patient. For patients with adequate cardiac function, V-V ECMO will be chosen and drainage and return cannulas will be placed in the femoral and jugular veins. These cannulas have the advantage of ease and can be placed percutaneously or via cut-down, without the need for fluoroscopy. Groin lines, however, limit the ability for patients to ambulate. Most centers have shifted to the use of a single (dual lumen) large cannula placed under fluoroscopic guidance as the preferred approach for adults requiring V-V ECMO.[120] The Avalon cannula is commonly used at our institution and drains the superior vena cava and inferior vena cava, and has a side hole on the reinfusion lumen that is oriented toward the tricuspid valve. Proper placement requires adequate imaging, typically fluoroscopy. Without proper placement, recirculation will be an issue and limit the effectiveness of ECMO therapy. The main advantage of these cannulas is that mobility of patients is greatly facilitated. If a patient is unstable for transport to the operating room for dual lumen cannula placement, two single-lumen cannulas can certainly be exchanged for a dual lumen cannula at a later date. Similarly, cannulas can be added at any time if blood flow resistance is too high such that there is inadequate venous drainage. If there is cardiac instability, venoarterial ECMO can be considered with cannulation typically of the femoral artery that provides pressurized blood return to augment cardiac function. It should be noted that in patients with severe respiratory compromise, cardiac function will often improve on V-V ECMO as the patient's respiratory status improves.[119]

Cannulas and lines are thrombogenic. Thrombotic and embolic risks are real with ECMO, and as such, patients are anticoagulated. Just prior to cannulating, a heparin bolus is given (ELSO recommends 50–100 units/kg), followed by a continuous infusion during the run of ECLS. An activated clotting time goal of 1.5 times normal is a typical goal. Partial thromboplastic time and thromboelastography may also be used to titrate effect of heparin. If bleeding is uncontrollable and anticoagulation must be stopped, flow should be kept high and a replacement circuit should be nearby if the circuit clots.[119]

The most appropriate strategy for weaning patients with ARDS from ECMO is a matter of debate. Typically, weaning from ECMO starts when improvement is noted in oxygenation, chest radiography findings, or lung compliance. At that time, the flow rate of sweep gas is decreased to compensate for increase in lung ventilation. Lung-resting ventilation is then transitioned to standard lung-protective settings or pressure-support ventilation. When ECLS support is less than 30% of total, native lung function may be adequate and a trial off is indicated.[119]

TABLE 59-7: Indications and Contraindications for ECMO in Severe Cases of ARDS

Indications:

1. In hypoxic respiratory failure due to any cause (primary or secondary), ECLS should be considered when the risk of mortality is 50% or greater and is indicated when the risk of mortality is 80% or greater
   a. 50% mortality risk is associated with a Pao_2/Fio_2 <150 on Fio_2 >90% and/or Murray score 2–3
   b. 80% mortality risk is associated with a Pao_2/Fio_2 <100 on Fio_2>90% and/or Murray score 3–4 despite optimal care for 6 h or more
2. CO_2 retention on mechanical ventilation despite high Pplat (>30 cm H_2O)
3. Severe air leak syndromes
4. Need for intubation in a patient on lung transplant list
5. Immediate cardiac or respiratory collapse (pulmonary embolus, blocked airway, unresponsive to optimal care)

Contraindications:

There are no absolute contraindications to ECLS, as each patient is considered individually with respect to risks and benefits. There are conditions, however, that are associated with a poor outcome despite ECLS and can be considered relative contraindications.

1. Mechanical ventilation at high settings (Fio_2 >0.9, Pplat >30) for 7 days or more
2. Major pharmacologic immunosuppression (absolute neutrophil count <400/mm^3)
3. Central nervous system (CNS) hemorrhage that is recent or expanding
4. Nonrecoverable comorbidity such as major CNS damage or terminal malignancy
5. Age: no specific age contraindication but consider increasing risk with increasing age

ARDS, acute respiratory distress syndrome; CO_2, carbon dioxide; ECLS, extracorporeal life support; ECMO, extracorporeal membrane oxygenation; Pplat, plateau pressure.
Source: Based on Extracorporeal Life Support Organization (ELSO) guidelines for adult respiratory failure.

The usual duration of ECLS in patients with ARDS is 7 to 10 days; however, survival rates of 50% to 70% with native lung recovery are increasingly reported in cases of prolonged-duration ECLS (>14 days).[112,121] With advances in component technology and the techniques used to perform ECLS, serious complications have been reduced significantly. In the CESAR trial, only one serious adverse event related to ECLS was reported (a death related to vessel perforation during cannulation). In the EOLIA trial, bleeding requiring transfusion was the most common adverse event (46%), although massive bleeding was rare (2%). Other common complications in the ECMO group included thrombocytopenia (40%), ventilator-associated pneumonia (2%), and cardiac rhythm disturbances (31%). Stroke incidence was rare (2%).[118]

PHARMACOLOGIC THERAPY OF ACUTE RESPIRATORY DISTRESS SYNDROME

The diversity of approaches to pharmacologic therapy for ARDS reflects the complex pathophysiology. Many therapies have been tested in randomized trials in humans including NO, corticosteroids, immunomodulating agents, pulmonary vasodilators, antioxidants, and surfactants.

Inhaled Nitric Oxide and Prostacyclin

NO is responsible for regulation of basal vascular tone. Inhaled NO (iNO) is a selective pulmonary vasodilator with no systemic side effects. Moreover, delivery of iNO exposes only ventilated alveoli to its vasodilatory effects. Selective vasodilation of pulmonary vessels in ventilated areas diverts blood away from nonventilated areas, improving ventilation/perfusion matching and hypoxemia. Inhaled NO decreases mean pulmonary artery pressure and, in doing so, lessens the hydrostatic pressure for pulmonary edema.[122] For all of these reasons, iNO has seemed very attractive for use in severely hypoxemic patients; however, data from clinical trials in humans have been disappointing. The largest multicenter RCT of iNO for treatment of ARDS assigned 385 patients to placebo (nitrogen gas) or iNO at 5 ppm until 28 days, discontinuation of assisted breathing, or death. iNO at a dose of 5 ppm resulted in short-term oxygenation improvements in patients with ALI not due to sepsis and without evidence of nonpulmonary organ system dysfunction; however, there was no substantial impact on the duration of ventilatory support or mortality.[123] A Cochrane Review of 14 prospective RCTs of iNO versus placebo or standard therapy showed a statistically significant but transient improvement in oxygenation in the first 24 hours but no statistically significant effect on overall mortality. Concerningly, iNO appeared to increase the risk of renal impairment among adults.

Currently, the role of iNO should be limited to short durations (24–96 hours) in patients with severe, refractory hypoxemia or pulmonary hypertension in whom iNO may act as a "bridge," allowing short-term physiologic support. Application of iNO in these situations may allow for possible patient survival until other therapies may be employed such as pronation or alternative modes of ventilation.

Aerosolized prostacyclins are potent vasodilators with similar effects as iNO including reduction of pulmonary arterial hypertension, improvement in right-heart function, and improvement in ventilation/perfusion matching.

There has been an interest in use of aerosolized prostacyclins as an alternative to iNO due to various advantages (cost, setup, and administration). Similar to iNO, trials of aerosolized prostacyclin have shown transient improvement in oxygenation but no significant differences in mortality, ventilator-free days, or reduction in disease severity.[124] These trials have been limited by small sample sizes, lack of appropriate control subjects, and varying doses, timing, and modes of delivery of the drugs.

Corticosteroids

The ability of corticosteroids to attenuate the inflammatory response would seem to make them ideal treatment for ARDS. From the first description of ARDS, corticosteroids were suggested as possible therapeutic agents. Controversy remains as to whether low-dose corticosteroids can reduce the mortality and morbidity ARDS without increasing the risk of adverse reactions. Early RCTs to assess the use of corticosteroids in patients with respiratory failure at risk of developing ARDS showed no role for steroids in the prevention of ARDS.[125] Large prospective clinical trials have also failed to show any survival benefit with high-dose steroids in early ARDS. The earliest trial, by Bernard et al,[126] tested 30 mg/kg of intravenous methylprednisolone every 6 hours for a total of four doses, with the hypothesis that this treatment would reduce 45-day mortality. However, the study was stopped early after enrolling 99 patients, with 60% mortality in the methylprednisolone group and 63% in the control group.[126] Another RCT by Meduri et al[127] in 2007 that examined the effect of low-dose methylprednisolone given during the first 72 hours of onset of ARDS showed improvement in pulmonary outcomes, including LIS and ventilator-free days, but no significant difference in mortality.

With evidence mounting against treatment with corticosteroids for prevention and early treatment of ARDS, trials have shifted toward evaluating the utility for treatment of the late, proliferative phase of ARDS, with the understanding that the pathogenetic mechanisms initiating early ARDS differ from those of the late stages. A number of anecdotal reports and small series have suggested that high-dose corticosteroids may be of some benefit during late ARDS.[128,129] The ARDSNet conducted a multicenter RCT of 180 patients with ARDS of at least 7 days in duration who were assigned to either methylprednisolone or placebo. Methylprednisolone treatment did increase the number of ventilator-free days, improved oxygenation and respiratory compliance, and resulted in less vasopressor use without a difference in ICU length of stay. There was no overall difference in 60-day mortality; however, among patients enrolled after day 13 of ARDS, mortality was 12% in the placebo group compared with 44% in the steroid group, suggesting that steroids may be harmful if administered too late in the course of ARDS. Interestingly, the rate of infectious complications was no different between the groups, but the methylprednisolone group had a higher incidence of neuromuscular weakness and hyperglycemia. Given the challenges of this patient group, any use of steroids for late ARDS must be individualized and, optimally, delivered before disease day 14. Several meta-analyses have failed to conclusively support routine use of corticosteroids for treatment of early or late ARDS.[125,130-132] Well-designed RCTs are needed to understand the potential benefits of steroid treatment in the face of short- and long-term risks, including delayed recovery and impairments in physical function and health-related quality of life.

Neuromuscular Blockade

Neuromuscular blockade or paralysis can improve ventilator dyssynchrony and also prevent phenomena such as breath stacking that can cause injury. The ACURASYS study used cisatracurium for 48 hours early in ARDS and found improved 90-day mortality, as well as more ventilator-free days in patients receiving paralytic. These data need to be confirmed, and we will have important insights after the Reevaluation of Systemic Early Neuromuscular Blockade (ROSE) trial is completed.[133]

Exogenous Surfactant

Surfactant dysfunction with quantitative and qualitative abnormalities of phospholipids and proteins is a pathologic feature of ARDS. Results for surfactant therapy in infants with the respiratory distress syndrome of prematurity were dramatic, with improvement in gas exchange and lung mechanics and decrease in CPAP requirement and barotrauma. Unfortunately, results in adult ARDS patients have not been consistent. This is likely due to differences in pathophysiology because ARDS is characterized by surfactant inhibition by plasma constituents and increased breakdown by activated oxidative and hydrolytic pathways, whereas the deficiency of surfactant is the primary pathology in premature infants.[134] Several RCTs of surfactant replacement in adults with ARDS have shown improvements in oxygenation indices but have failed to produce any demonstrable survival benefits, as noted by a recent meta-analysis of nine RCTs.[135] Further understanding of which patients may benefit the most from this type of therapy as well as refinement of surfactant preparations may offer hope in the future use of this therapy.

Antioxidants

It is well known that indices of oxidative damage, including neutrophil recruitment, lipid peroxidation, and protein degradation, are higher in patients who die of ARDS. Natural antioxidants such as glutathione have been shown to be depleted in the lungs of ARDS patients. This has been the rationale behind using agents that increase glutathione levels such as *N*-acetylcysteine (NAC) and procysteine. A Cochrane

analysis of five studies using NAC that randomized 239 patients showed no statistically significant effect of NAC on early mortality and inconclusive results regarding duration of mechanical ventilation or ventilator-free days to day 28.[132] Currently, no clear evidence exists for use of NAC or procysteine in the treatment of ARDS patients.

Anti-Inflammatory Therapies

Neutrophil elastase, a serine protease with antimicrobial and anti-inflammatory actions, has been implicated in the pathogenesis of ARDS. Silvelestat, a neutrophil elastase inhibitor, was investigated in the STRIVE trial, an international, multicenter RCT.[136] The study was stopped prematurely due to an increase in 180-day all-cause mortality. A recent meta-analysis of eight clinical trials (including STRIVE) has shown no benefit in short-term mortality and a worse outcome for 180-day mortality.[137]

Statins have also been tested as anti-inflammatories to treat patients with ARDS. Two large trials have compared either rosuvastatin (SAILS trial) or simvastatin (HARP-2 trial) to placebo. No difference was found in either mortality or ventilator-free days, suggesting statins should not be used routinely in ARDS.[138,139]

Antiplatelet Therapy

Because of the observational data showing platelets may contribute to lung injury and aspirin may prevent lung injury, a randomized trial was done giving aspirin therapy to patients deemed at being at elevated risk for ARDS development. Unfortunately, this trial did not show any benefit to aspirin in regard to ARDS development, ventilator-free days, or survival.[140]

β-Agonist

Because of data showing β_2-agonists can accelerate resolution of pulmonary edema, trials have been performed using salbutamol in ARDS patients and to prevent ARDS. It can in fact decrease pulmonary edema; however, the trials have failed to show a survival benefit, and one was terminated early because of increased mortality in patients receiving salbutamol.[141,142]

Nutritional Support

Nutrition support in critically ill patients with ALI and ARDS is a vital aspect of treatment. The proinflammatory and hypercatabolic response seen with ALI/ARDS can lead to significant nutrition deficits. Proper nutrition support is necessary to prevent cumulative caloric deficits, malnutrition, loss of lean body mass, and deterioration of respiratory muscle strength. Early enteral nutrition has been shown to attenuate disease severity and immune response to injury. The optimal dosage, composition of fatty acids, and ratio of individual immune-modulating nutrients in specialized enteral formulations remain controversial; however, a meta-analysis of three trials showed that a diet enriched with eicosapentaenoic acid (EPA), γ-linolenic acid (GLA), and antioxidants resulted in reduction in mortality, increase in ventilator- and ICU-free days, improvement in oxygenation, and reduction in the risk of developing new organ failures.[143] The Omega arm of the ARDSNet EDEN-Omega study, which was studying enteral omega-3, GLA, and antioxidant supplementation, was terminated early due to futility.[144] The EDEN arm compared enteral trophic feeds to full enteral feeds for the first 6 days after ALI and found no difference in mortality or ventilator-free days between the groups.[145] However, based on existing data, American Society for Parenteral and Enteral Nutrition/Society of Critical Care Medicine guidelines, and the Canadian clinical practice guidelines, an enteral diet enriched with omega-3 fatty acid, GLA, and antioxidant supplementation should be considered in patients with ALI/ARDS.[146]

Careful monitoring of nutritional support may be necessary in patients with tenuous respiratory status. An indirect calorimeter can be helpful in providing estimates of CO_2 production and the respiratory quotient. The respiratory quotient should be kept below 0.9 by appropriate adjustment of the proportion of lipid and total calories administered. Overfeeding patients or administering excess carbohydrates can lead to excess production of CO_2. In the setting of marginal ability to execute work of breathing, this may, in theory, precipitate or prolong hypercapnic pulmonary failure. Our goals for nutritional support are to deliver 21 to 25 nonprotein cal/kg/d and 0.25 to 0.30 g of nitrogen/kg/d. The primary goal of carbohydrate administration should be a rate of less than 5 mg/kg/min.

OUTCOME OF ACUTE RESPIRATORY DISTRESS SYNDROME

Mortality associated with ARDS has historically been reported from 30% to 60% with significant variation due to age and risk factors (see the section "Risk Factors for Acute Respiratory Distress Syndrome"). The majority of deaths are related to sepsis and MOF (see Chapter 63). Respiratory failure is a cause of death in only 15% of patients. There has been a gradual improvement in overall incidence and mortality of ARDS patients across several RCTs in the past two decades, with the most recent rates as low as 20% to 25%.[147] Going beyond mortality, survivors of ARDS have significant physical limitations, even at 5 years after their illness despite normal or near-normal lung function, showing the physical impact an episode of ARDS can have on long-term outcomes.[148]

The principal therapy that improves outcome in patients with ARDS appears to be low tidal volume ventilation,[149] but other improvements in critical care delivery and goal-directed care reduce ARDS incidence as well (Fig. 59-4).

NIH NHLBI ARDS Clinical Network Mechanical Ventilation Protocol Summary

PART I: VENTILATOR SETUP AND ADJUSTMENT

1. Calculate predicted body weight (PBW)
   - **Males** = 50 + 2.3 [height (inches) -60]
   - **Females** = 45.5 + 2.3 [height (inches) -60]
2. Select any ventilator mode
3. Set ventilator settings to achieve initial V_T = 8 ml/kg PBW
4. Reduce V_T by 1 ml/kg at intervals ≤ 2 hours until V_T = 6 ml/kg PBW.
5. Set initial rate to approximate baseline minute ventilation (not > 35 bpm).
6. Adjust V_T and RR to achieve pH and plateau pressure goals below.

OXYGENATION GOAL: **PaO_2 55-80 mmHg or SpO_2 88-95%**
Use a minimum PEEP of 5 cm H_2O. Consider use of incremental FiO_2/PEEP combinations such as shown below (not required) to achieve goal.

Lower PEEP/higher FiO_2

FiO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12

FiO_2	0.7	0.8	0.9	0.9	0.9	1.0
PEEP	14	14	14	16	18	18-24

Higher PEEP/lower FiO_2

FiO_2	0.3	0.3	0.3	0.3	0.3	0.4	0.4	0.5
PEEP	5	8	10	12	14	14	16	16

FiO_2	0.5	0.5-0.8	0.8	0.9	1.0	1.0
PEEP	18	20	22	22	22	24

pH GOAL: 7.30-7.45
Acidosis Management: (pH < 7.30)

- **If pH 7.15-7.30**: Increase RR until pH > 7.30 or $PaCO_2$ < 25 (Maximum set RR = 35).
- **If pH < 7.15**: Increase RR to 35.
  If pH remains < 7.15, V_T may be increased in 1 ml/kg steps until pH> 7.15 (Pplat target of 30 may be exceeded).
  May give $NaHCO_3$

Alkalosis Management: (pH > 7.45): Decrease vent rate if possible.

I: E RATIO GOAL: Recommend that duration of inspiration be ≤ duration of expiration.

PLATEAU PRESSURE GOAL: ≤ 30 cm H_2O
Check Pplat (0.5 second inspiratory pause), at least q 4h and after each change in PEEP or V_T.
If Pplat > 30 cm H_2O: decrease V_T by 1ml/kg steps (minimum = 4 ml/kg).
If Pplat < 25 cm H_2O and V_T < 6 ml/kg: increase V_T by 1 ml/kg until Pplat > 25 cm H_2O or V_T = 6 ml/kg.
If Pplat < 30 and breath stacking or dys-synchrony occurs: may increase V_T in 1ml/kg increments to 7 or 8 ml/kg if Pplat remains ≤ 30 cm H_2O.

PART II: WEANING

A. Conduct a SPONTANEOUS BREATHING TRIAL daily when:

1. FiO_2 ≤ 0.40 and PEEP ≤ 8 OR FiO_2 ≤ 0.50 and PEEP ≤ 5.
2. PEEP and FiO_2 ≤ values of previous day.
3. Patient has acceptable spontaneous breathing efforts. (May decrease vent rate by 50% for 5 minutes to detect effort.)
4. Systolic BP ≥ 90 mmHg without vasopressor support.
5. No neuromuscular blocking agents or blockade.

B. SPONTANEOUS BREATHING TRIAL (SBT):
If all above criteria are met and subject has been in the study for at least 12 hours, initiate a trial of UP TO 120 minutes of spontaneous breathing with FiO_2 ≤ 0.5 and PEEP ≤ 5:

1. Place on T-piece, trach collar, or CPAP ≤ 5 cm H_2O with PS ≤ 5
2. Assess for tolerance as below for up to two hours.
   a. SpO_2 ≥ 90: and/or PaO_2 ≥ 60 mmHg
   b. Spontaneous V_T ≥ 4 ml/kg PBW
   c. RR ≤ 35/min
   d. pH ≥ 7.3
   e. No respiratory distress (distress = 2 or more)
      - HR > 120% of baseline
      - Marked accessory muscle use
      - Abdominal paradox
      - Diaphoresis
      - Marked dyspnea
3. If tolerated for at least 30 minutes, consider extubation.
4. If not tolerated resume pre-weaning setting

Definition of UNASSISTED BREATHING
(Different from the spontaneous breathing criteria as PS is not allowed)
1. Extubated with face mask, nasal prong oxygen, or room air, OR
2. T-tube breathing, OR
3. Tracheostomy mask breathing, OR
4. **CPAP less than or equal to 5 cm H_2O without pressure support or IMV assistance.**

FIGURE 59-4 ARDS Network mechanical ventilation protocol. CPAP, continuous positive airway pressure; HR, heart rate; PEEP, positive end-expiratory pressure; Pplat, plateau pressure; PS, pressure support; RR, respiratory rate. Gastrointestinal Failure

Jose J. Diaz • Bryan Collier

KEY POINTS

- In the critically ill or injured patient, gut dysfunction commonly occurs and can take various forms, from food intolerance to life-threating conditions that can progress to multiple organ dysfunction syndrome (MODS) or persistent inflammatory, immunosuppressed, catabolic syndrome (PICS).
- Gut injury can be described as an ischemia/reperfusion event that can present as severe as nonocclusive small bowel ischemia to the abdominal compartment syndrome.
- More commonly, gastrointestinal (GI) dysfunction will manifest as gastroesophageal reflux, gastroparesis, duodenogastric ileus, or malabsorption as a manifestation of food intolerance.
- Recognition of the human microbiome as an important component of gut health and the alterations in the microbiome during critical illness has spurred renewed interest in the microbiology of the GI tract.
- The chapter will review the pathophysiology and the current best practice recommendations for medical management.

INTRODUCTION

In the critically ill or injured patient who survives the initial 48 hours in the intensive care unit (ICU), multiple organ dysfunction syndrome (MODS) and multiple organ failure (MOF) are the leading causes of death in the ICU (see Chapter 63). First, there is strong evidence that during the early stages of shock and reperfusion, episodes of abdominal compartment syndrome (ACS) and gut hypoperfusion can lead to organ dysfunction and death.[1-3] Second, there is growing evidence that the gut microbiome changes soon after injury. The proximal gut, which is typically sterile, develops heavy colonization that can be harmful. These bacteria can have harmful effects on the gut homeostasis and barrier function.[4-12] Third, gut-focused medical therapies such as selective gut decontamination, early enteral nutrition, and most recently immune-enhancing enteral diets have been shown to reduce these nosocomial infections.[6,13-18] The focus of this chapter is to provide an overview of the gut dysfunction of the injured and critically ill patient and how it contributes to overall morbidity and mortality. The discussion will then focus on the pathogenesis and clinical monitoring of specific gut dysfunctions. Based on this information, potential therapeutic strategies to prevent and/or treat gut dysfunction to enhance patient outcome will be discussed.

HOW GUT DYSFUNCTION CONTRIBUTES TO ADVERSE PATIENT OUTCOME

Multiple Organ Failure

MOF results from a dysfunctional, hyperinflammatory response producing two distinct patterns (ie, early vs late) (see Chapter 57). Soon after a traumatic insult, patients are found to be in a state of systemic hyperinflammation, referred to as the systemic inflammatory response syndrome (SIRS).[19-21] The intensity of SIRS is dependent upon (1) innate host factors (genotype/phenotype), (2) the degree of shock, and (3) the amount of tissue injured (mechanism of injury). Of the three, shock is the predominant factor that produces a maladaptive, overexuberant SIRS response.[22,23] The inflammatory response to injury is an evolutionary developed, expected, and maintained response in all organisms. Mild-to-moderate SIRS is most likely beneficial and probably necessary at some basic physiologic level. Severe SIRS has the potential to result in early organ failure and death.[24] As time proceeds, negative feedback systems downregulate certain aspects of acute SIRS to restore homeostasis and limit potential autodestructive inflammation (see Chapter 63).

In a Glue Grant Study by Tompkins et al,[25] blood samples of 167 patients at varying time intervals were taken to better understand the genomic makeup after severe trauma or burn using microarray analysis. They referred to what they found as "genomic storm" in that of "circulating white cells of the 167 patients studied when compared with those of the 35 normal volunteers, more than 80% of the WBC [white blood cell] genes changed significantly."[25] Tompkins et al[25] further described the genomic patterns of complicated patients (eg, who developed MOF or nosocomial infections) as demonstrating higher levels of deviation from normal gene expression, and these changes quantitatively persisted longer than those same genes in the uncomplicated patients. They concluded there were 5136 genes changed at a twofold level in the circulating WBCs of patients compared with normal volunteers. These changes were long-lasting, and in the complicated patients, more than 50% of these genes remained abnormal even at 28 days after injury."[25] The question remains regarding what drives the inflammatory response after the acute insult to potentially cause MOF or death.

In all three phenotypes of MOF (SIRS, compensatory anti-inflammatory response syndrome [CARS], and persistent inflammatory, immunosuppressed, catabolic syndrome [PICS]), it is hypothesized that the gut can be both an instigator and victim of the characteristic dysfunctional inflammatory response.[1,4-6,25-28] Shock is associated with obligatory gut ischemia as a commensurate physiologic response to hypotension. The gut ischemia may lead to essential mucosal damage.[7] With a robust resuscitation, reperfusion results in a locally intense inflammatory response that can further injure the gut, setting the stage for ACS or MOF.[2,3] The reperfused gut releases inflammatory mediators, including proteins such as cytokines and lipids such as those derived from phospholipase A_2, via the mesenteric lymph, that amplify SIRS.[29] Moreover, for patients undergoing laparotomy, bowel manipulation and anesthetics cause further gut dysfunction.[30] Finally, standard ICU therapies (narcotics, proton pump inhibitors, H_2-antagonists, catecholamines, and broad-spectrum antibiotics) and intentional disuse (delayed start of enteral feeds, inappropriate use of the open abdomen, delayed bowel anastomosis, use of total parenteral nutrition rather than enteral nutrition) promote additional gut dysfunction. The result is a progressive dysfunction characterized by gastroesophageal reflux (GER), gastroparesis, duodenogastric reflux, gastric alkalization, decreased mucosal perfusion, impaired intestinal transit, impaired absorptive capacity, increased permeability, decreased mucosal immunity, increased colonization, and gut edema. As time goes on, the normally sterile upper gut becomes heavily colonized, mucosal permeability increases, and local mucosal immunity decreases. Intraluminal contents (eg, bacteria and their toxic products) disseminated by aspiration or translocation can cause systemic sepsis, which promotes further gut dysfunction. The normal gut microbiome with its relationships with immunity, the brain, and injury becomes an important component of gut heath. It has also been recognized to be altered within hours of injury in small animal models. Earley et al[31] demonstrated that burn injury induces a dramatic dysbiosis of the intestinal microbiome of both humans and mice and allows for similar overgrowths of gram-negative aerobic bacteria. The bacteria increasing in abundance have the potential to translocate to extraintestinal sites. McDonald et al[32] collected and processed several samples as part of the Global Gut Study. They demonstrated that critical illness may be associated with the loss of normal, "health-promoting" bacteria, allowing overgrowth of disease-promoting pathogenic bacteria (dysbiosis), which, in turn, makes patients susceptible to hospital-acquired infections, sepsis, and organ failure.[32]

If this dysfunction goes unchecked for long enough, a certain threshold is reached that propels a patient into a vicious cycle of PICS. This persistent inflammation is characterized by increased production of interleukin (IL)-6, a persistent acute phase response, neutrophilia with increased immature granulocyte count, anemia, lymphopenia, and, often, tachycardia.[8,9] Unfortunately, this deranged inflammatory, immunosuppressive state consumes a large amount of energy derived from protein catabolism. The catabolic state despite aggressive nutritional support gives way to the new phenotype that produces substantial lean body mass loss and proportional decrease in functional status.[33,34] It is the PICS phenotype that clinically depicts chronic critical illness (CCI—defined as requiring >14 days of ICU care).[35-37]

A patient meets PICS criteria if he or she is in the ICU more than 14 days with evidence of organ dysfunction and has persistent inflammation, defined by C-reactive protein concentration greater than 50 μg/dL and retinol binding protein concentrations less than 1 mg/dL; immunosuppression, crudely defined by a total lymphocyte count less than 0.80×10^9/L; and a catabolic state, defined by serum albumin concentrations less than 3.0 g/dL, creatinine height index less than 80%, and weight loss of more than 10% or body mass index less than 18 kg/m^2 during the current hospitalization.[8,9] Although these clinical markers are not direct measurements of inflammation, immunosuppression, or protein catabolism, they can serve as surrogates that are readily available in most critical care settings.

Moore and colleagues defined PICS as a new phenotype that has replaced late-appearing MOF. The major challenges for this new paradigm are: (1) to identify PICS early in its course, (2) to understand its underlying pathophysiology, and (3) to initiate appropriate multimodal therapies that target specific components of the syndrome.[38] Medical care resource consumption associated with PICS has yet to be measured but is likely to be a large multiple of the costs associated with the short-term treatment of trauma, severe sepsis, and septic shock.[39] The incidence of PICS will likely increase as our population ages and our ICU technology improves.[40] Characterization and management of PICS will require technologies for direct monitoring and modulation of the patient's nutritional status and immune responses. PICS is likely to be the new horizon for surgical intensive care (Fig. 60-1).[41]

After the initial insult, there is a simultaneous SIRS/CARS response. Some patients develop severe SIRS and proceed to the early MOF and fulminant early death trajectory. Modern

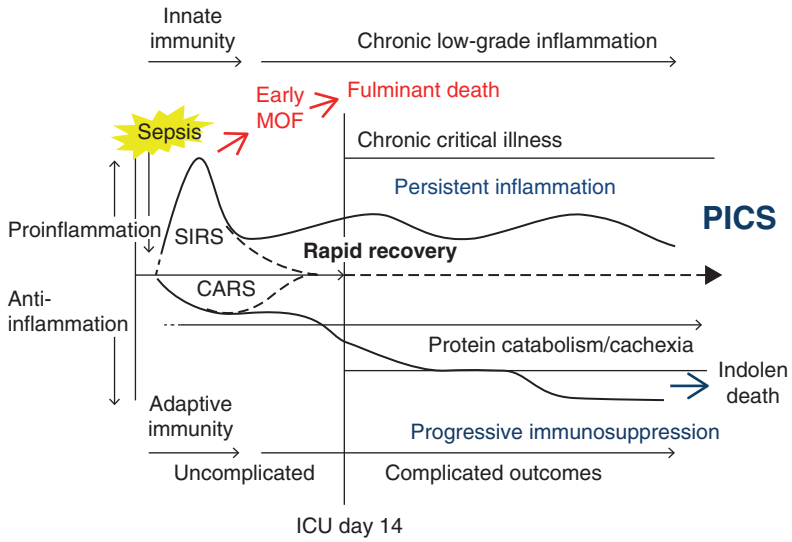

FIGURE 60-1 Persistent inflammatory, immunosuppressive, and catabolic state (PICS) algorithm. CARS, compensatory anti-inflammatory response syndrome; ICU, intensive care unit; MOF, multiple organ failure; SIRS, systemic inflammatory response syndrome.

ICUs, however, are becoming increasingly effective in preventing the full expression of this phenotype (ie, early death). Some patients rapidly recover, but most patients linger in the ICU with manageable organ dysfunctions for prolonged periods and develop CCI. A substantial portion of these CCI patients (40%–60%) exhibit ongoing protein catabolism with poor nutritional status, poor wound healing, and recurrent infections.[8,9] In addition, they have persistent low-grade inflammation, with defects in innate and adaptive immunity. It is likely this response is driven in large part by bone marrow dysfunction, with expansion and release of the myeloid-derived suppressor cells (MDSCs).[42]

Although expansion of the MDSC population can be explained in part by increased myelopoiesis, defects in the maturation and differentiation of this cell lineage render them ineffective at fighting infections and are responsible for producing a persistent low-level inflammatory state through cytokine secretion. The University of Florida Sepsis and Critical Illness Research Center is investigating the genomic makeup of PICS, trying to predict patients at high risk of developing PICS, elucidate the role of MDSCs, and recommend possible interventions. With a recently awarded a P50 grant by National Institute of General Medical Sciences entitled, "PICS: A New Horizon for Surgical Critical Care," the funding will provide a strong foundation to make this achievement possible. It is believed that PICS patients who are ultimately discharged to long-term acute care facilities rarely rehabilitate, hardly ever return to functional life, and usually experience prolonged decline and an indolent death.[36,39,43-52]

Abdominal Compartment Syndrome

Intra-abdominal pressure (IAP) is monitored by urinary bladder pressure measurements (gold standard). As these pressures approach 20 to 25 cm H_2O, organ dysfunction begins (see Chapter 42). Although intra-abdominal hypertension can occur during the entire ICU stay, IAP on the first day of admission appears to have greatest impact on mortality.[53] When IAP is coupled with any organ dysfunction, by definition, this is ACS. There are three types of ACS: primary, secondary, and tertiary.[2,3,54-56] Primary ACS occurs in patients with abdominal injuries who typically have undergone "damage control" laparotomy (where obvious bleeding is rapidly controlled and the abdomen is packed) and have entered the "bloody vicious cycle" of coagulopathy, acidosis, and hypothermia, which promotes ongoing bleeding (see Chapter 16). Intra-abdominal sepsis with significant volume free air, contamination, ascites, and/or bowel wall edema can also present as primary ACS. Accumulation of blood, worsening bowel edema from resuscitation, and the presence of intra-abdominal packs all contribute to increasing IAP that causes ACS. Secondary ACS occurs when extra-abdominal bleeding (eg, mangled extremity or pulmonary hilar gunshot wound) or extra-abdominal pathology (eg, burns or necrotizing soft tissue infections) requires massive resuscitation that causes bowel edema, increasing IAP and eventually resulting in secondary ACS. Tertiary ACS occurs in the setting of a temporary abdominal closure and ongoing IAP increases or a new ACS that follows closure of the abdominal wall after previous open abdomen care. The increased use of the open abdomen has likely moved this scenario from a gastrointestinal failure to a treatment for a current or potential gastrointestinal failure. However, what is important to note is that markedly elevated IAP decreases gut perfusion, which may adversely affect a variety of gut functions. Clinical studies have clearly documented the poor outcome of patients developing ACS and the frequent association of ACS and MOF.[2] In addition, the decreased gut perfusion creates a potential cycle of ileus or decreased gut transport and less than ideal nutrient

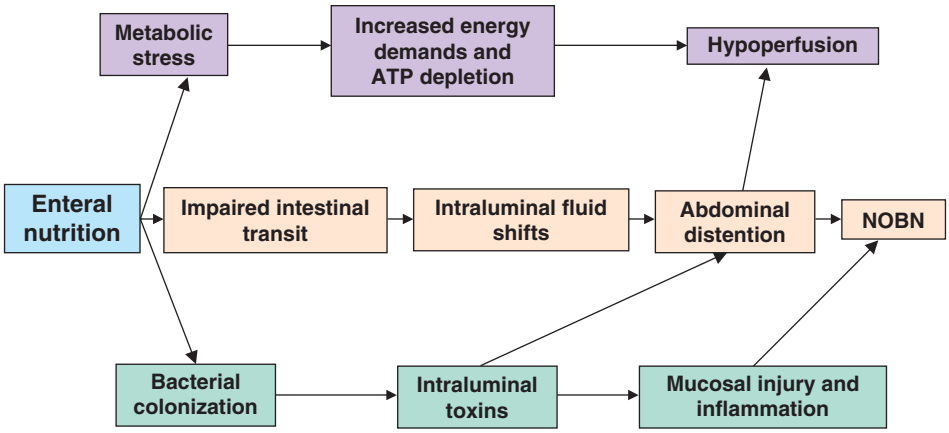

FIGURE 60-2 Proposed pathogenesis of nonocclusive bowel necrosis (NOBN). ATP, adenosine triphosphate.

absorption. Clinically, these patients typically receive less than goal caloric provision.[57,58]

Nonocclusive Small Bowel Necrosis

Nonocclusive small bowel necrosis (NOBN) is a relatively rare but frequently fatal entity that is associated with critical illness. In addition, vasoactive agents while in the critical care unit and drugs such as methamphetamines can create an environment of normal patent arteries, but "clamped" down vessels can decrease oxygen supply. Combined with any shock state that early on diverts blood away from the gut, an imbalance between supply and demand can create ischemia or even necrosis. In some studies, the use of enteral nutrition in critically ill patients has been implicated.[59]

Patients present with complaints of cramping abdominal pain and progressive distention, at times associated with SIRS or severe SIRS. ACS, pressor requirement, and oliguria can also be markers of NOBN.[60] Computed tomography (CT) may reveal pneumatosis intestinalis or thickened dilated bowel in more advanced stages. In 2015, Lasierra in a review described a need for clinical, laboratory, and radiographic evaluation in critically ill patients with a potential for NOBN.[61] For patients who progress and require exploratory celiotomy, ischemia and/or patchy necrosis of the small bowel is found, usually on the antimesenteric border. Pathologic analysis of the resected specimens yields a spectrum of findings from acute inflammation with mucosal ulceration to transmural necrosis and multiple perforations.

The association with enteral nutrition indicates that inappropriate administration of nutrients into a dysfunctional gut may play a pathogenic role. There are three popular hypotheses (Fig. 60-2).[9] First, metabolically compromised enterocytes become adenosine triphosphate (ATP) depleted as a result of increased energy demands induced by the absorption of intraluminal nutrients, leading to hypoperfusion and subsequent NOBN.[62] The second hypothesis is that when nutrients are delivered into the dysmotile small bowel, fluid shifts into the lumen as a result of the presence of hyperosmolar enteral formula, leading to intestinal distention, which when severe progresses to NOBN. Third, bacterial colonization leads to intraluminal toxin accumulation, which can result in mucosal injury and inflammation and, if significant, NOBN. Despite these hypotheses, it is well accepted that a critically ill surgical/trauma patient should receive appropriate euvolemic resuscitation and early (<48 hours) initiation of enteral nutrition. Most of the time, the benefits of this early initiation of enteral nutrition outweigh the risk of small bowel ischemia or necrosis.

SPECIFIC GUT DYSFUNCTIONS

The gut is a complex organ that performs a variety of functions, some of which are vital for ultimate survival of critically ill patients (ie, barrier function, immune competence, and metabolic regulation). Unfortunately, gut dysfunction in critically injured patients is poorly characterized, and routine monitoring of gut function is crude. Currently, the best parameter of normal gut function is tolerance to enteral nutrition (see Chapter 62). Intolerance results in a spectrum of critically ill patients from stress gastritis to intolerance of tube feeds manifested as either distention, diarrhea, or obstipation. First, tolerance to enteral nutrition requires integrative gut functioning (eg, secretion, digestion, motility, absorption). Second, locally administered nutrients improve perfusion and optimize the recovery of other vital gut functions (eg, motility, barrier function, mucosal immunity). Third, tolerance correlates with patient outcome, and improving tolerance will likely improve patient outcome. Fourth, refined therapeutic interventions to improve enteral nutrition tolerance will lessen the need to use parenteral nutrition and decrease its associated complications (see Chapter 62).

Gut dysfunction certainly contributes to enteral feeding intolerance. The pathophysiology and pathogenesis of each dysfunction and how they may be monitored clinically will be reviewed. This can provide the rationale for therapeutic strategies to improve tolerance to enteral nutrition.

Gastroesophageal Reflux

GER is an important contributing factor to aspiration of enteral feedings, which is a common etiology of pneumonia in ICU patients. GER occurs for several reasons in the critically ill patient. Decreases in resistance at the lower esophageal sphincter can be due to relaxation of the sphincter muscle in response to many stimuli, including mediators released during injury and resuscitation. Additional contributing factors include (1) forced supine position, (2) the presence of a nasoenteric tube, (3) hyperglycemia, and (4) narcotics. Pressure differences between the stomach and esophagus become great enough to overcome the resistance offered by the lower esophageal sphincter. GER may occur as a result of increased IAPs due to crystalloid resuscitation and bowel edema.

Delayed gastric emptying in critically ill patients results in abnormal delivery, digestion, and potentially absorption of nutrition. There are preclinical data regarding the pathophysiologic role of the enterohormones peptide YY and ghrelin in this population. Studies have not clearly demonstrated a connection, but critically ill patents' ghrelin levels tend to be lower.[63]

Historically, clinical monitors include laboratory testing for presence of glucose in tracheal secretions or observing blue food dye that has been added to the enteral formula in the setting of tracheal aspiration. Detection of glucose lacks specificity. False-positive results can occur with high serum glucose levels or presence of blood in tracheal secretions. The blue food dye is no longer recommended and carries a US Food and Drug Administration black box warning. It was also poorly standardized, as indiscriminate amounts were added to tube feeds, lacking sensitivity, and it is considered dangerous to patients. Several reports document that absorption of blue food dye in critically ill patients is associated with death.[64] This is potentially associated with toxic effects that blue food dye has on mitochondrial function. A recent consensus conference recommended that the technique be abandoned.[65] Unfortunately, there are no simple monitors of GER other than observing for vomiting or regurgitation, which are not very sensitive. The head of the bed should be elevated 30° to 45° to decrease the risk that when GER occurs that it is less likely to result in pulmonary aspiration (see Chapter 59). Gastric residual volumes (GRVs) should be monitored with the presumption that a distended stomach will lead to higher volume GER.

Gastroparesis and Duodenogastric Reflux

Gastroparesis is common in ICU patients and predisposes to increased duodenogastric reflux (a potential contributing factor for gastric alkalization) and GER (a contributing factor for aspiration). The mechanisms responsible for gastroparesis in critical illness have not been well studied. The current model is an impairment of the esophageal peristalsis. In addition, there is a hypotensive lower esophageal sphincter pressure. This is in the setting of isolated pyloric pressure waves resulting in increased pyloric tone.[66] This results in gastric stasis and, in the setting of H_2-receptor blockers or proton pump inhibitors, bacterial overgrowth. In addition, potential factors include (1) medications (eg, narcotics, pressors), (2) sepsis mediators (eg, nitric oxide), (3) hyperglycemia, and (4) increased intracranial pressure/traumatic brain injury.

The common clinical monitors for gastroparesis are intermittent measurement of GRVs when feeding into the stomach or measurement of continuous suction nasogastric tube output when feeding postpyloric. First, it must be performed with a standard sump nasogastric tube. Small-bore single-lumen tubes do not adequately empty the stomach and should not be used to measure GRV. The practice of using GRV is poorly standardized and is a major obstacle to advancing the rate of enteral nutrition.[67] GRVs appear to correlate poorly with gastric function, and GRVs less than 200 mL generally are well tolerated. GRVs of 200 to 500 mL should prompt careful clinical assessment and the initiation of a prokinetic agent. With GRVs of more than 500 mL, enteral nutrition was traditionally stopped. After clinical assessment excludes small bowel ileus or obstruction, placement of a post–ligament of Treitz feeding tube should be considered (see Chapter 62). However, a study by Reignier et al[68] in *JAMA* demonstrated that not monitoring GVR and allowing patients to advance to goal tube feed rates for adequate nutritional supplementation was not inferior to checking GVR in preventing ventilator-associated pneumonia.

Critically ill mechanically ventilated patients are known to have a high incidence of gastroduodenal reflux. It is seen in patients who are mechanically ventilated while being fed via nasojejunal feeding tubes and can occur during fasting and feeding periods.[69,70] In a study of antral, duodenal, and proximal jejunal motility, Toumadre et al[71] demonstrated that postoperative gastroparesis occurs after major abdominal surgery and is associated with discoordinated duodenal contractions, of which 20% migrated in a retrograde fashion. Heyland et al[72] administered radiolabeled enteral formulas through a standard postpyloric nasoenteric feeding tube in ventilated ICU patients and documented an 80% rate of radioisotope label reflux into the stomach, 25% reflux rate into the esophagus, and a 4% reflux rate into the lung. Finally, Wilmer et al[70] reported monitoring bile reflux in the esophagus of ventilated ICU patients using a fiberoptic spectrophotometer that detects and quantifies bilirubin concentration. Endoscopy was performed and documented erosive esophagitis in half of the patients, of whom 15% had pathologic acid reflux and 100% had pathologic bile reflux. These studies provide convincing evidence that duodenogastric reflux is a common event in ICU patients.

Gastric Alkalization

After major traumatic injuries, patients can develop gastric luminal alkalization, which may be related to bile acid duodenal gastric reflux.[73,74] The stomach, through secretion of hydrochloric acid, normally has a pH below 4.0. This acid environment has been correlated with the relatively low

bacterial counts found in the stomach. Reviews of several studies have shown that alkalization of the stomach through the use of antacids, H_2 antagonists, and proton pump inhibitors results in gastric colonization by bacteria not normally found in the stomach, and several, but not all, studies have shown that gastric colonization predisposes patients to ventilator-associated pneumonia[75] and can increase the risk of community-acquired *Clostridium difficile*–associated disease.[76]

Several animal studies have shown that both lipopolysaccharide administration and mesenteric ischemia/reperfusion result in the gastric accumulation of an alkaline fluid.[77] This most likely results from a decrease in gastric acid secretion with continued gastric bicarbonate secretion and the reflux of duodenal contents into the stomach. Even more recently, reports have indicated that the pH of gastric contents in trauma patients is also elevated, possibly due to similar events.[73] Thus, even without the administration of antacids or inhibitors of acid secretion, gastric alkalization and bacterial colonization of the stomach are likely in this group of patients. When this is combined with the gastroparesis often seen in these patients (see earlier discussion), it is easy to envision the stomach becoming a major source of bacteria for ventilator-assisted pneumonia and perhaps translocation to other organs.

Impaired Mucosal Perfusion

Current resuscitation techniques from hemorrhagic shock cause a persistent and progressive splanchnic vasoconstriction and hypoperfusion despite hemodynamic restoration with intravenous fluid therapy or blood products. The pathophysiologic response to shock is a decrease in splanchnic blood flow. Hemorrhage-induced activation of endothelial cell Na^+/H^+ exchanger results in cellular swelling, which physically impedes capillary filling and compromises gut perfusion. Paradoxical endothelial cell swelling occurs early during hemorrhagic shock because of activation of the Na^+/H^+ exchanger. This cellular edema, which is not resolved by correction of the vascular volume deficit, explains the persistent postresuscitation endothelial cell dysfunction and gut hypoperfusion.[78]

The gut mucosa appears to be especially vulnerable to injury during hypoperfusion. The arterioles and venules in the small bowel mucosal villi form "hairpin loops." This anatomic arrangement improves absorptive function, but it also permits a countercurrent exchange of oxygen from the arterioles to the venules in the proximal villus. Under hypoperfused conditions, a proximal "steal" of oxygen is believed to reduce the Po_2 at the tip of the villi to zero. The gut mucosa is further injured during reperfusion by reactive oxygen metabolites and recruitment of activated neutrophils (see Chapter 63). This mucosal injury, however, appears to quickly repair itself. Mucosal blood flow does not always return to baseline with resuscitation, and this is in part due to defective vasorelaxation. The gut mucosa is also vulnerable to recurrent episodes of hypoperfusion from ACS, sepsis, and use of vasoactive drugs. Whether recurrent hypoperfusion results in additional ischemia/reperfusion injury is not known, but it is reasonable to assume that hypoperfusion would decrease gut nutrient absorption and render the patient more susceptible to NOBN.

Monitoring gastric mucosal perfusion in the clinical setting can be done by gastric tonometry. With hypoperfusion, intramucosal carbon dioxide (CO_2) increases due to insufficient clearance of CO_2 produced by aerobic metabolism or due to buffering of extra hydrogen ions produced in anaerobic metabolism. As intramucosal CO_2 accumulates, it diffuses into the lumen of the stomach. The tonometer measures the CO_2 that equilibrates in a saline-filled balloon (a newer monitor uses an air-filled balloon) that sits in the stomach. This is the regional CO_2 tension ($PrCO_2$) and is assumed to equal the intramucosal CO_2 tension. Using this measured $PrCO_2$ and assuming that arterial bicarbonate equals intramucosal bicarbonate, the intramucosal pH (pHi) is calculated by using the Henderson-Hasselbalch equation. Numerous studies have documented that a persistently low pHi (or high $PrCO_2$ level) despite effective systemic resuscitation predicts adverse outcomes and that attempts to resuscitate to correct a low pHi do not favorably influence mortality.[79]

Direct peritoneal resuscitation (DPR) has been shown to increase survival after intestinal ischemia and reperfusion injury in small animal models. DPR has been demonstrated to have significant therapeutic potential for improving mesenteric perfusion, intestinal injury, and the local inflammatory response after the intestinal ischemia/reperfusion event.[80-83]

Impaired Intestinal Transit

Laboratory models of shock, bowel manipulation, and sepsis demonstrate that small bowel transit is impaired.[84] This impairment in turn is expressed as a decrease in the number and/or force of contractions or as an abnormal pattern of contractions. Although the results in animal models are convincing, surprisingly, clinical studies indicate that small bowel motility and transit are more often than not well preserved after major elective and emergency laparotomies.[85] This observation coupled with the observation that small bowel absorption of simple nutrients is relatively intact provided the rationale for early jejunal feeding (see Chapter 62).

In addition to injury, patients undergoing laparotomy are likely to have postoperative ileus, which is assumed to result from myeloid cells infiltrating the intestinal muscularis externa. In a small animal study, during the postlaparotomy recovery phase, monocyte-derived MΦs acquired proresolving features that aided in the resolution of inflammation. This study showed a critical role for monocyte-derived MΦs in restoring intestinal homeostasis after surgical trauma.[86]

Clinical studies have documented that the majority of critically ill patients tolerate early jejunal feeding.[87] In a recent study, severely injured patients had jejunal manometers and feeding tubes placed at secondary laparotomy.[85] Surprisingly, 50% had fasting patterns of motility that included components of the normal migrating motor complexes (MMCs). These patients tolerated advancements of enteral nutrition without problems. The other 50% who did not have fasting MMCs did not tolerate early advancement of enteral

nutrition. Of note, none of the patients converted to a normal-fed pattern of motility once they reached full-dose enteral feeding. This could be due to infusion of caloric loads insufficient to bring about conversion. On the other hand, the failure to develop fed activity, a pattern of motility promoting mixing and absorption, might explain why diarrhea is a common problem in this patient group.

Although manometry can be used to monitor motility, it is not practical. Unfortunately, simpler indicators of motility such as the presence of bowel sounds or the passing of flatus are unreliable. Other minimally invasive methods to monitor transit are needed. Contrast studies through the feeding tubes are relatively simple but not validated.

Impaired Gut Absorptive Capacity

Small bowel absorption of glucose, lipids, and amino acids is depressed after trauma and sepsis.[88] Multiple factors have been identified including (1) cytosolic calcium overload, (2) ATP depletion, (3) diminished brush border enzyme activity, (4) decreased carrier activity, (5) decreased absorptive epithelial surface area, and (6) hypoalbuminemia. In an animal study, intestinal ischemia/reperfusion caused significant mucosal injury and significant depletion of mucosal ATP.[51] When this was combined with exposure of the bowel to a nonmetabolizable nutrient, the damage and ATP depletion were more severe, and the absorption of glucose was impaired. In contrast, exposure of the bowel to metabolizable nutrients (eg, glucose) preserved ATP levels, protected against mucosal injury, and improved gut absorptive capacity (GAC).[89]

There does appear to be some degree of GAC that is maintained after injury. In a small animal model after burn injury, intestinal absorption of the dipeptides was preserved 24 hours following thermal injury.[90] These findings support the use of less complex enteral diets in the critically ill patient.

The clinical significance of these observations remains unclear because most patients tolerate enteral nutrition when delivered into the small bowel. However, decreased GAC may be a cause of diarrhea and may explain why patients commonly experience diarrhea with reinstitution of enteral nutrition after prolonged bowel rest. Unfortunately, there are no easily performed clinical monitors for GAC. D-Xylose absorption is clinically available but is used most frequently to diagnose chronic malabsorption.

Diarrhea may be indicative of depressed GAC, but there are other causes for diarrhea in the critically ill. These include impaired transit, bacterial overgrowth (ie, presence of *C difficile*), contaminated enteral formulas, abnormal colonic responses to enteral nutrition (ie, ascending colon secretion rather than absorption, or impaired distal colon motor activity), and administration of drugs that contain sorbitol (eg, medication elixirs) or magnesium (eg, antacids).

Increased Gut Permeability

Trauma results in hemorrhagic shock, which leads to mucus damage and gut dysfunction through the generation of free radical species.[91]

Enhanced paracellular permeability represents a type of barrier dysfunction that allows increased passage between viable cells and may induce an inflammatory cascade. The major components of the epithelial barrier are tight junctions, which bind cells together and serve as the gateways to the underlying paracellular spaces. The integrity of the tight junctions is modulated by the actin cytoskeleton. Under conditions of ATP depletion, such as would occur during shock, disruption of the actin cytoskeleton with consequent opening of the tight junctions and loss of the integrity of the permeability barrier can occur.[62]

Intestinal barrier dysfunction has been suggested as a means by which inflammatory cytokines can lead to SIRS and MOF. Additionally, increased intestinal permeability has been documented in high-risk patients after burns, sepsis, and shock, in most but not all studies.[92]

Decreased Gut Mucosal Immunity

During periods of intestinal disuse, critically injured patients are subject to a reduction in gut mucosal immunity. Lack of enteral stimulation (eg, during starvation or with use of parenteral nutrition) quickly leads to lack of immunologic protection by mucosal-associated lymphoid tissue (MALT), which normally provides protection for both the gastrointestinal (GI) and respiratory tracts against microbial flora and infectious pathogens. Kudsk[93] has demonstrated a link between intestinal immunoglobulin A (IgA), intestinal cytokine production, and the vascular endothelium of the GI tract. With enteral stimulation, IL-4 and IL-10 production from the lamina propria of the small intestine stimulates production of IgA on the mucosal surface and inhibits intracellular adhesion molecule-1 (ICAM-1) of the vascular endothelium and subsequent neutrophil-associated inflammation and injury.[93]

Increased Gut Colonization

With progressive gut dysfunction, the normally sterile upper GI tract becomes colonized with organisms that become pathogens in nosocomial infections. Gastric alkalization, paralytic ileus, loss of colonization resistance due to broad-spectrum antibiotics, and decreased local gut immunity have all been proposed mechanisms by which the upper GI tract becomes colonized.

In an effort to decrease the incidence of infectious complications, selective digestive decontamination (SDD) has been proposed. SDD generally consists of topical nonabsorbed antibiotics along with a short course of parenteral antibiotics. There have been numerous clinical trials and at least six meta-analyses addressing this practice. Most studies have examined the incidence of ventilator-associated pneumonias and mortality and, in general, have demonstrated a decrease in both. Despite rather impressive results of these trials, most of which have been performed in Europe, intensivists in the United States have generally avoided use of SDD due to concerns of inducing antimicrobial resistance.[94]

The human microbiome has emerged as a critical component of health and disease, and the microbial communities

within the intestinal tract appear to contribute to it.[95] Head injury is known to induce a hypercatabolic state, disimmunity, and septic complications that increase morbidity and mortality. In a small animal model, head injury changed the gut microbiota homeostasis and thus could contribute to infection.[96]

Gut Edema

From the 1950s and through the Korean War and the Vietnam conflict, intravenous fluid administration was associated with improved mortality.[97,98] The mechanism at that point in time was improved resuscitation via improved cardiac output and subsequently better gut perfusion. However, the lessons learned after the Vietnam conflict in both clinical and laboratory models included the concept that excess fluids produced acute respiratory distress syndrome and GI dysfunction in the form of ascites, bowel edema, ACS, and at times, poor healing of bowel anastomosis. A number of clinical studies, although not performed in resuscitated trauma patients, have demonstrated the benefit of fluid restriction on postoperative bowel function and complications.[99]

The precise mechanisms by which bowel edema adversely affects bowel function have not been fully elucidated. Laboratory investigations by Moore-Olufemi et al[100] have shown that bowel edema alone (not associated with gut ischemia/reperfusion or hemorrhagic shock) is associated with impaired intestinal transit. This can be reversed with enteral feeding. In addition, evidence indicates that enteral nutrition with the open abdomen is associated with fewer complications and early closure of the abdomen.[101] This reinforces the notion that although enteral nutrition may be associated with small bowel ischemia/necrosis, the benefits of early enteral nutrition are greater than the risks.

During the resuscitation of the hemorrhagic shock patient, a multipronged approach has been adopted to prevent overresuscitation, bowel edema, ACS, bowel ischemia, and the perpetuation of the open abdomen. Through improved timely hemorrhage control, damage control resuscitation with the use of early blood products in the form a massive transfusion protocol, and less crystalloid resuscitation, patients have suffered subsequently less open abdomen care and greater primary fascial closure. This also has translated into less GI failure, by means of fewer ACS and ICU days, less enterocutaneous fistulae, and subsequently fewer long-term (9–12+ months) abdominal reconstruction projects.

STRATEGIES TO IMPROVE GUT DYSFUNCTION

Gut-Specific Resuscitation and Monitoring for Abdominal Compartment Syndrome

Traditional resuscitation is aimed at optimizing systemic perfusion, with initial administration of 2 L of isotonic crystalloids and then addition of packed red blood cells at a ratio of 3:1 crystalloid to blood (see Chapter 16).

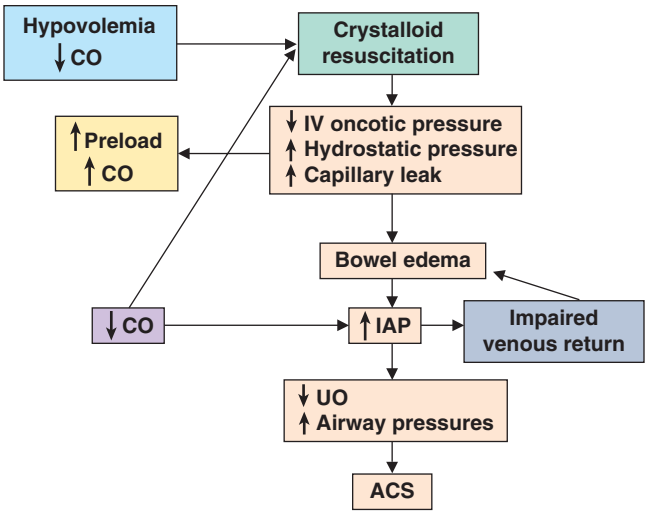

FIGURE 60-3 Crystalloid vicious cycle leading to abdominal compartment syndrome. ACS, abdominal compartment syndrome; CO, cardiac output; IAP, intra-abdominal pressure; IV, intravenous; UO, urine output.

If–then resuscitation protocols need to be devised to optimize early gut perfusion and prevent reperfusion injury. Although this approach is effective in some patients, it is associated with problematic bowel edema in patients at high risk for MOF and subsequent shock-induced gut hypoperfusion, leading to gut dysfunction. As edema worsens and IAP increases, bowel perfusion becomes further impaired, setting up a vicious cycle that leads to ACS (Fig. 60-3).[55]

IAPs should be measured routinely in patients in whom significant resuscitation is anticipated, because intra-abdominal hypertension can be predicted early in at-risk patients.[21] A high index of suspicion and knowledge of these predictors is warranted. In the past, surgeons have not decompressed the abdomen until clear signs of organ dysfunction were present (ie, decreased urine output, decreased Pao_2/Fio_2 ratio, decreased cardiac output despite volume loading) in part because of fear of creating an open abdomen with consequent need for planned ventral hernia and delayed reconstruction (see Chapter 42). Thus, based on prediction models,[3] patients who meet defined high-risk criteria and require ongoing aggressive resuscitation may be considered for a "presumptive" decompressive laparotomy. However, medical or nonsurgical strategies have been proposed to address and effectively treat rising IAPs, subsequently avoiding an open abdomen. If the medical strategy is not effective, early decompressive laparotomy can occur. In fact, a recent prospective study demonstrated that early decompression in at-risk patients reduced mortality from intra-abdominal hypertension/ACS.[102] In addition, current critical care treatment plans for patients with an open abdomen include strategies to address not only organ dysfunctions that are affected by intra-abdominal hypertension but also the actual IAP and the systemic inflammation associated with ACS. Included are resuscitation strategies that utilize early use of blood products

for hemorrhage and coagulopathy, which may lessen bowel edema and therefore reduce the incidence of ACS.[103]

Analgesics and Sedatives

There are three types of opioid receptors—δ, κ, and μ—and all have been identified as having GI side effects including delayed gastric emptying and delayed transit time in both the small bowel and colon. One major cause of ileus is stress-related stimulation of opioid receptors. In animal models and humans, both endogenously released and exogenously administered opioids act on receptors in both the central nervous system and in the enteric nervous system to alter intestinal function, especially motility. Although actions at both the central nervous system and enteric nervous system are involved, recent studies indicate that if opioid actions at the enteric nervous system are blocked, ileus may be prevented or resolved without interfering with the desired opioid actions on the central nervous system and other systems. An investigational opioid receptor antagonist that has limited systemic absorption after oral administration and minimal access to the central nervous system has been shown to speed recovery of bowel function and shorten the duration of hospitalization after surgery.[104] There is also a peripherally acting μ-receptor antagonist, alvimopan, that has recently been shown in a prospective, randomized controlled trial to accelerate time to recovery of GI function in patients undergoing elective major abdominal surgery.[105] μ-Receptor antagonists are attractive agents for postoperative patients in that they are peripherally acting (gut specific), thereby maintaining centrally mediated pain reduction. A recent Cochrane Review on μ-opioid antagonists for opioid-induced bowel dysfunction concluded that both alvimopan and methylnaltrexone were effective in reversing increased transit time and constipation. Additionally, alvimopan is safe and efficacious in treating postoperative ileus.[106] However, long-term data are lacking, and further studies are indicated. Both of these agents need to be studied in patients at high risk for postoperative bowel dysfunction, particularly patients who have undergone major resuscitation from shock.

Ketamine, an antagonist of the *N*-methyl-D-aspartate receptor, combines both analgesic and sedative effects and may represent an alternative to benzodiazepines for sedation and opioids for pain control in ICU patients. There are reports in burn patients of the opiate-sparing effect of ketamine minimizing prolonged gut dysfunction and ileus.[107] Additionally, both proinflammatory cytokines and mediators have been suppressed in laboratory models of sepsis following ketamine administration.[108]

ENTERAL AGENTS

Benefits of Enteral Versus Parenteral Nutrition

Several prospective randomized controlled trials (PRCTs) performed in the late 1980s and early 1990s had significant impact on clinical practice in surgical, and particularly trauma, ICUs. These single-institution trials all randomized trauma patients to early enteral nutrition or parenteral nutrition and demonstrated that patients receiving early enteral nutrition had significantly fewer infectious complications (see Chapter 62). A meta-analysis that combined data from eight PRCTs (six published and two unpublished) was then conducted to assess the nutritional equivalence of enteral nutrition compared to parenteral nutrition in high-risk trauma and/or postoperative patients.[22] Similar to the single-institution trials, fewer infectious complications developed in patients receiving enteral nutrition. Even when patients with catheter-related sepsis were removed from the analysis, a significant difference in infections between groups remained. Taken together, these trials provide convincing evidence that enteral nutrition is preferred to parenteral nutrition in patients sustaining major torso trauma. A recent meta-analysis evaluating the effect of early versus delayed enteral nutrition in acutely ill (medical and surgical) patients also confirmed a decrease in infectious complications in patients receiving early enteral nutrition.[109]

Based on available data, we can now explain how enteral nutrition interrupts this sequence of events to prevent late nosocomial infections and MOF. In a variety of models (ie, sepsis, hemorrhagic shock, and gut ischemia/reperfusion), intraluminal nutrients have been shown to reverse shock-induced mucosal hypoperfusion.[110] In the laboratory, we have also shown that enteral nutrition reverses impaired intestinal transit when given after a gut ischemia/reperfusion insult.[111] Improved transit should decrease ileus-induced bacterial colonization. Moreover, enteral nutrition attenuates the gut permeability defect that is induced by critical illness.[112] Finally, and most important, the gut is a very important immunologic organ, and infections may be lessened by feeding the gut. Kang and Kudsk[113] performed a series of laboratory studies that have nicely elucidated a mechanistic explanation of how this occurs. Enteral nutrition supports the function of the MALT that produces 70% of the body's secretory IgA. Naive T and B cells target and enter the gut-associated lymphoid tissue (GALT) where they are sensitized and stimulated by antigens sampled from the gut lumen and thereby become more responsive to potential pathogens in the external environment. These stimulated T and B cells then migrate via mesenteric lymph nodes to the thoracic duct and into the vascular tree for distribution to GALT and extraintestinal sites of MALT. Lack of enteral stimulation (ie, use of total parenteral nutrition [TPN]) causes a rapid and progressive decrease in T and B cells within GALT and simultaneous decreases in intestinal and respiratory IgA levels. Previously resistant TPN–fed laboratory animals, when challenged with pathogens via respiratory tree inoculation, succumb to overwhelming infections. These immunologic defects and susceptibility to infection are reversed within 3 to 5 days after initiating enteral nutrition.

The severely injured or open abdomen patient undergoes tremendous systemic inflammation. Therefore, by at least one definition, this patient is suffering from severe protein-calorie malnutrition.[114] Secondarily, these patients are typically fed

less than goal, even by criteria of permissive underfeeding. Frequent operative interventions and resuscitations typically preclude adequate nutrition provision. Therefore, it is not uncommon for the clinician to ask whether parenteral nutrition should be started.

With the large prospective randomized trial published in 2011, supplementation with early (<48 hours) parenteral nutrition in the critically ill has been generally avoided. Patients who were randomized to early parenteral nutrition had higher costs and increased mortality risk compared to patients who had delayed initiation of parenteral nutrition until day 5 to 7.[115] Similar conclusions were found by Kutsogiannis et al,[116] who stated that critically ill patients receiving parenteral nutrition suffered worse outcomes. However, other studies focusing on supplemental parenteral nutrition have not reached the same conclusions. Harvey et al[117] showed no difference in infectious complications or mortality in the critically ill when parenteral nutrition was initiated within that 48-hour window. Doig et al[118] demonstrated that patients who had a "contraindication" for enteral nutrition and had parenteral nutrition started early also did not suffer an increased risk of mortality. In fact, the early parenteral nutrition group had reduced ventilator days. Two systemic reviews also did not demonstrate an increased mortality between early and late parenteral nutrition.[119,120] Further analysis showed fewer ventilator days but increased infectious complications.

Unfortunately, no study has focused on abdominal surgical patients, much less on those with open abdomen care. Guidelines support early enteral nutrition, even in open abdomen patients, as not only safe but also beneficial.[121] In addition, through extrapolation of the previously mentioned studies, it is recommended to delay parenteral nutrition for approximately 5 to 7 days. In the scenario of the open abdomen for the first 5 to 7 days, attempts should be made to optimize provision of early enteral nutrition, even in low "trophic" (>30% goal) amounts and between operative interventions.[122,123]

Modified Enteral Formulas

Basic and clinical research suggests that the beneficial effects of enteral nutrition can be amplified by supplementing specific nutrients that exert pharmacologic immune-enhancing effects beyond the prevention of acute protein malnutrition. The proposed immune-enhancing agents include glutamine, arginine, omega-3 polyunsaturated fatty acids (PUFAs), and nucleotides, although the individual contributions of each have not been well investigated. Glutamine has received the most attention in the trauma patient and critical care patients with mixed recommendations. It is actively absorbed across the intestinal epithelium and then metabolized in the small bowel to ammonia, citrulline, alanine, and proline and serves as an energy source for the enterocyte. Glutamine is therefore acknowledged to be the preferred fuel of the enterocyte and stimulates lymphocyte and monocyte function. The demand for glutamine is increased during stressed states, and supplementation at pharmacologic doses may be required.

Eight published PRCTs tested high doses (0.3–0.5 g/kg) of enteral glutamine in critically ill patients. The majority demonstrated improved clinical outcomes and primarily decreased infection. Additionally, findings associated with enteral glutamine were decreases in (1) urinary lactulose/mannitol ratios, (2) serum diamine oxidase levels, (3) circulating endotoxin levels, and (4) gram-negative bacteremia, all of which suggest that glutamine is achieving these benefits through a gut-specific mechanism.

In a recent meta-analysis, glutamine (parenteral and enteral) administered to critically ill and surgical patients resulted in a lower mortality, less infectious complications, and shorter hospital stay.[124] High-dose and parenteral glutamine had the greatest effect, although the study was not designed to examine these parameters. A randomized trial of glutamine-enriched enteral nutrition in severely injured patients demonstrated a decrease in pneumonia, sepsis, and bacteremia.[125] However, with heterogeneity of the surgical critically ill patient, some doubt exists about the need for routine supplementation in this patient population.[126] In addition, recent data from a large prospective randomized trial suggested supplemental glutamine in high doses may, in fact, be toxic with increased mortality in patients with acute renal injury and MOF.[127] Although this conclusion included severe sepsis patients, enthusiasm surrounding the use of glutamine has decreased tremendously.

Enteral Glutamine During Shock Resuscitation

Patients in shock are not given enteral nutrition because of concerns over the safety of feeding the hypoperfused small bowel. However, evidence supports the feasibility of enteral nutrition in this setting.[128] In addition, despite the presence of vasopressors, enteral nutrition has been noted to be tolerated and absorbed. An alternative concept that has been studied in the laboratory and then pursued clinically is enteral administration of glutamine in the setting of shock.[129] There are several reasons why this would be beneficial. First, intraluminal glutamine infusion reverses shock-induced splanchnic vasoconstriction. Second, glutamine is a preferred fuel source and promotes protein synthesis in the gut mucosa. Glutamine is also a preferred fuel for lymphocytes and is a precursor for glutathione and nucleotides. Glutathione protects against oxidant stress, and nucleotides are required for rapid cellular proliferation of enterocytes and lymphocytes under stressful conditions. Third, glutamine induces a variety of protective mechanisms. Glutamine protects against oxidant- and cytokine-induced apoptosis.[130] Glutamine has been shown to induce antioxidant enzymes (ie, heat shock protein and heme oxygenase-1). In a rodent gut ischemia/reperfusion model, intraluminal glutamine provided protection via a novel molecular mechanism of activating the anti-inflammatory transcription factor peroxisome proliferator activator receptor gamma (PPARγ).[103] Of note, enteral glutamine also favorably modulates SIRS. In a well-established model in which manipulation of the small bowel initiates local gut inflammation and

dysfunction that ultimately causes remote lung inflammation and dysfunction, pretreatment with oral glutamine abrogates both local and remote events.[131] Finally, glutamine plays a crucial regulatory role in enterocyte proliferation, which restores villous surface area. This is critical in restoring gut digestive and absorptive capacity and the ability to tolerate enteral nutrition. As noted previously, negative studies with glutamine and septic shock have blunted the enthusiasm for its use.

Prokinetic Agents

Because gastroparesis and small and large bowel ileus are commonly seen postoperatively and following resuscitation, they can complicate initiation of enteral feeding. Therefore, agents to restore motility have been sought. Evaluation of such prokinetic agents is difficult because it is not enough to just stimulate contractions, but contractions at adjacent sites must also be coordinated in order for normal digestion, absorption, and transit to take place. Coordinated contractions are under the control of hormonal and neural, both central and peripheral, pathways, and it is these pathways that are affected by the cytokines and other mediators that are upregulated following a traumatic insult. Prokinetic strategies are aimed at either blocking these mediators or overriding them by stimulating normal pathways.

Agents such as erythromycin that act on receptors for motilin, the naturally occurring hormone responsible in part for regulating normal GI motility, have been shown to enhance gastric emptying and intestinal transit in animal models and in some clinical trials. Although clinical studies have documented their effectiveness in promoting gastric emptying, their effectiveness in reducing postoperative ileus has been disappointing.[132] A recent Cochrane Review of systemic-acting prokinetic agents to treat postoperative ileus after abdominal surgery failed to recommend any of the currently available agents.[133] Erythromycin showed uniform absence of effect, whereas there was insufficient evidence to recommend cholecystokinin-like drugs, dopamine-antagonists, propranolol, or vasopressin. Most trials had small sample size and inadequate reporting of methods to draw meaningful conclusions. In addition, it appears that combining agents such as erythromycin and metoclopramide or erythromycin and neostigmine is more effective than using a single agent.[134-136] Lower gastric residual volumes and increased tolerance to enteral nutrition are appreciated; however, outcomes such as infections and mortality remain unchanged. However, Taylor et al[137] showed that distal feeding access was superior after failed single-agent metoclopramide was used. In addition, although gastric versus distal access feeds continue to be a debate, gastric feeds have been shown to be safe, if not more than adequate, to start enteral nutrition.[138]

A promising new peptide, ghrelin, has been shown in a rodent model to not only accelerate gastric emptying and small intestinal transit in unoperated animals, but also reverse postoperative gastric ileus.[106] Ghrelin has been shown to be decreased in critically ill patients.[63] However, small clinical trials examining the efficacy in postoperative and critically injured patients have yet to demonstrate enough benefit for ghrelin or its analogs/agonists to be used in the critical care population.[139,140]

Antioxidants

The cycle of organ hypoperfusion during shock followed by reperfusion during resuscitation results in the formation of detrimental reactive oxygen species. Thus, it is logical to propose that administration of antioxidants could prove beneficial. In many animal models, administration of agents such as superoxide dismutase, ethyl pyruvate, and melatonin limits damage induced by ischemia/reperfusion.[84] In an animal study, administration of α-melanocyte–stimulating hormone preserved both the function and the structural integrity of the intestine following mesenteric ischemia/reperfusion.[84]

Clinically, antioxidant replacement strategies have demonstrated overall reduction in mortality and specific end-organ protection. A randomized prospective trial of antioxidant supplementation with vitamins C and E to critically ill surgical patients, primarily trauma patients, demonstrated a significant reduction in organ failure.[141] Likewise, Collier et al[142] demonstrated a significant risk reduction in mortality in severely injured patients who received high-dose antioxidants compared to historical controls. A systemic review of aggregated clinical trials in critically ill patients demonstrated an overall reduction in mortality with antioxidant supplementation.[143] After subgroup analysis, selenium appeared to be the predominant antioxidant responsible for the positive effects.

The REDOXS study demonstrated worse outcome with glutamine and antioxidants in severe sepsis, especially with acute kidney injury. In addition, the effect appeared to be related to glutamine and not the antioxidants.[127] Despite these results, the use of antioxidants prior to sepsis, organ failure, or specifically kidney injury has been discouraged clinically at the bedside. When the literature is arrogated, early use of antioxidants is still supported in the trauma population.

Probiotics and Prebiotics

A probiotic is defined as a live microbial feed supplement that improves the host's intestinal microbial balance. Commonly used probiotics include lactobacilli, bifidobacteria, and *Saccharomyces*. A prebiotic is defined as a nondigestible food ingredient that beneficially affects the host by selectively stimulating the growth and/or activity of specific bacteria in the colon. Probiotics are usually nondigestible oligosaccharides. The most extensively studied are the fructooligosaccharides (FOS) such as oligofructose. FOS are fermented in the colon, which promotes the proliferation of bifidobacteria with a reduction in clostridia and fusobacteria. Manipulation of the colonic microflora may reduce the incidence of enteral nutrition–associated diarrhea by suppressing enteropathogens.

Clinically, enteric formulas containing probiotics have shown a significant reduction in a variety of postoperative complications. One randomized clinical trial demonstrated

a significant decrease in postoperative infections in patients who have undergone major abdominal surgery and received postoperative enteral formulas containing probiotics.[144] Results of clinical trials employing probiotics, prebiotics, or a combination in critically ill and burn patients, however, have been disappointing.[145]

Synbiotics are a combination of pro- and prebiotics, and the combination is postulated to improve the survival of the probiotic organism by having a specific substrate readily available for probiotic fermentation. In a study in trauma patients, patients receiving symbiotic supplementation had decreased intestinal permeability and lower combined infection rates than those receiving other immunomodulating formulas. The authors postulated that the presence of synbiotics in the GI tract reduced pathogenic flora and thereby decreased the incidence of pneumonia.[146] These findings represent the immunomodulatory potential for synbiotic enteral formulas in the setting of severe systemic inflammation. A recent study by Shimizu et al[147] demonstrated that, in septic patients, prophylactic synbiotics modulated the gut microbiota and environment and may have preventive effects on the incidence of enteritis and ventilator-associated pneumonia.[147]

Great enthusiasm has emerged regarding changes with microbiota in the critically ill.[148] However, more than one meta-analysis failed to demonstrate sufficient evidence to recommend prebiotic, probiotics, or synbiotics to critically ill patients.[149]

Renal Failure

Robel T. Beyene • Richard S. Miller • Shannon C. Eastham

KEY POINTS

- Eighty-five percent of renal blood flow perfuses the outer cortical glomeruli, whereas the remaining 15% perfuses the juxtamedullary glomeruli.
- The final concentration and volume of urine vary with plasma volume, serum osmolality, release of antidiuretic hormone (ADH), and other factors.
- Renal failure is classified by the RIFLE (Risk, Injury, Failure, Loss, and End Stage), AKIN (Acute Kidney Injury Network), or KDIGO (Kidney Disease: Improving Global Outcomes) systems.
- The incidence of renal failure after trauma is 3% to 9%.
- Causes of renal failure after trauma include hemorrhage, hypovolemia, functional prerenal renal failure, toxins (eg, antibiotics), contrast nephropathy, sepsis, and rhabdomyolysis.
- Current KDIGO guidelines promote the use of isotonic crystalloid solutions over colloids for the initial volume resuscitation in patients at risk for or with acute kidney injury.
- Overall energy use is not affected by renal failure alone, and calorie repletion should not be increased based solely on this finding.
- Much as with patients with chronic kidney disease, indications for acute renal replacement therapy include hyperkalemia resistant to usual therapy, acidosis, uremia, and severe volume overload.

INTRODUCTION

Fluid is distributed in the human body through three separate compartments: the intracellular fluid (ICF), and the extracellular fluid (ECF), which is itself broken down into the interstitial and intravascular compartments. The majority of the fluid, roughly two-thirds, is in the intracellular compartment. The extracellular one-third is itself divided such that roughly one-third to one-fourth of the fluid is in the intravascular space as the solute portion of plasma and the remaining two-thirds to three-quarters is interstitial fluid. There is a relatively volumetrically insignificant volume of fluid in the transcellular space, which is to say secretions, cerebrospinal fluid, and ocular fluid.[1,2]

Fluid and some small molecules move in and out of the intravascular space, both in normal and pathologic states. In normal cases, fluid outside of the vasculature distributes between the interstitial and intracellular compartments and can return to the vascular compartment. Vascular endothelial injury leads to vascular leak, with escape of larger molecules and proteins that would normally stay within the vasculature. This extravascular fluid accumulates and becomes edema when more fluid that can be reabsorbed through the lymphatic system is lost into the interstitial space.[1] Functionally, this space, when pathologically engaged, is the so-called "third space."[2] This fluid is trapped and is essentially nonfunctional, or unable to participate in the essential functions of intravascular volume expansion.

In the setting of direct injury, such as traumatic swelling, this can be well circumscribed and have a negligible volume. In critical pathologic states, especially sepsis, this is a widespread process that makes volume estimation and replacement a complex process. There is no clear measure of "third-space" losses, only surrogates, such as ultrasound, physical exam, or patient weight. When this extravascular fluid accumulation happens in organ tissues, this can also contribute to organ dysfunction, as seen in bowel edema or pulmonary edema, which can lead to ileus or respiratory compromise. These states exist in an even more complex interplay with the body's endocrine system and the kidney.

In the prototypical 70-kg person, the 42 L of fluid is divided into 28 L into the ICF and 14 L in ECF, with 11 L in the interstitial fluid space (IFS). The cardiac output in this 70-kg person is 5 L/min with 20% of this flow going to the

kidneys, which leads to a renal blood flow (RBF) of 1250 mL/min. This unusually large RBF reflects the vital renal role in regulating the ICF and ECF, controlling fluid and electrolyte balance, modulating acid-base balance, and excreting undesirable catabolites.[3,4]

NORMAL RENAL FUNCTION

The 1250 mL/min of RBF passes through the renal artery into the interlobar, the arcuate, and, finally, the intralobar arteries; 85% of the RBF perfuses the outer cortical glomeruli; the remaining 15% of RBF perfuses the juxtamedullary glomeruli (Fig. 61-1). The glomeruli (Bowman's capsules) are like capillaries except that proteins, normally, are not filtered.[4,5] While passing through the glomeruli, 20% of the plasma is filtered as a cell-free, protein-free filtrate. The effective renal plasma flow (ERPF) through these tubular vessels is determined by the clearance of para-aminohippurate (PAH) that is filtered and secreted but not reabsorbed by the renal tubules. Normally, 91% of PAH is cleared in one passage; 9% remains bound to the plasma protein. Renal oxygen consumption parallels ERPF, which averages 650 mL/min. True renal plasma flow is calculated by dividing ERPF by 0.91 and averages 710 mL/min. The extraction ratio of PAH, however, may vary with injury and sepsis.

The normal glomerular filtration rate (GFR) averages 125 mL/min (180 L/d) and is measured by the renal clearance (urine concentration × volume/plasma concentration) of exogenous inulin (C_{in}) or endogenous creatinine (C_{cr}), both of which are completely filtered; the C_{in} is slightly higher than the C_{cr} since creatinine in humans is partially reabsorbed by the renal tubules.[5,6] The work of GFR is performed by the heart. The protein-free filtrate passes through the proximal convoluted tubules, where approximately 80% of the sodium and water are reabsorbed by active sodium transport and the passive movement of water, thereby maintaining an iso-osmolar state. The nonfiltered blood, now protein rich, perfuses the efferent arterioles and the peritubular vessels, and augments tubular reabsorption and secretion.[7]

The juxtaglomerular nephrons that receive 15% of the RBF are unique; each has a loop of Henle with descending and ascending straight segments that pass into the inner

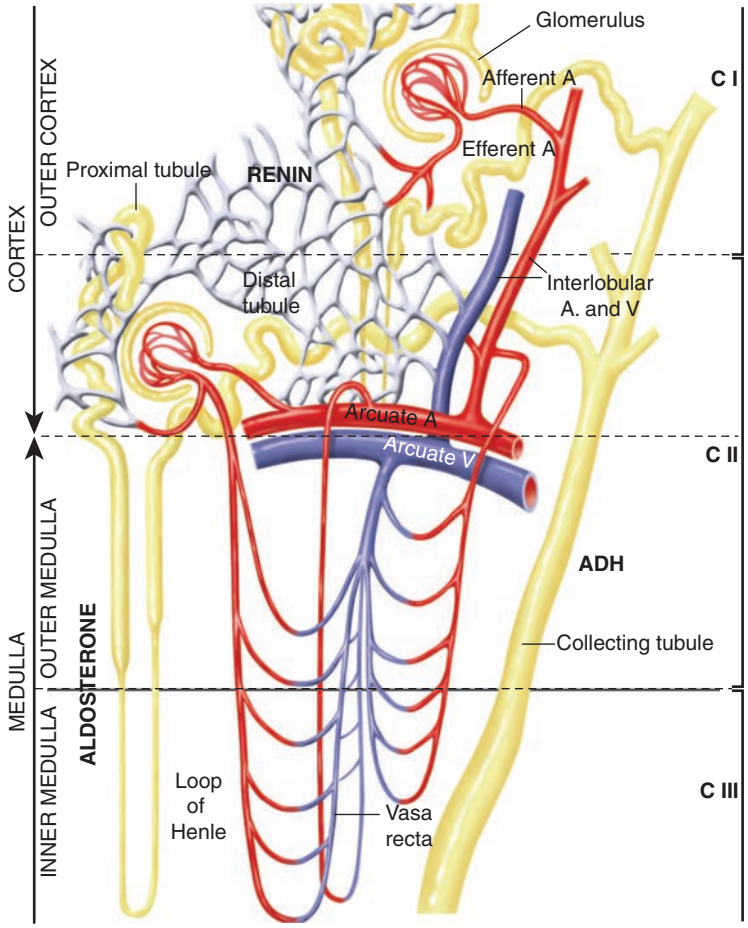

FIGURE 61-1 The kidney is divided into three components. The outer cortex (CI) contains 85% of the glomeruli. The inner cortex/outer medulla (CII) contains the remaining juxtamedullary glomeruli whose peritubular vessels extend to the vasa recta in the inner medulla (CIII) that establishes the hyperosmolality within the loops of Henle.

medulla.[4,5] These segments actively reabsorb sodium against a gradient and, thereby, create a hypertonic medullary interstitium that facilitates the subsequent concentration of glomerular filtrate and the preservation of salt and water in response to antidiuretic hormone (ADH) and aldosterone. Glucose and electrolytes, namely, chloride, phosphate, and potassium, are likewise absorbed at this site. This hypertonic medullary interstitium is further regulated by the peritubular vessels and vasa recta passing close to the loop of Henle (Fig. 61-1). Rapid blood flow through these vessels may cause a "washout" of sodium ions and osmoles, resulting in transient "paralysis" of the renal concentrating mechanism; inadequate blood flow with ischemia injury to these tubular cells impedes sodium reabsorption against a gradient, thus preventing medullary hypertonicity and normal filtrate preservation.[4,5]

Approximately 20% (ie, 36 L/d) of protein-free filtrate and sodium enters the distal convoluting tubules, where additional sodium is reabsorbed by active transport as chloride follows passively.[5,7] This process is facilitated by aldosterone. The distal tubular aldosterone effect is estimated by dividing the free water clearance (C_{H2O}) by the C_{H2O} plus sodium clearance (C_{Na}) in patients with a positive C_{H2O}. When the product is greater than 0.73, the "aldosterone" effect has been blocked. The distal tubule also exchanges sodium for either potassium or hydrogen depending on pH and potassium load. Each distal tubule returns to its own glomerulus at the afferent arteriole where the macula densa and Polkissen body, known as the juxtaglomerular apparatus (JGA), are located. The JGA serves as a "feedback" loop for each nephron affecting sodium and water balance, which are mediated by distal tubular sodium concentration, afferent arteriole pressure, afferent arteriole pulse pressure, and others.[5-8]

After passing through the distal convoluted tubules, the remaining hypotonic filtrate (18 mL/min or 36 L/d) enters the collecting ducts where water reabsorption occurs; this is facilitated by ADH as the filtrate passes through the hypertonic inner medullary interstitium to the renal pelvis.[5] The final concentration and urine volume, therefore, vary with plasma volume, serum osmolality, ADH release, and other factors; urine concentration may range from isosmolar to 1400 mOs/L. Alteration of this highly integrated system occurs with hemorrhagic shock so that the renal concentrating ability may be restricted to 600 mOs/L.[9] The collecting ducts normally reabsorb approximately 17 mL/min or 34 L/d, with the remaining 1 mL/min (1440 mL/d) being excreted as urine.

The renal handling of sodium, osmoles, and water is expressed as the clearances of sodium (C_{Na}), osmoles (C_{osm}), and free water (urine volume – C_{osm}).[4] With normal water and solute intake, the C_{Na} and C_{osm} average 1% to 3% of the GFR; C_{H2O} is usually negative, reflecting the excretion of concentrated urine. A decrease in RBF or plasma volume causes C_{Na} and C_{osm} to fall due to sodium preservation.[3] Likewise, a breakdown in the countercurrent mechanism brought about by a selective insult to the juxtamedullary nephrons and their loops of Henle causes increased C_{Na} and C_{osm} from impaired tubular concentration of sodium.[5,9]

DEFINING ACUTE RENAL FAILURE

The struggle to classify renal failure has been long lasting, but in the 21st century, great strides have been made at codifying the criteria into a meaningful system. In the past two decades, the most successful attempts have been the RIFLE (Risk, Injury, Failure, Loss, and End Stage) criteria, the AKIN (Acute Kidney Injury Network) classification, and the KDIGO (Kidney Disease: Improving Global Outcomes) definition. Unsurprisingly, each of these has benefits and drawbacks.

The RIFLE classification was the product of the Acute Dialysis Quality Initiative, whose aim was to find easily applied, sensitive, and specific criteria based on serum creatinine, GFR, and urine output[10] (Table 61-1).

GFR is a difficult thing to accurately measure, but it is routinely estimated based on endogenous filtration markers, such as creatinine and inulin. Rising serum creatinine, another measure of renal function, has been shown to be independently associated with mortality, possibly through volume derangements or increased risk of infection or anemia.[11] As serum creatinine rises, GFR falls, or urine output decreases, the patient is classified as being at risk of kidney injury, having kidney injury, or having renal failure; to be acute, this has to occur within 7 days of kidney insult and be sustained for a least 24 hours. If the patient suffers complete loss of function for 4 weeks or 3 months, they are said to progress to loss or function or end-stage kidney disease, respectively. This is most useful in the setting of known, preinsult serum creatinine, but in the absence of that information, estimates of baseline values are allowed. While this method has been validated to correlate with outcomes (eg, mortality and length of stay), it has limitations, which are particularly germane to the trauma population. The need for a baseline serum

TABLE 61-1: RIFLE Classification

Class	SCr and GFR	Urine output
Risk	↑ SCr × 1.5 *or* ↓ GFR >25%	<0.5 mL/kg/h × 6 h
Injury	↑ SCr × 2 *or* ↓ GFR >50%	<0.5 mL/kg/h × 12 h
Failure	↑ SCr × 3 or ↓ GFR >75% *or* (if baseline SCr ≥353.6 µmol/L [≥4 mg/dL]) ↑ SCr >44.2 µmol/L (>0.5 mg/dL)	<0.3 mL/kg/h × 24 h or anuria × 12 h
Loss of kidney function	Complete loss of kidney function >4 weeks	Anuric
End-stage kidney disease	Complete loss of kidney function >3 months	Anuric

GFR, glomerular filtration rate; RIFLE, Risk, Injury, Failure, Loss, and End Stage; SCr, serum creatinine.

TABLE 61-2: AKIN Classification

Stage	SCr	Urine output
1	↑ SCr ≥26.5 µmol/L (≥0.3 mg/dL) or ↑ SCr ≥150%–200%	<0.5 mL/kg/h (>6 h)
2	↑ SCr ≥150%–200%	<0.5 mL/kg/h (>12 h)
3	↑ SCr ≥300% *or* (if baseline SCr ≥353.6 µmol/L [≥4 mg/dL]) ↑ SCr ≥44.2 µmol/L (≥0.5 mg/dL)	<0.3 mL/kg/h (>24 h) *or* anuria (12 h)

Note. All patients on RRT, despite SCr or Urine output, belong in stage 3.
AKIN, Acute Kidney Injury Network; SCr, serum creatinine.

TABLE 61-3: KDIGO Classification

Stage	SCr	Urine output
1	1.5–1.9 times baseline *or* ≥0.3 mg/dL (≥26.5 mmol/L) increase	<0.5 mL/kg/h for 6–12 h
2	2.0–2.9 times baseline	<0.5 mL/kg/h for ≥12 h
3	3.0 times baseline *or* Increase in SCr to ≥4.0 mg/dL (≥353.6 mmol/L) *or* Initiation of renal replacement therapy *or* In patients >18 years, decrease in eGFR to <35 mL/min/1.73 m^2	<0.3 mL/kg/h for ≥24 h *or* Anuria for ≥12 h

eGFR, estimated glomerular filtration rate; KDIGO, Kidney Disease: Improving Global Outcomes; SCr, serum creatinine.

creatinine and GFR makes this system very problematic in trauma. Methods used to estimate these values are validated in chronic kidney disease, but not in acute injury or trauma.[12] Despite these limitations, its ease of application and intuitive nature have kept it in use in many institutions.

The AKIN classification was created at a 2005 meeting of nephrologists, intensivists, and other interested parties and published in 2007 (Table 61-2).[13] In many ways, this method was just a clarification or modification of the RIFLE criteria, which stipulated that it could only be applied after adequate hydration and exclusion of urinary obstruction; it also removes GFR from consideration and does away with baseline creatinine in favor of two separate serum creatinine measurements within 48 hours of kidney injury. It continues to use urine output in the classification system.

This classification system stratifies renal failure into three stages, simply described as stage 1 through 3, based on rising serum creatinine and urine output. Stage 3 of this system also requires the initiation of renal replacement therapy. This system is more sensitive to small creatinine increases, which were found to correlate to outcome. Again, this system correlates with length of stay, but there is little evidence that there is improved stratification relative to RIFLE. Furthermore, if the creatinine elevation occurs over more than 48 hours, it is difficult to apply the AKIN classification. The inclusion of renal replacement therapy also complicates the utility of this system, as patient presentations and caregiver practices are variable.[12]

The final diagnostic classification system to consider is the KDIGO criteria, which take into consideration aspects of both of the previously discussed criteria including GFR (similar to RIFLE) and a change in creatinine over 48 hours with three levels of stratification (similar to AKIN)[11] (Table 61-3).

Per the recommendations, acute kidney injury (AKI) is defined by certain thresholds of increased creatinine or falling urine output within hours to days. The working group also recommends managing risk and injury based on stratification of risk and stage of AKI. In high-risk patients, this means mitigating exposure to nephrotoxins, ensuring volume status and perfusion pressure, avoiding hyperglycemia, monitoring creatinine and urine output, and potentially using functional hemodynamic monitoring. As patients progress into stages of injury, further escalation of care, including renal replacement and intensive care unit (ICU) admission, are considered. In comparison studies between all three classification systems, KDIGO has proven equivalent at diagnosis with AKIN and RIFLE.[14,15] There is also very little from an outcome standpoint to differentiate between these systems, especially KDIGO and AKIN, which have similar predictive qualities in length of hospital stay and mortality. This is not surprising because all of these systems are based on the same laboratory parameters.

CAUSES OF ACUTE RENAL FAILURE IN TRAUMA

Hemorrhage

Early mortality in trauma is strongly associated with hemorrhage. In the prehospital setting and in the first 24 hours following injury, hemorrhage is the primary cause of mortality following trauma.[16] Among patients who survive the initial insult, hemorrhage continues to be a contributor to long-term morbidity and mortality. With respect to kidney injury, the body's ability to preserve function through homeostatic regulation of RBF across a wide range of blood volumes represents a robust protective mechanism. These neuroendocrine and hydrostatic-driven mechanisms, however, primarily preserve GFR through alterations in vascular resistance to increase filtration fractions.[17,18] Other compensatory adaptations occur simultaneously to maintain cardiac output, but short of rapid restitution of renal plasma flow, these are measures that are unlikely to be effective in avoiding renal failure.[19] These mechanisms are always at work, even within the normal range of blood volumes that occur in the absence of trauma, but as hemorrhage progresses to hypotension, they

fall short and can lead to cell death, tubular necrosis, and acute renal failure.[18] Platelet and red cell aggregates in renal arterioles have been described in trauma patients who progress to renal failure.[17] The damage to the kidney in trauma also includes direct ischemic insult, inflammatory response, and resultant immune response.[18] In the case of patients with preexisting conditions that predispose them to renal injury, the risk of renal failure is even greater.[20] Still, in acute posttraumatic renal failure, hypovolemia is the most commonly described cause and, for the most part, represents a failure to achieve adequate resuscitation.

In the era of damage control resuscitation, it is increasingly common for trauma patients with significant blood loss to have limited crystalloid resuscitation. Although crystalloid resuscitation is still part of the protocol for some prehospital response teams, it has been shown to increase mortality in trauma and is falling out of favor.[21] In high-volume blood loss, most trauma centers will try to achieve a ratio of 1:1:1 of packed red blood cells to fresh frozen plasma to platelets.[21-23] It is widely agreed that these and other improvements in trauma care have likely reduced the incidence of renal failure after trauma.[20] These advances in trauma care were not strictly aimed at curbing the relatively low incidence of posttraumatic acute renal failure, but it has been serendipitous that the same measures taken to capture the patient dying of massive hemorrhage have simultaneously improved our understanding of renal injury in trauma and, in the right hands, decreased its incidence.

Even as our understanding of trauma and our methods continue to improve, there will always be patients who exist at the outer limits of our resuscitation efforts, so vigilant attention must be maintained. While some centers practice permissive hypotension in the setting of hemorrhage in trauma, for example, the degree of hypotension and length of time of that therapy are questionable and not necessarily easily controlled or the same in all patients.[21,24] Taken to extremes, permissive hypotension is likely to contribute to renal failure to some degree, but its utility in the setting of trauma may still make the risk of renal failure worth it. While hemorrhagic posttraumatic renal failure should be avoided whenever possible, it is not unexpected in a subset of patients who survive massive injury through heroic resuscitation.

Hypovolemia

Prerenal renal failure is caused by inadequate renal perfusion. As perfusion to the kidney decreases beyond compensatory mechanisms, GFR is reduced, leading to increased fluid and salt reabsorption.[25] There are several pathologic states that can lead to renal hypoperfusion, which can be broadly divided into third spacing, decreased effective volume, and decreased extracellular volume. Trauma patients are susceptible to all of these pathologic states but are especially likely to suffer from decreased circulating volume. This can occur due to hemorrhage early in their course, but even beyond that timeline, they remain at risk of hypovolemia. Vomiting, diarrhea, limited oral intake, diuresis, and, more recently, open abdomen management associated with damage control surgery can all contribute to hypovolemic renal failure.[26] While shock unquestionably represents a significant risk, even normotensive patients who remain in a state of diminished extracellular volume are at risk of renal failure due to prolonged exposure to compensatory mechanisms to maintain GFR, including efferent arteriole vasoconstriction.

TABLE 61-4: Urinary Indices for Diagnosing Acute Renal Failure

Measure	Prerenal	Intrinsic	Postrenal
Urine specific gravity	>1.020	Roughly 1.010	Roughly 1.010–1.000
Urine osmolality (mOsm/L)	>400–500	280–320	260–340
Urine sodium	<20	>40	<30
FE_{Na} (%)	<1%	>1%	1%–4%
BUN/Cr	20:1	10:1	10:1
Urine Cr/plasma Cr	>40	<20	<20
Urine urea/plasma urea	>8	<3	N/A
FE_{Urea}	<35%	>50%	N/A

BUN, blood urea nitrogen; Cr, creatinine; FE_{Na}, fractional excretion of sodium; FE_{Urea}, fractional excretion of urea; N/A, not applicable.

Diagnostically, prerenal azotemia is characterized by a physical exam consistent with renal hypoperfusion and confirmed by several urinary and blood test findings (Table 61-4). Specifically, an elevated urine osmolality (>500 mOsm/L); urine specific gravity (>1.020); ratios of urine/plasma osmolarity (>1.5), urine/plasma urea nitrogen (>8), and urine/plasma creatinine (>40); and a blood urea nitrogen (BUN)–to–creatinine ratio of 20 or greater are suggestive of a prerenal cause in an oliguric patient.

The fractional excretion of sodium (FE_{Na}), however, remains the most sensitive diagnostic test.[27,28]

$$FE_{Na} = (U_{Na} \times P_{Cr}/P_{Na} \times U_{Cr}) \times 100$$

The FE_{Na} test quantifies the amount of sodium excreted in the urine relative to the amount filtered by the kidney, which, in a purely prerenal state, should be low since the kidney is normal and can avidly reabsorb the majority of filtered sodium. When patients are treated with diuretics, which can alter the active transport of sodium, fractional excretion of urea (FE_{Urea}) is the preferred diagnostic method. In theory, because urea is primarily reabsorbed in the proximal nephron, diuresis should have less of an effect on the sensitivity of this test than does FE_{Na}; however, its clinical utility is controversial at best.[28,29]

$$FE_{Urea} = (U_{Urea} \times P_{Cr}/P_{Urea} \times U_{Cr}) \times 100$$

Burns

The association between severe burn injury and acute renal failure has long been observed and studied. As we understand

it, burns (especially large ones) lead to a profound inflammatory response, which leads to mediator release, capillary leak, changes in microvascular hydrostatic pressure, and protein loss, all of which contribute to potential renal failure. This combines with the significant open surface area associated with burns, which leads to sizable evaporative fluid loss. The incredible advances in burn care throughout the 20th century, such as categorization by total body surface area and the prioritization of early excision and grafting, have all positively influenced the outcome of renal failure in burn patients.[30] The introduction of the Parkland formula, a strategy that integrates many of these concepts into an early resuscitation guide, has specifically been recognized as a driving force in the drop in the incidence of renal failure after significant burns. The burn community has come to realize that the Parkland formula may in fact lead to excessive crystalloid resuscitation, which comes with several negative side effects, including acute respiratory distress syndrome, heart failure, and multiorgan system failure.[30-32]

Burns can cause renal failure through other mechanisms beyond hypovolemia. Burn eschar can act as a volume-limiting compartment and, much like fascial compartment syndrome, can cause rhabdomyolysis, myoglobinuria, and intrinsic renal injury. Electrical injuries also present a risk of rhabdomyolysis. Burns associated with traumatic injuries, sepsis, and significant comorbidities may also predispose patients to renal failure. These etiologies only explain the incidence of early renal failure in burns, but a second spike in renal failure has also been described. This renal failure is often initially polyuric, less easily tied to a prerenal state or myoglobinuria, and occurs around 5 days after the time of injury.[33,34] As early resuscitation became more standardized, this late form of renal failure became more prominent, but the etiology remains somewhat unclear and may be multifactorial. For example, as patients live longer, they are more likely to develop sepsis or be exposed to nephrotoxic agents. Evidence of mixed tubular and glomerular damage, as well as glomerular microthrombosis, indicates that late renal failure may in fact be intrinsic.

Although burn-related renal failure is less common than it previously was, it does still come with a concerningly high mortality. The mortality of acute renal failure in burns has been reported to be anywhere between 50% and 100%, but is most frequently cited at around 85%, and is attributable to multiple organ failure in most cases.[33-35] Even with renal replacement therapies, this mortality rate makes avoidance of renal failure an important hallmark of burn care.

Functional Prerenal Renal Failure

Prerenal causes of acute renal failure are not limited to extracellular volume status. Decreased effective volume, even in the setting of adequate intravascular volume, may lead to renal failure. This is easily conceptualized in the medical patient, but the perception that trauma patients are generally young and previously healthy, whether true or not, tends to place this farther down the differential diagnosis, but acute coronary syndromes and myocardial infarctions do occur in the trauma population. As the population ages, more people continue to present as trauma patients with preexisting cardiac pathologies, including heart disease, arrhythmias, valvular disease, and polypharmacy with cardiac consequences.[36] In the setting of trauma, these conditions prime the patient for decreased renal perfusion significant enough to cause renal injury. Even among patients who fit the prototypical trauma demographic of young and previously healthy, thoracic injury, and especially significant blunt cardiac injury, can lead to a cardiogenic limitation of effective circulating volume.[37] This can potentially be severe enough to cause acute renal failure. Cardiac injury through dissection of coronary occlusion can also happen as a result of trauma but is rare.

As with the elective surgical population, operative intervention also exerts a cardiac stress on trauma patients but without the opportunity to identify and optimize risk. On top of the risks from trauma, the negative inotropy and vasodilation associated with induction and continuation of general anesthesia can precipitate a cardiac event.[26] This is likelier in older patients, but in emergent trauma operations, it is not uncommon that the patient is still in the midst of active resuscitation and is relatively volume-down at the time of operation, so it is not out of the question that an acute coronary syndrome sufficient to lead to renal failure is possible.[38]

It is important to remember that prerenal azotemia, while potentially reversible, will progress to intrinsic disease if not managed appropriately.[26] Prolonged limitation of RBF will eventually cause an ischemic injury to the renal tubule. Once this occurs, restoration of the renal perfusion will no longer be sufficient to reverse the renal failure. This is especially true if ischemia progresses to cortical necrosis or microvascular coagulation. This is true no matter what the prerenal mechanism initially was; once prerenal patients progress to acute tubular necrosis, they are effectively on a different trajectory of injury and recovery.

Toxins

Intrinsic renal failure occurs when there is injury to the renal tubule, interstitium, vessels, or glomerulus. This is most commonly seen as acute tubular necrosis secondary to ischemia, which is generally from prolonged prerenal azotemia. The second most common cause, however, is toxic tubular necrosis.[26] In the trauma patient who survives the initial resuscitation, there are several common medications that can bring this on. Antibiotics are commonly cited causative agents of toxic acute renal failure in hospitalized patients. Aminoglycosides, which are still used for gram-negative coverage, can produce tubular necrosis in the proximal tubule. They also have a prolonged tissue half-life and can continue to cause injury beyond their immediate usage. Dose, duration, and concomitant use of other nephrotoxic agents can perpetuate this injury, so vigilance is necessary to avoid renal injury when using aminoglycosides.[39] Vancomycin, which is used for resistant gram-positive pathogens, which are more common in surgical and bloodstream infections, is also a known

nephrotoxin. As with aminoglycosides, the mechanism is not completely elucidated but is believed to include oxidative stress. Again, vigilant monitoring of renal function and potential change to an alternative agent are necessary when using these medications.

Nonsteroidal anti-inflammatory drugs (NSAIDs) remain a vital part of pain management. As the true risk of opioid exposure is better understood, the use of NSAIDs is likely to only grow.[39] Renal failure with NSAIDs follows two mechanisms. In one case, inhibition of cyclooxygenase leads to inhibition of renal prostaglandin synthesis. Under normal conditions, this is unlikely to cause renal failure, but in patients dependent upon prostaglandin for renal perfusion, including patients with any prerenal insult, such as acute hemorrhagic anemia, the resultant afferent arteriole vasodilation can cause a drop in the GFR and result in renal failure.[40] NSAIDs can also cause an acute interstitial nephritis, which can progress to nephrotic syndrome.

Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists are generally well tolerated, but they also cause efferent arteriole vasodilation. When added to their desired effect of lowering systemic blood pressure, this may lead to a hemodynamic cause of acute renal failure.[39] Although this is a well-known complication, it is not common that trauma patients get put on angiotensin-converting enzyme inhibitors and angiotensin receptor blockers in the hospital setting.

Methicillin is classically implicated in a direct insult to the kidney leading to acute interstitial nephritis, but this can also occur with penicillin, cephalosporin, sulfonamides, and NSAIDs. Toxic acute interstitial nephritis presents with elevated creatinine, fever, possible rash, and urine sediment of red blood cells, white blood cells and their casts, and eosinophils. There may be mildly increased protein excretion.[39] If renal function does not improve with supportive therapy and medication discontinuation, renal biopsy to identify tubulointerstitial damage would be called for, as well as possible steroid administration.

Other medications implicated in renal injury are acyclovir, sulfonamides, antifungals, some chemotherapeutic agents, and some volatile fluorinated anesthetics, especially halothane.[39] The mechanisms involved are variable and not completely understood, but in general, they work through some combination of renovascular changes and direct insult. Colloids also present an underappreciated risk to the kidney. Just the plasma oncotic pressure increase from colloids can potentiate acute renal failure, especially in the hypovolemic patient. Although all colloids can cause this, the least likely offender is albumin. Colloids may also cause tubular obstruction or direct tubular toxicity.

Environmental agents, such as venom, or endotoxins, such as heme pigment, myeloma chain proteins, or other products, can also be nephrotoxic. Nephrotoxic renal failure tends to cause a nonoliguric nephritis and, in general, is associated with a lower mortality than oliguric renal failure.[40] Broadly speaking, most cases of toxic kidney injury can be reversed with withdrawal of the offending agent and limitation of other renal injuries, as well as treatment of underlying disease. If allowed to progress, however, an irreversible renal cortical necrosis may occur.[26]

The classic presentation of toxic nephropathy can be muddied by the simultaneous presence of ischemic insults to the kidney, such as patients with sepsis or HIV. This occurs because patients with acute illnesses or complicated comorbidities are more likely to have exposure to several, potentially nephrotoxic medications.[26] Patients with any underlying renal insufficiency or diabetes are very susceptible to renal injury from toxin exposure, as are the elderly. Hydroxyethyl starch, for example, is relatively unlikely to cause renal injury in a patient with preserved renal function, but in patients with already compromised renal function from sepsis or cardiac surgery, there was found to be a significant worsening of renal function after it was infused.[39]

Many of these discussed toxins are necessary or common medications that can and should be given when they are needed, but they do warrant close monitoring. In some cases, that means monitoring levels, such as gentamicin or vancomycin, but in other cases, it may simply mean watching renal function and having a high index of suspicion for renal injury secondary to the prescribed medication. Appropriate supportive treatment, such as judicious fluid administration, early withdrawal of injurious agents, and electrolyte management, are all necessary measures to avoid or mitigate toxic nephropathy.

Contrast Nephropathy

Every clinician will eventually have to face the risk or the fallout of radiocontrast nephropathy at some point, but it is a particularly ever-present issue for the trauma surgeon. The nature of the presentation of the trauma patient is such that you do not routinely get the details of their past medical history, previous exposures to contrast, preinjury laboratory findings, or occasionally, even their name. Within those limitations, you have to decide on a moment's notice whether they are or are not appropriate for computed tomography (CT) and whether they will or will not get contrast. In most American College of Surgeons designated Level I trauma centers, patients who come in as high-level activations and are deemed appropriate for CT will get at least intravenous (IV) contrast at presentation, despite their limited presentation, because the CT can be instrumental to clinical decision making.

The historical literature on contrast-induced AKI (CI-AKI) is primarily concentrated on iodinated contrast media and focused on cardiac angiography. Iodinated contrasts are water-soluble benzene rings linked to iodine atoms and, in their earliest formulations, were hyperosmolar.[41] The suggested mechanism of contrast-induced nephropathy is medullary hypoxia due to contrast-induced vasoconstriction and direct renal tubular toxicity through oxidative stress, cell failure, impaired calcium management, and increased apoptosis.[41,42] As with other nephrotoxins, patients with normal preexposure renal function are less likely to progress to renal failure. Other risk factors are diabetes, old age, hypertension, heart failure, volume depletion, hemodynamic instability, and concurrent use of other nephrotoxins.[11]

The clinical relevance of this proposed pathophysiology is now being questioned. As clinical use of hyperosmolar contrast has fallen almost completely out of practice, it has been replaced primarily with either low-osmolar or isosmolar contrast media, both for CTs and for traditional angiography.[11] In the modern era, both of these contrast media have been shown by meta-analysis to have much lower risk of CI-AKI than was previously thought.[43,44] It has even been suggested that the very idea of contrast-induced kidney injury is more a matter of our failure to understand the risk factors for kidney injury in hospitalized patients than a legitimate pathophysiologic state. Aycock et al,[45] in a meta-analysis, demonstrated no difference in renal dysfunction between patients who underwent CT either with or without contrast. While even this study contends that high-osmolar agents are associated with kidney injury, they are all but completely out of use, and the new agents seem to be very safe. The authors pointedly recommend moving away from even using the phrase "contrast-induced nephropathy."

The AKI guidelines from the KDIGO group support this finding and further point out that significant variation is found in the serum creatinine of hospitalized patients, irrespective of either their exposure to contrast or their diagnosis of kidney injury.[11] This variation is great enough that up to 35% of patients who did not receive contrast would qualify for the diagnosis of CI-AKI at the same serum creatinine if they had received contrast. Similarly, the focus on contrast exposure secondary to cardiac angiography may have been misleading. Not only are the indications and protocols different between cardiac angiography and CT contrast exposure, but also it is difficult to dissociate the risk of the contrast from the risk of cardiac dysfunction, hypotension, arrhythmia, renal artery embolization, hemorrhage, or atheroma dislodgement that may be encountered in cardiac angiography.[46]

Gadolinium-based contrast agents used in magnetic resonance imaging are clinically believed to be safer than iodinated contrast from the standpoint of nephrotoxicity, although there is some suggestion that they may be nephrotoxic in high-risk patients. However, in patients with chronic kidney disease or end-stage renal disease, they are known to cause a nephrogenic systemic fibrosis, which can be lethal.[42]

In the end, our feeling is that the data have significantly overstated the risk of kidney injury secondary to contrast administration. This is based on data that were found with contrast media of only historical significance or with the conflation of cardiac angiography and CT-related exposure. Our practice relies heavily on diagnostic CT early after presentation in most high-level trauma contacts, well before kidney function labs return, but we remain confident that the greater risk to these patients is in having undiagnosed pathology or nontherapeutic operations and interventions as a result of avoiding what is likely a safe CT.

Sepsis

The incidence of sepsis in trauma patients has been cited at anywhere from 2% to 14.4%, but what is certain is that septic patients have worse outcomes than patients without sepsis, with mortality of up to 23%.[47-49] This is despite the fact that we have become better in treating both trauma and sepsis over time. Injury Severity Score, Revised Trauma Score, and admission Glasgow Coma Scale score were all independent predictors of sepsis in trauma patients, and once a patient had sepsis, not only their mortality, but also their ICU and hospital length of stay, significantly increased. Progression from sepsis to organ dysfunction occurs through several factors, including impaired tissue oxygenation through hypotension, red blood cell dysfunction, and microvascular thrombosis.[50] Other factors, including proinflammatory and anti-inflammatory processes, mitochondrial damage, and capillary leak, also contribute to worsening organ dysfunction. These are the same processes at work in trauma patients with septic renal failure.

Renal failure has been demonstrated to occur with greater incidence in patients with worse sepsis, with 19% incidence in moderate sepsis and 51% in patients with septic shock and positive blood cultures.[6] The arterial vasodilation that occurs with sepsis activates neurohormonal and sympathetic pathways, leading to activation of the renin-angiotensin-aldosterone system (RAAS) in an effort to maintain perfusion. In brief, RAAS is stimulated by low RBF at the renal juxtaglomerular cells (through shock or any other mechanism) triggering conversion of prorenin to renin. That leads to hepatic angiotensinogen being converted to angiotensin I, which is itself converted by angiotensin-converting enzyme into angiotensin II. This triggers the secretion of aldosterone from the adrenal cortex, which leads to reabsorption of sodium and water in the renal tubules and excretion of potassium, which should lead to volume expansion. That and the vasoconstrictive effects of angiotensin II should support blood pressure. However, the renal vasoconstriction and retention of sodium and water may lead to worsening renal failure. Use of vasoactive agents to support blood pressure may also contribute by worsening RBF and limiting GFR. In patients who undergo excessive volume administration, increased interstitial volume and pulmonary edema may precipitate acute respiratory distress syndrome and still lead to multiple organ dysfunction.

A phenomenon of "inappropriate polyuria" has previously been described as occurring in septic patients and, in some cases, preferentially occurring in patients with sepsis following trauma.[17] It has been proposed that these patients exhibit decreased RBF, leading to reduced filtration fraction and oncotic pressure. In response, there is less salt and water reabsorbed in the distal tubules and a resultant diuresis and enuresis.[9] In these patients, polyuria of up to 400 mL/h has been reported. These findings were primarily described in the 1970s, however, and it may be the case that these patients were likely suffering from nonoliguric renal failure.[40] These patients are not unique to sepsis and, in fact, are more commonly seen in nephrotoxic exposure, but also have a high-output renal failure and can progress to oliguric renal failure. The cause of this trajectory of renal failure is unclear, but it has been described throughout most of the 20th century.

The combination of sepsis and renal failure has a very high associated mortality of 70%.[6] For this reason, predictors and markers for renal failure in sepsis have been sought, but no clear evidence has been found for a method better than a high clinical suspicion and appropriate supportive care. Controlling blood glucose and associated immune dysfunction and avoiding disseminated intravascular coagulation and microthromboses also help prevent progression to, or mitigate the effects of, renal failure in sepsis.[6]

Rhabdomyolysis

The definition of rhabdomyolysis is leakage of contents of the muscle cells such as electrolytes, myoglobin, and sarcoplasmic proteins into the circulation. There are several categories of this disease entity. However, this chapter will focus on trauma-related rhabdomyolysis from crush syndrome, limb compression, and/or major artery occlusion.[51]

Myoglobinuria is unique to rhabdomyolysis. In this circumstance, the urine appears tea colored when serum myoglobin levels reach 100 mg/dL. In more severe cases with prolonged muscle ischemia or necrosis prior to treatment, the urine appears black.[52] AKI associated with myoglobinuria is the most serious complication of severe rhabdomyolysis and may be life-threatening. Approximately 7% to 10% of all cases of AKI in the United States are related to rhabdomyolysis.[53]

The mechanism by which rhabdomyolysis causes impaired renal function is thought to be simultaneous vasoconstriction, tubular ischemia, and obstruction primarily at the level of the distal tubule. Hypovolemia and vasoconstriction augment myoglobin accumulation along the renal tubules. The nephrotoxic effects of myoglobin appear to only occur in an acidotic environment.[51,54,55] Major crush injury or prolonged ischemia of a limb causes massive necrosis of the muscle. The patient usually presents with limb swelling, weakness, and severe myalgia. As mentioned, the urine appears dark brown to black in the setting of markedly elevate serum creatine kinase (CK) levels (Fig. 61-2).

Although no specific CK level determines if the patient will develop AKI, some data support the theory that as the CK rises, the incidence of AKI increases. The risk of AKI is very low if the admission CK levels are below 15,000 to 20,000 units/L. Heme-positive urine without red cells confirms the production of myoglobin.[54,56,57] Oliguric or anuric renal failure may occur in severe cases. Rapidly rising plasma creatinine is a common finding. Major electrolyte abnormalities can occur when components of muscle breakdown are released into the circulation and can contribute to the severity of the AKI that may ensue (Table 61-5).

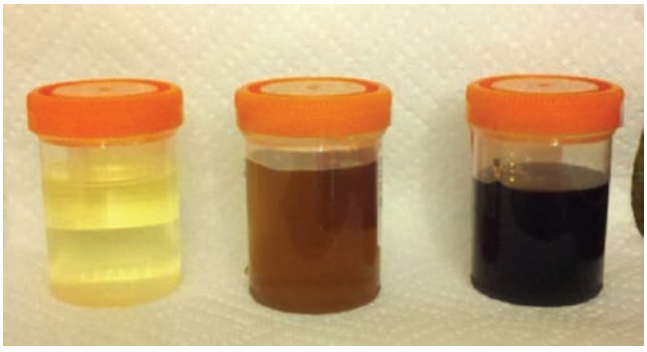

FIGURE 61-2 Urine progression from clear (normal) to tea colored (myoglobinuria) to black (rhabdomyolysis).

TABLE 61-5: Electrolyte Abnormalities Associated with Rhabdomyolysis

Hyperkalemia, can be life-threatening
Hyperphosphatemia
Hyperuricemia
Metabolic acidosis, high anion gap
Hypermagnesemia
Hypocalcemia
Hypercalcemia, after recovery from acute kidney injury

Hyperkalemia can occur rapidly and may reach life-threatening levels. One unique finding during the recovery from rhabdomyolysis-induced AKI is hypercalcemia, which occurs when calcium is mobilized after being deposited in the muscle during the ischemic event.[58]

The literature on this disease entity clearly shows that early, aggressive fluid resuscitation is the mainstay of treatment. Hypovolemia causing the renal vasoconstriction and ischemia decreases adenosine triphosphate production due to hypoxia in the renal tubules This causes cellular necrosis and accumulation of cellular debris in the tubular lumen with precipitation of myoglobin that obstructs the distal convoluted tubules. Volume loading and "flushing" of the casts is the proposed benefit of fluid resuscitation.[55,59]

The key to avoiding AKI is to start fluid therapy as soon as possible. Reports of starting fluids in the field with crush injuries demonstrate improved outcome. The earlier the fluid management, the better are the outcomes. Up to 10 L of fluid per day may be required depending on the severity of the rhabdomyolysis.[54]

There have not been any randomized studies determining which type of fluid replacement is favored. The benefits of alkalization of the urine are based on animal studies, and there is no evidence that it is any better than simple volume replacement.[51,54,60] Normal saline and half normal saline with sodium bicarbonate are the most frequently used salt solutions. There are several suggested steps in the management of myoglobinuria and rhabdomyolysis (Table 61-6).

Diuretics should not be used during the initial management of rhabdomyolysis. Mannitol is the preferred diuretic and should only be used after maximum fluid replacement has been achieved. Its benefit stems from the fact that myoglobin toxicity affects the kidney by lipid peroxidation and the production of oxygen free radicals. Tubular obstruction by myoglobin is also associated with AKI. Mannitol has the theoretical benefits in this setting of being a free radical scavenger and an osmotic diuretic improving urinary flow and

TABLE 61-6: Steps in Management of Myoglobinuria and Rhabdomyolysis

Measure serum creatine kinase, urine dipstick, myoglobin, electrolytes, BUN, and Cr.
Initiate volume repletion as soon as possible with normal saline at rate between 200 and 1000 mL/h.
Target urine output at 200–300 mL/h.
Check electrolyte levels, especially potassium and calcium, frequently.
Check urine pH and attempt to keep above 6.5. Consider adding sodium bicarbonate if urine remains acidotic or systemic acidosis.
Mannitol only if needed to maintain desired urine output despite adequate fluid administration.
Maintain volume resuscitation until myoglobin is cleared.
Use CRRT for symptomatic, resistant hyperkalemia, volume overload, severe acidosis, and oliguria/anuria despite fluids and mannitol.

BUN, blood urea nitrogen; CR, creatinine; CRRT, continuous renal replacement therapy.

flushing of tubular toxins.[61,62] Long-term survival in patients who develop rhabdomyolysis-induced AKI is favorable, with 80% recovering full renal function.[63]

Severe acidosis, volume overload, or intractable life-threating electrolyte abnormalities in the setting of AKI requires hemodialysis. Continuous renal replacement therapy (CRRT) can rapidly correct electrolyte abnormalities and helps clear myoglobin effectively from the renal tubules and the bloodstream. Despite the usefulness of CRRT in clearing myoglobin and correcting electrolyte levels, mortality in this setting has not improved with the use of hemodialysis.[55,64-67]

PREVENTION AND TREATMENT

Resuscitation as Treatment

The topic of fluid management as it relates to renal injury is one of balance. Hypotension and, in turn, renal hypoperfusion can lead to temporary renal impairment or permanent injury. Conversely, volume overload can also potentiate harm and poor outcomes. Thus a balance between adequate fluid resuscitation, with vasopressor support as needed, and attention to volume overload must exist.

The ideal resuscitation fluid has yet to be determined and is certainly related to the specific patient and the patient's underlying problem. In the hemorrhagic trauma patient, blood and its components must be administered, but in the complex ICU patient, fluids may vary. The Saline versus Albumin Fluid Evaluation (SAFE) study noted no difference in the use of 4% albumin versus normal saline with regard to 28-day mortality. The fluids were also similar in relation to organ failure rate, ICU and hospital days, mechanical ventilation days, and days of renal replacement therapy (RRT).[68] Similar findings were noted in the Colloids Versus Crystalloids for the Resuscitation of the Critically Ill (CRISTAL) trial, which again noted no difference in 28-day mortality between colloid and crystalloid administration in the hypovolemic shock patient. Of note, 90-day mortality was found to be lower in the colloid group, a finding that must be further evaluated.[69] Development of AKI in critical patients requiring fluid administration was also addressed in the 0.9% Saline versus Plasma-Lyte 148 for ICU Fluid Therapy (SPLIT) trial to determine if buffered crystalloid therapy would offer any advantage. No difference in the development of AKI was found between these two groups.[70]

Therefore, current KDIGO guidelines promote the use of isotonic crystalloid solutions over colloid products for the initial volume resuscitation in patients at risk for or with AKI, excluding those patients in known hemorrhagic shock.[11] This is based on the lack of evidence proving colloid administration to be superior. Colloids may, however, offer an advantage in certain patient populations or those at risk for volume overload.[71]

Fluid overload may also be problematic. The Program to Improve Care in Acute Renal Disease (PICARD) group determined that critically ill patients with volume overload, defined as a greater than 10% increase in body weight from baseline, were at much higher risk of 60-day mortality.[72] Additionally, they found that among patients requiring dialysis, those with a lower overall fluid accumulation at the start of dialysis had a lower rate of mortality. Similar findings were noted by the FINNAKI study group, which found twice the 90-day mortality in patients with volume overload (again defined as >10% increase from baseline body weight) at the time of RRT initiation.[73]

Glucose Control

Hyperglycemia is a marker of critical illness. Stress hormones, inflammatory mediators, and counterregulatory hormones all function to disrupt the signaling of insulin and promote insulin resistance.[74] Determination of hyperglycemia as cause of organ dysfunction and mortality in critically ill patients has remained in question.

Higher glucose levels were found to be associated with increased risk of death in critically ill trauma patients by Wahl et al.[75] Using glucose ranges of greater than 200, 141 to 200, and 140 mg/dL or lower, the mortality rates were 40%, 20%, and 3.3%, respectively. Van den Berghe et al[76] determined that tighter glucose control, defined as at or below 110 mg/dL, resulted in decreased morbidity and mortality in surgical ICU patients. However, their subsequent studies comparing medical and surgical ICU patients showed no difference in mortality with tight glucose control.[77] There was a reduced incidence of AKI and need for RRT in the intensive insulin therapy surgical ICU group,[76] but only a reduction in AKI without an associated reduction in use of RRT in the intensive insulin therapy medical ICU group.[77] The Efficacy of Volume Substitution and Insulin Therapy in Severe Sepsis (VISEP) study observed that critically ill septic patients treated with either tight glucose control (glucose range, 80–110 mg/dL) or conventional glucose control (glucose range, 180–200 mg/dL)

showed no difference in AKI, 28- or 90-day mortality, or Sequential Organ Failure Assessment (SOFA) scores.[78] Notably, severe hypoglycemia (glucose <40 mg/dL) was found in the intensive insulin therapy group. Similar results were found by Thomas et al,[79] showing no significant difference between the intensive versus conventional insulin therapy groups in 28- or 90-day mortality, AKI rates, or SOFA scores, with hypoglycemia again found more frequently in the intensive insulin therapy group. A meta-analysis of randomized controlled trial data, including the NICE-SUGAR (Normoglycemia in Intensive Care Evaluation—Survival Using Glucose Algorithm Regulation) study,[80] again showed that intensive insulin therapy significantly increased the risk of hypoglycemia without reduction in mortality benefit in critically ill patients, although surgical ICU patients may need further evaluation.[81]

Based on the variability of findings and the risk of potential patient harm, KDIGO guidelines recommend insulin use in critically ill patients, with a glucose target of 110 to less than 150 mg/dL in critically ill patients.[11] Further evaluation of target ranges and specific patient populations may be warranted in the future.

Nutrition

Renal failure can include alterations in metabolism, a state of inflammation, and nutrient imbalance. Malnutrition is predictive of mortality among patients with AKI.[82] AKI is frequently found in the setting of other comorbidities, and all organ dysfunction must be taken into account.

Overall energy use is not affected by renal failure alone, and caloric repletion should not be increased based solely on this finding. Additional comorbidities, multiple systems of organ dysfunction, and/or sepsis may increase total energy expenditure to a maximal addition of 25% to 30%.[83] Current American Society for Parenteral and Enteral Nutrition (ASPEN) and KDIGO guidelines recommend standard total energy intake of 25 to 30 and 20 to 30 kcal/kg/d, respectively.[11,84] Overfeeding does not necessarily result in positive nitrogen balance and may result in complications associated with hypertriglyceridemia, hyperglycemia, and volume overload.[85]

Carbohydrate metabolism in acute renal failure is often associated with the finding of hyperglycemia secondary to an increase in muscle protein degradation,[86] alterations in hepatic glucose uptake, and insulin resistance.[87] Recommendation of 3 to 5 g carbohydrates/kg body weight with close glucose monitoring is advisable.[11]

Lipid metabolism in AKI is affected by lipolysis inhibition resulting in hypertriglyceridemia. There may also be slowed clearance of supplemented lipids.[88] Recommendation for fat administration is 0.8 to 1 g/kg body weight.[11]

Protein catabolism in acute renal failure is multifactorial and related to increases in muscular release and degradation of amino acids with negative nitrogen balance, resistance to growth factors, inflammation, and increased hepatic uptake of amino acids, insulin resistance, acidosis, and other factors. Overall catabolism is also affected by underlying disease processes, type and degree of renal dysfunction, and, if applicable, the type of RRT used.[88]

Simply increasing protein supplementation may not achieve positive nitrogen balance and may in fact produce azotemia and further acidosis without improvement in overall outcome.[89] With the use of CRRT, fluid balance and azotemia and higher protein intake can be better tolerated.[90,91] KDIGO guidelines recommend 0.8 to 1.0 g/kg/d of protein in noncatabolic AKI patients without dialysis, 1.0 to 1.5 g/kg/d in patients with AKI on RRT, and up to a maximum of 1.7 g/kg/d in patients on CRRT and hypercatabolic patients.[71] ASPEN guidelines advise a general goal of 1.2 to 2 g/kg/d and up to a maximum of 2.5 g/kg/d for those on CRRT or frequent hemodialysis, with weight determined by usual weight for average-weight patients and ideal body weight for obese and critically ill patients.[84]

Trace elements, such as selenium and copper, and certain water-soluble vitamins may need to be replaced, especially with RRT use. Vitamin C supplementation in patients with AKI should be 50 to 100 mg/d or higher with CRRT. Other micronutrients may need to be monitored and supplemented as required.

Adequate nutritional support offers a reduction in mortality and morbidity for critically ill patients. The enteral route for nutrition is preferred whenever possible. Enteral nutrition promotes gut motility, protection, and immune function.[92,93] Early enteral feeding should be used and supplemented with parenteral nutrition if needed to offer complete nutritional support.[94] ASPEN guidelines suggest start of nutritional support with enteral nutrition within 24 to 48 hours of admission to ICU.[84]

Renal Replacement

AKI remains a complicating factor for many trauma patients, with shock and sepsis being major risk factors for RRT.[95] Indications for RRT in the acute setting may differ from those in chronic kidney disease. Metabolic disturbances such as hyperkalemia not responsive to therapeutic interventions, acidosis, uremia, and severe volume overload may require RRT consideration. Certain toxins and drug overload may also require intervention. Ideally, RRT can serve to promote fluid and electrolyte balance, offset dysfunction in other organ systems, and prevent further renal injury.

Volume overload, in particular, may result in poor outcome in the setting of AKI. The Program to Improve Care in Acute Renal Disease (PICARD) group noted that dialyzed survivors had significantly less fluid overload when dialysis was started compared to nonsurvivors. Patients not undergoing dialysis also had less volume overload at the time of peak creatinine, whereas those with fluid overload at the time of peak creatinine were less likely to recover kidney function. Fluid overload at the time of AKI diagnosis resulted in less recovery of kidney function.[72]

Although there is certainly benefit to RRT, complications may arise resulting in prolonged renal dysfunction or

poor recovery of renal function. Associated hypotension with impaired RBF may result in ischemic renal injury.[96] Fluid and electrolyte imbalance and access-related complications may also be problematic.[97] Therefore, timing of RRT must be carefully considered.

The PICARD group conducted a multicenter study of critically ill patients requiring dialysis for severe AKI. Therapy timing was determined by BUN concentration at the start of RRT, with the early group defined by a BUN of 76 mg/dL or lower and the late group defined by a BUN of greater than 76 mg/dL. Mortality within 60 days was found to be lower in the early RRT group, with a relative risk for death in the late therapy group of 1.85 (95% confidence interval, 1.16–2.96).[98]

Another study evaluated the timing of RRT in surgical ICU patients after major abdominal surgery with utilization of the RIFLE classification system.[10] Simplified RIFLE classification was used to differentiate the early dialysis group (RRT with sRIFLE-R [risk] or sRIFLE-0) and the late dialysis group (RRT with sRIFLE-I [injury] or sRIFLE-F [failure]). Late initiation of RRT was determined to be an independent predictor for in-hospital mortality.[99]

Regarding type of RRT for use in AKI, each has advantages and disadvantages. CRRT allows for slower fluid removal with less abrupt solute shifts. Hemodynamic stability can be maintained throughout, and titration can be performed based on the patient's overall status. Intermittent RRT (IRRT) can be performed more quickly with rapid effect and offers opportunity for patient mobilization for other clinical interventions.

In hemodynamically stable patients, IRRT versus CRRT does not appear to make a significant difference.[100-102] A Cochrane Collaboration review evaluating 15 randomized controlled trials determined no survival advantage of CRRT over IRRT, as well as a similar degree of renal function recovery. Of note, the CRRT group had a higher mean arterial pressure at treatment end and less elevation in vasopressor support.[103]

In patients with tenuous hemodynamic status or those with acute brain injury, CRRT may be beneficial. CT imaging performed before and after intermittent hemodialysis (IHD) and continuous veno-venous hemofiltration (CVVH) showed that significant changes in the density of white and gray matter were observed after IHD, indicating brain edema.[104] Cerebral perfusion pressure may be altered by changes in mean arterial pressure or alteration in intracranial pressure from rapid solute shifts. These issues can be avoided or handled more consistently with the use of CRRT.[105]

Determination of the timing of the ending of renal support can be difficult and depends on the type of RRT used. In IHD, clearance of solutes is variable between treatment sessions, whereas CRRT allows for more reliable determination of kidney function. Values including urine output, creatinine excretion, and change in BUN and serum creatinine must be evaluated. Wu et al[106] evaluated dialysis termination in postoperative patients and determined that the risk of redialysis was reduced with increased urine output, shorter duration of dialysis, age less than 65 years, and lower disease severity score. The BEST Kidney (Beginning and Ending Supportive Therapy for the Kidney) study evaluated multiple centers and also found that urine output at the time of CRRT cessation was the most important predictor of successful discontinuation. Of note, the use of diuretic was found to negatively affect the predictive ability of urine output, consistent with lack of effect on overall GFR. In addition, patients weaned successfully without subsequent need for further dialysis treatment had better outcomes.[107] Overall, RRT is associated with significant impact on morbidity and mortality, and goals of care often come into play with regard to continuation of care.[108]

MAJOR RENOVASCULAR INJURIES AND NEPHRECTOMY AFTER TRAUMA

Major renovascular injuries are uncommon, and thus there is significant controversy related to the appropriate treatment and the subsequent outcomes related to observation, repair, or immediate nephrectomy. Attempts at renal arterial revascularization for trauma are generally poor, and the potential for subsequent renal impairment, including renovascular hypertension and renal failure, is high[109] (Fig. 61-3).

A Western Trauma Association multicenter report on major renovascular injuries suggests that the majority of patients have associated abdominal injuries, and over half arrived in the emergency department in hemorrhagic shock. An algorithm suggests that all patients with grade V renal injuries and hemodynamically unstable patients with grade IV renal injuries should undergo nephrectomy.

The best results for renal salvage for grade IV injuries are with renal vein and parenchymal repair only.[110] Case reports of endovascular repair and stenting of renal arterial injuries are rare and seldom result in successful outcome.[111,112]

The only studies related to long-term outcomes after nephrectomy are for patients undergoing live kidney donation. A recent analysis showed that life expectancy may be reduced by 0.5 to 1 year in this patient population.[113] There is no literature, however, describing the long-term risks related to nephrectomy as a result of trauma, including chronic kidney disease, end-stage renal disease, or life expectancy. Long-term follow-up studies are needed to determine this potential risk.

OUTCOMES AFTER RENAL FAILURE

While the incidence of renal failure in trauma has declined (now in the single-digit range of 3%–9%), when it does occur, the outcomes remain unsatisfactory.[20,114] In critically ill patients, acute renal failure has been linked to a greater than 20% mortality, which is even higher when considering all in-hospital mortality.[115] In fact, stable survival is not achieved until after 30 to 60 days.[10] In one study, risk of mortality was about three times greater in patients with acute renal failure than those without renal failure, whether they were in the ICU or the ward.[116] That study also linked AKI to earlier onset of multiorgan system failure (24 vs 48 hours after admission).

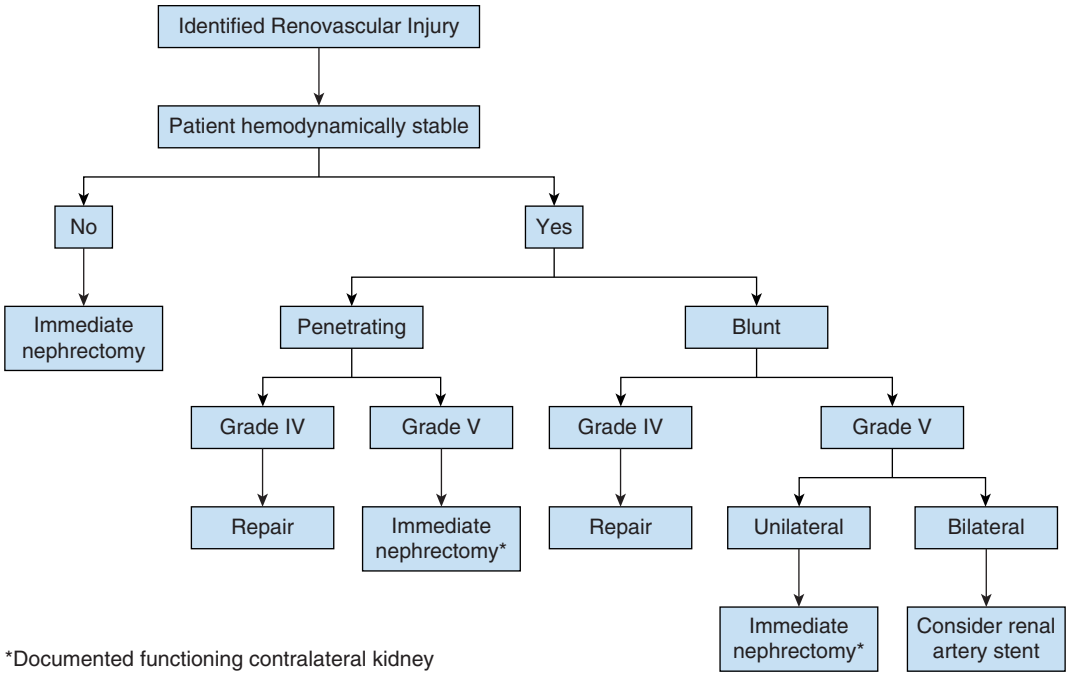

FIGURE 61-3 Algorithm for renovascular injury. (Reprinted with permission from Knudson MM, Harrison PB, et al. Outcome after major renovascular injuries: a Western Trauma Association multicenter report. *J Trauma.* 2000;49(6):1116-1122.)

Among survivors, it is important to understand what the renal-specific outcomes may be; in other words, who is discharged free of renal replacement. The rate of patients requiring dialysis after discharge has been previously stated to be in the mid-30% range, but this may not be the case.[117,118] A more recent study demonstrated a rate of 18.6%, which they attributed to continuous renal replacement rather than intermittent replacement.

Patients who require RRT have been shown to have even higher mortality and higher level of care, based on diagnostic and therapeutic needs associated. The associated mortality is also fourfold that of patients who did not progress to RRT, even when matched to patients with similar levels of care.[119] This supports the idea that renal failure is an independent risk factor for these poor outcomes. Proposed causes in the RRT group are physiologic dysfunction associated with renal failure, versus the negative direct effects of renal replacement itself. Predictably, secondary diagnoses requiring critical care, such as cardiac irregularity or mechanical ventilation, were associated with even worse outcomes. The risk associated with continuous versus intermittent renal replacement is unclear.[119]

These findings, however, were primarily studied in nontrauma patients, rather than in the trauma population. In this group, the causes are multifactorial and the trauma itself is an additional risk, which makes it difficult to assign incidence specific to trauma.[115] Unfortunately, there is no work that specifically predicts the outcome of renal failure among trauma patients and helps predict outcome of those who survive their hospitalization. This represents a potential area of future research.

Nutritional Support and Electrolyte Management

Robert D. Becher • Kimberly A. Davis

KEY POINTS

- Nutritional therapy should be integrated into the overall management of all trauma, surgery, and critically ill patients.
- Nutritional needs and requirements are different in healthy patients compared to the critically ill and severely injured, hypermetabolic trauma patients.
- Early enteral/oral feeding is a proactive therapeutic strategy that may reduce disease severity, decrease complications, and favorably impact outcomes.
- Enteral/oral feeding is the preferred mode of nutrition for trauma, surgical, and critically ill patients.
- Early parenteral nutrition should be considered if enteral feeds are contraindicated or are not expected to be started for 3 days.
- Avoid long periods without enteral or parenteral nutrition..
- Underfeeding during the stress-related catabolic phase or the immediate postoperative period is a risk factor for complications.

INTRODUCTION AND HISTORICAL PERSPECTIVE

Dietary choices impact disease. In the outpatient setting, dietary choices influence our risk for heart disease, cancers, obesity, diabetes, and stroke[1,2]; poor dietary choices increase the chance for developing these chronic and acute conditions, many of which are among the leading causes of morbidity and mortality in the United States and the world.[3,4] Five of the 10 leading causes of death in the United States are directly associated with dietary factors (heart disease, cancer, stroke, diabetes, and atherosclerosis).[5] In addition, dietary interventions can be a primary treatment for these conditions, with outcomes equivalent to or better than drug therapy.[6]

In the inpatient, hospital-based setting, a patient's nutritional status also impacts clinical outcomes. This notion was first reported in surgical patients in the year 1936, in a study demonstrating that patients with baseline malnutrition undergoing peptic ulcer surgery had mortality rates of 33% compared to 3.5% in well-nourished controls.[7] This pattern has been reported repeatedly since then, with preoperative malnutrition leading to increased morbidity and mortality in the surgical and trauma literature. With the prevalence of baseline malnutrition among hospitalized medical and surgical patients as high as 40%,[8,9] many patients are at high risk for poor outcomes and complications.

Anticipating and addressing hospitalized patients' dietary needs can therefore substantially impact their disease as well as their outcome. Simply put, providing adequate nutrition is essential to high-quality patient care, and given the extreme physiologic, metabolic, and homeostatic changes that can occur after severe injury, nowhere in medicine is this more true than in trauma, surgery, and critical care.

This chapter is about nutrition, the inflammatory stress responses to injury, and the nutritional needs of the polytrauma patient, for both macro- and micronutrients. The first major section on nutritional support provides a thorough, up-to-date guide on nutrition: first, nutritional needs and requirements are addressed in both the healthy patient and the critically ill, hypermetabolic trauma patient; second, we outline the specifics of nutritional intervention, including both enteral and parenteral nutritional support; and last, we cover some special patient populations. The second major section of this chapter on electrolyte management is divided into the management strategies of four major electrolytes and their associated abnormalities: sodium and disorders of water balance; potassium; phosphorus; and magnesium.

NUTRITIONAL SUPPORT: OVERVIEW

Normal Nutritional States of Health

Normal health implies homeostasis, when there is balance among the metabolic regulatory mechanisms that act to keep the body in a smooth, continuous condition of regular physiologic function. Part of homeostasis involves ensuring that the body has adequate energy reserves as well as other nutrients to maintain this physiologic normalcy.[10] We discuss nutrient utilization and requirements in a state of normal health and provide a conceptual framework underlying the basis and terminology of nutritional needs support. We cover the three principle classes of food—namely proteins, carbohydrates, and fats (collectively the macronutrients)—as well as the other fundamental compounds without which humans could not survive: water and the micronutrients (vitamins and minerals). See Box 62-1.

NUTRITIONAL SUPPORT: NUTRIENT UTILIZATION AND REQUIREMENTS IN A STATE OF NORMAL HEALTH

Nutrient Utilization and Needs

Humans need energy to live: to do physical work; to maintain body temperature and concentration gradients; and to transport, synthesize, degrade, and replace molecules that make up our body's tissues.[11] This energy is generated by the oxidation of various organic substances consumed in the diet, primarily the macronutrients: carbohydrates, fats, and proteins. The energy produced in the human body by the oxidation of macronutrients is the same as the heat of combustion of these substances in a lab. The major difference is that the body's oxidation is carried out though multiple steps, allowing humans to capture the energy in an intermediate chemical form.

A human's daily energy requirement allows for maintenance of metabolism and activity. This requirement is the level of energy intake from food that will balance energy expenditures. Although the word *energy* is often used repeatedly in a discussion of nutrition, its use in this sense is overly general and nonspecific. *Energy* can refer to food energy; basal energy expenditure; potential energy; energy density; or many other aspects of nutrition. As it relates to what we eat, food energy (as measured in kilocalories or kilojoules) specifically refers to the energy derived from protein, carbohydrates (ie, sugars), and fat.

In addition to energy requirements, humans also have nutrient requirements and therefore need protein (for essential amino acids), fats (for essential fatty acids), water, vitamins, and minerals to survive. Macronutrients and micronutrients, along with water, build the basis of nutrient utilization and needs. Each will be reviewed here.

ENERGY = CALORIES = KILOCALORIES

A patient's daily kilocaloric needs (ie, total energy requirement) are often referred to as their total energy expenditure (TEE); strictly speaking, this is not completely accurate, as the energy needs (ie, requirements) are *determined by* the

BOX 62-1: The Confusing Language of Food Energy

There are two widely accepted units of measuring and quantifying food energy:

- The International System of Units (SI; aka the "modern" metric system), which is the official system of measurement in almost every country in the world, measures energy in joules (J).[13,14] Within this system, food-related quantities of energy are typically expressed in kilojoules (kJ).
- The "old" metric system measures energy in calories; as a unit of energy, it officially is the upper-case Calorie, or equally kilocalorie (kcal): 1 kcal (aka 1 Calorie) is equal to 1000 calories. The scientific definition of 1 *kilocalorie* is the amount of energy needed to raise the temperature of 1 *kilogram* of water 1 degree Celsius from 14.5°C to 15.5°C at 1 atmosphere. A conversion from the old to the new (SI) metric system is: 1 kcal = 1 Cal = 4.184 kJ.

The terminology is confusing. When speaking of nutrition and food energy, it is common to use the term "calorie," with an implied meaning of kilocalories. For example, in the United States, the daily recommended value (DRV) for an average adult female is 2000 calories per day; this more accurately should be written 2000 kcal (2000 kcal = 2000 Calories). Therefore, it is technically incorrect to use calorie interchangeably with kilocalorie; the calories counted by clinicians and dieticians for nutritional purposes are really kilocalories.[15]

To make it even more confusing, the standard units used for food energy vary by region of the world, depending on a country's adoption of the SI system. In some parts of the world, including the United States, food labels use the older system, and list Calories or kcals (even though, as noted earlier, the US Food and Drug Administration's (FDA) Food Labeling Guide drops the "kilo-" and simply refers to food energy incorrectly as "calories"[16]). In most other parts of the world, food energy is expressed in the SI unit of kilojoules. In the European Union, food labels list both kJ (kilojoules) and kcal (kilocalories).[17]

In nutrition circles, including the Committee on Nomenclature of the International Union of Nutritional Sciences,[18] it has been proposed that the SI unit of the kilojoule replace the old metric unit of kilocalorie as the unit of choice for defining the energy value of food. Such a change would align the nomenclature of food sciences with that of most other sciences, which use SI units and the metric system. In this chapter, however, we will not adopt the modern metric system; rather, we will use the language common in the United States: the kilocalorie.

energy expenditure. A better way to think about this is to appreciate that energy requirements are based on estimates of energy expenditure.[10]

The basal metabolic rate (BMR) reflects the energy needed to sustain and maintain metabolism; it is the energy cost of living. The BMR "describes the rate of energy expenditure that occurs in the post-absorptive state, defined as the particular condition that prevails after an overnight fast, that subject having not consumed food for 12 to 14 hours and resting comfortably, supine, awake, and motionless in a thermoneutral environment. This standardized metabolic state corresponds to the situation in which food and physical activity have minimal influence on metabolism."[11] Basal energy expenditure (BEE), expressed as kcal/24 hours, is the BMR extrapolated to 24 hours.

TEE in healthy subjects is made up of three components: resting energy expenditure (REE) (and thus BEE), activity-induced energy expenditure (AEE), and diet-induced energy expenditure (DEE).[11]

1. REE, or energy expenditure under resting conditions, is about 60% of TEE. Note that REE is made up of three variables: BEE, thermoregulation, and energy expended in depositing new tissue. As such, REE is usually about 10% to 20% higher than BEE. Therefore, REE includes all the homeostatic reactions in the human body.
2. AEE is about 30% of TEE. AEE is highly variable, depending on baseline physical activity level as well as a person's physical capacity. For example, in obese patients, with a decreased level of activity, an AEE estimate of 30% TEE is accepted to be too high. However, in very active individuals, AEE can be over 50% of TEE.[11]
3. DEE is about 10% of TEE. This is also referred to as the thermic effect of food.

From these three components, we see that four factors determine an individual's daily energy requirements: gender, age, body size, and level of activity. Males require more kilocalories than females; the young require more kilocalories than the old; large people with more body mass require more kilocalories than smaller individuals; and the more active you are, the higher your kilocaloric needs.

For example, a nonactive, frail 85-year-old woman who weighs less than 100 lb and is 4 ft tall requires only 1000 kilocalories per day, whereas a college-age male athlete weighing 220 lb and standing over 6 ft tall needs over 3000 kilocalories per day. On average, most adult men need about 2500 kilocalories per day, and most adult women need about 2000 kilocalories per day.

Estimated energy requirements (EER) should, as far as possible, be based on estimates of energy expenditure. Energy expenditure can be derived in two ways: direct measurement or predictive equations (mathematical formulas).

The first method to determine EER is by direct measurement of TEE. This can be done by whole-body calorimetry (the gold standard), indirect calorimetry, or the doubly labeled water (DLW) technique. These methods are rarely used nowadays and will not be discussed in this chapter; a thorough discussion can be found elsewhere.[11-13]

The second method to determine EER is by predictive equations that estimate TEE. Three common formulas are as follows: a simplified approach using ideal body weight; a more complex and traditional approach using the Harris-Benedict equation (rarely used clinically anymore but presented for its historical significance); and a more modern predictive equation developed by the Institute of Medicine (IOM). Other excellent predictive equations not presented here include the Mifflin-St. Jeor equation[14] and the Penn State equations.[15,16]

IDEAL BODY WEIGHT TEE EQUATION

The easiest formula to use to calculate energy requirements is based on a predictive equation for TEE using a patient's ideal body weight (IBW):

$$\text{24-hour kcal requirement} = \text{TEE} = \text{IBW (in kg)} \times 30 \text{ kcal/kg}$$

This will give you a person's kilocalorie energy needs over 24 hours. To find a person's IBW, IBW tables exist, as do user-friendly smartphone applications. This simple formula is useful for clinical purposes as an initial estimate. Given the components of TEE, however, the fixed value of 30 kcal/kg will vary depending on the clinical circumstances, such as during the postinjury stress response or after a major burn.

It is important to know that IBW, much like daily caloric needs, is derived from a calculation. There are various methods to calculating IBW; a few of the more well-known methods to calculate IBW were derived by Lorentz[17] in 1929, Robinson et al[18] in 1983, Devine[19] in 1974, and Hamwi[20] in 1964. They all produce approximately the same value of IBW[21] and are all derived by calculations based on height and gender. IBW should not be confused with two other types of body weight calculations, namely the adjusted body weight (ABW)[22] and the lean body weight (LBW).[23]

Although IBW is recommended in this simplified predictive formula for calculating kilocaloric needs, there are exceptions. In obese patients, IBW is much lower than their actual body weight. If a patient is overweight to the point that actual body weight is greater than 30% over calculated IBW, the ABW is recommended for determining daily caloric needs (ABW can also be found in tables, smartphone/tablet applications, or online calculators).

LBW, meaning the total weight of all tissue in the body excluding fat (sometimes also referred to as fat-free mass), is the weight measure most closely correlated to BEE, REE, and TEE.[11] LBW explains about 70% to 80% of the variance in energy expenditure. The other 20% to 30% is affected by age, gender, baseline nutritional state, inherited variations, and different endocrine states.

LBW is extremely variable at different stages of life. For example, from birth to adulthood, the brain increases its LBW fivefold; the liver, heart, and kidneys, which are even more metabolically active, increase 10- to 12-fold; and muscle multiplies its LBW by about 40-fold.[24] The lean tissue content of the body declines with age, and this accounts in part for a progressive fall in BMR in relation to body size.[25]

In the elderly, there is a decrease in the proportion of skeletal mass, as well as muscle.[26] For all of these reasons, IBW is used to predict energy expenditure, not LBW.

There are times when it is important to calculate a healthy patient's basal energy requirements (BEE). To do this via the IBW method, a patient's BEE would be:

$$\text{BEE} = \text{IBW (in kg)} \times 24 \text{ kcal/kg}$$

BEE is thus IBW multiplied by a smaller factor of 23 to 24 kcal/kg. TEE equation of 30 kcal/kg represents a 25% increase over BEE of 24 kcal/kg.[27,28] Very limited activity increases the requirement to 28 kcal/kg.

HARRIS-BENEDICT EQUATION FOR BEE

The Harris-Benedict equations (HBEs)[29] are perhaps the best known equation to determine a patient's total kilocaloric needs over a 24-hour period. The equations were derived using indirect calorimetry. There are separate equations for males and females, and each is based on weight (in kilograms), height (in centimeters), and age (in years). The HBEs predict BEE (not TEE):

$$\begin{aligned}\text{Male 24-hour kcal requirement} = {} & (13.7516 \times \text{weight}) \\ & + (5.0033 \times \text{height}) \\ & - (6.755 \times \text{age}) \\ & + (66.4730)\end{aligned}$$

$$\begin{aligned}\text{Female 24-hour kcal requirement} = {} & (9.563 \times \text{weight}) \\ & + (1.8496 \times \text{height}) \\ & - (4.6756 \times \text{age}) \\ & + (655.095)\end{aligned}$$

Once the BEE has been calculated from the HBE, one needs to apply an activity factor multiplier to determine the TEE; the predicted value for TEE is then used as the EER for 24-hour kilocalorie needs. To do this, the baseline HBE values are multiplied as follows (the multipliers are the same for males and females)[30]:

24-hour baseline HBE BEE kcal requirement ×
- 1.2 (little to no exercise)
- 1.375 (low activity; exercise 1–3 d/wk)
- 1.55 (moderately active; exercise 3–5 d/wk)
- 1.725 (very active; exercise 6–7 d/wk)
- 1.9 (very active; vigorous exercise daily and physical job)

IOM TEE EQUATIONS

The IOM has published a set of formulas that predict TEE based on age, height, weight, and physical activity level. They were derived using the DLW method for directly measuring TEE and represent a more modern approach to determining EER[11] (the IOM equations were defined in 2005, whereas the HBE was derived >100 years ago, in 1918[29]). These IOM TEE equations have replaced the Schofield equation[31] to define and develop the US Food and Drug Administration's (FDA) dietary guidelines and formulate Recommended Dietary Allowances (RDAs).

The IOM TEE prediction formula to calculate EER for males age 19 years and older is as follows (with age in years, weight in kilograms, and height in meters):

$$\begin{aligned}\text{Male 24-hour kcal requirement} = {} & 662 - (9.53 \times \text{age}) \\ & + [\text{PA} \times \{(15.91 \times \text{weight}) + (539.6 \times \text{height})\}]\end{aligned}$$

where PA is the physical activity coefficient:

PA = 1.00 if sedentary
PA = 1.11 if low active
PA = 1.25 if active
PA = 1.48 if very active

The IOM TEE prediction formula to calculate EER for females age 19 years and older is as follows (with age in years, weight in kilograms, and height in meters):

$$\begin{aligned}\text{Female 24-hour kcal requirement} = {} & 354 - (6.91 \times \text{age}) \\ & + [\text{PA} \times \{(9.36 \times \text{weight}) + (726 \times \text{height})\}]\end{aligned}$$

where PA is the physical activity coefficient:

PA = 1.00 if sedentary
PA = 1.12 if low active
PA = 1.27 if active
PA = 1.45 if very active

It has been suggested that the HBE and IOM equations for TEE do not add that much more accuracy beyond the simple IBW equations; this is confirmed in multiple guidelines, which base TEE recommendations on predictive formulas[32-36] (Table 62-1).

TABLE 62-1: Comparison of Various Methods Used to Determine 24-Hour Kilocalorie Energy Requirements

Method[a]	Female[b]	Male[c]
IBW-based TEE	1695	2100
HBE (baseline BEE)	1429	1799
HBE TEE, sedentary	1715	2159
HBE TEE, low activity	1965	2474
HBE TEE, moderate activity	2216	2789
HBE TEE, very active	2466	3104
IOM TEE, sedentary	1907	2529
IOM TEE, low activity	1984	2672
IOM TEE, moderate activity	2081	2854
IOM TEE, very active	2197	3152

[a]Methodologies, equations, activity level multipliers, and references for calculating energy requirements can be found in the text.
[b]Female TEE in kcal was calculated for averages in United States: 40 years old, 69 kg, 163 cm (5 ft, 3 in); IBW (Lorentz) 56.5 kg.
[c]Male TEE in kcal was calculated for averages in the United States: 40 years old, 81.6 kg, 176.1 cm (5 ft, 9 in); IBW (Lorentz) 70 kg.

BEE, basal energy expenditure; HBE, Harris-Benedict equation; IBW, ideal body weight; IOM, Institute of Medicine; TEE, total energy expenditure.

Protein

Proteins are large, nitrogenous organic compounds that are made up of long chains of amino acids; there are 20 different amino acids in our body's proteins. Proteins exist in every cell, tissue, and organ in the human body and are an essential part of all living organisms. Proteins are major structural components of muscle, bones, skin, and collagen; along with amino acids, proteins function as enzymes, antibodies, membrane receptors, hormones, and carriers of nutrients in the blood. Protein balance is often referred to as nitrogen balance.

Humans obtain proteins solely from the diet; once ingested, proteins are digested into their component amino acids. Dietary proteins come in two general forms: complete proteins and incomplete proteins. *Complete proteins* (ie, whole protein; high-quality protein) come from animal-based products and supply all the amino acids, most importantly a group called the essential amino acids. There are nine *essential amino acids* (ie, indispensable amino acids) that cannot be synthesized de novo by humans: histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. *Incomplete proteins* come from plants and lack one or more of the nine essential amino acids. When two or more incomplete proteins are combined to provide adequate amounts of all nine essential amino acids, they are referred to as *complementary proteins.*

Unlike fat (stored as adipose tissue) and carbohydrates (stored as glycogen in the liver and skeletal muscle), protein is not stored in the body. In contrast to other sources of energy, if more protein is ingested than is needed for metabolic purposes, all that excess nitrogen is metabolized and the end products are excreted. If less protein is ingested than is needed for homeostasis, leading to a persistent negative nitrogen balance, the body adapts by breaking down muscle, leading to a loss of LBW.[10] See Box 62-2.

What is a safe level of intake of dietary protein per 24 hours, and how are the nutritional protein needs determined? The protein requirement of an individual is defined as the lowest level of dietary protein intake that will balance the losses of nitrogen from the body (principally in the urine, but also in feces and through the skin) in persons maintaining energy balance at modest levels of physical activity.[24] Furthermore, we cannot simply maintain nitrogen balance; rather we must ensure that the required dietary protein intake includes both the essential amino acids and the nonessential amino acids. The amount of essential amino acids required in a healthy adult diet is 27.7%.[37]

There are two general methods for determining the daily recommended allowance for protein: direct measurement or predictive mathematical formula. The first method is to measure nitrogen loss, when the diet contains no protein, which will provide an estimate of nitrogen requirement. This has been done in nitrogen balance studies by collecting nitrogen losses in the urine, feces, skin, and sweat/secretions and subtracting these losses from measured nitrogen content of protein intake; the process is repeated multiple times, across several levels of protein intake, over many days, each time ensuring metabolic steady state has been reached. This

BOX 62-2: The Relationship Between Energy and Protein

Conceptually, there can be confusion about the link between energy and protein. On the one hand, food energy *includes* the energy from protein, which makes sense because protein not only provides a source of nitrogen and amino acids for the body, but also provides energy in the form of 4 kcal/g protein. In fact, the FDA's daily recommended value for protein is based on 10% of kilocaloric energy coming from protein.[16] However, on the other hand, nutritionists *separate* energy requirements from protein requirements. This practice seems to imply that the energy derived from protein is not included in the total energy needs, which is not true.

In practice, the total energy requirement (as determined by TEE) is calculated first, with no differentiation in how that energy will be derived (all three of the macronutrients can supply energy in the form of kilocalories). Next, the requirement for protein is calculated; one method to determine daily protein requirements is as a percentage of the TEE (see Protein section for specifics). In this manner, total energy requirements are determined independently of protein requirements, although protein requirements can be dependent on the total energy requirement calculation.

Energy and protein are fundamentally different in terms of how the body maintains and stores each. For energy, an individual's intake must match his output if he is to remain in a steady state, and physiologic mechanisms exist by which this balance is normally maintained. For example, when energy intake is below the requirement level, the body uses stores of energy to adapt. The opposite is true as well: when energy intake is above the required level, the body will store that excess energy, mostly as fat.

For protein, in contrast, there is no regulatory mechanism that matches intake to requirement. This is partly due to the fact that humans do not have protein reserves in the same way we have energy stored as glucose and fat; we are therefore dependent on protein intake to achieve required levels, as there are no protein stores to break down. In addition, if we take in more protein than meets the needs of the body, then this excess nitrogen is excreted.

Therefore, the body handles excess protein very differently compared to how it handles excess energy. This is a fundamental concept, and these considerations have led to very different approaches to deciding the amount of dietary protein to maintain nitrogen balance versus deciding the amount of dietary energy to maintain energy balance.

- For energy requirements, one intake achieves energy balance; we therefore determine the *average* requirement for energy.
- For protein requirements, on the other hand, there is a range of intakes to choose from to achieve nitrogen balance; therefore, we determine one intake within a *safe range of intake* for protein.[11]

process is quite impractical, although it is this process that forms the basis for estimating protein requirements using the predictive formula methodologies.[10]

The second method is to use one of two different mathematical formulas: the first based on a person's weight, and the second based on daily energy requirements.

PROTEIN REQUIREMENT USING WEIGHT-BASED METHOD

Determining dietary protein needs for healthy subjects using IBW is based on long-term nitrogen balance studies.[37] Specific equations have been derived from these studies, by both the World Health Organization[38] and the IOM,[39] and provide nearly identical results. The RDA for protein is as follows[38-40]:

24-hour protein requirement (in grams)
= 0.8 g protein/kg IBW

There are three factors that went into determining this 24-hour requirement value. The first is the average amount of high-quality protein needed to maintain nitrogen balance: 0.6 g protein/kg IBW/d. The second is a safety factor to ascertain that 95% of the healthy population's protein needs are covered: 0.15 g protein/kg IBW/d. The third is a buffer to allow for intake of proteins that are not high-quality proteins: 0.05 g protein/kg IBW/d.[37]

The equation is the same for both healthy adult men and women. Although differences in LBW exist between genders, as well as older and younger individuals, these differences are offset partially by differences in weight.[39] Accordingly, there is simply one equation for all healthy adults.

PROTEIN REQUIREMENT BASED ON ENERGY NEEDS

The most recent dietary reference intakes[11,39] for macronutrients are designed to reflect a broadened view of protein needs in relation to carbohydrate and fat requirements. This method, termed the *acceptable macronutrient distribution range* (AMDR), more clearly reflects the interrelation between the macronutrients and allows for some level of flexibility in diet planning. If an individual consumes below or above the AMDR range, there is potential to affect long-term health by increasing the risk of chronic diseases as well as increasing the risk of insufficient intakes of essential nutrients.[41] See Table 62-2 for AMDRs for all macronutrients.

The AMDR for dietary protein is a safe range of intake, from 10% to 35% of the total daily kilocalorie requirement.[39] This affords the ability to provide protein intake in excess of the RDA but within the AMDR; this has spawned the term *flexible calories*, because a clinician can use the AMDR for all three macronutrients to create varied dietary plans while still achieving kilocalorie needs.[40]

This alternative to the weight-based approach to determining protein needs is therefore based on the calculation for daily energy requirements. For example, the AMDR for protein is 10% to 35%; the FDA bases the daily recommended value (DRV) for protein on all food labels in the United States on a 10% rule (the low end of the AMDR for protein): 10% of 24-hour energy needs (as measured in kilocalories) should come from protein.[42] The equation for the 10% rule is:

24-hour protein requirement (in grams)
= (24-hour kilocaloric needs × 0.10)/4 kcal/g

A simpler way to calculate this is:

24-hour protein requirement (in grams)
= (24-hour kilocaloric needs × 0.025)

Although the FDA uses 10%, which is at the RDA level of 0.8 g protein/kg/d, one needs to consider the patient circumstances and thus consider other values within the AMDR for protein. For example, there are good data to show that physically active people should have protein intakes in the range of 1.2 to 2.0 g protein/kg/d (15%–25% of energy from protein).[43-45] There is other research that now demonstrates the benefits of increased protein intake in elderly adults to levels nearly double the RDA of 0.8 g protein/kg/d, the goal being to preserve lean body mass and promote functional ability with age.[46-48]

TABLE 62-2: Acceptable Macronutrient Distribution Ranges (AMDRs) for Macronutrients

Macronutrient	AMDR (as a percentage of 24-hour energy requirements)[a]
Carbohydrate	45%–65%
Protein	10%–35%
Fat	20%–35%
n-3 polyunsaturated fatty acids (linolenic acid)	0.6%–1.2%
n-6 polyunsaturated fatty acids (linoleic acid)	5%–10%

[a]Please see text for a full discussion of the meaning of AMDRs and the values for each macronutrient, as well as references for more information about AMDRs.

Carbohydrates

Carbohydrates are organic compounds that contain only carbon, hydrogen, and oxygen atoms in a ratio usually of 1:2:1; most carbohydrates, but not all, follow the general chemical formula of $C_n(H_2O)_n$. What distinguishes one carbohydrate from another is the different ways the atoms combine.

Carbohydrates (also called carbs) are the most important energy source for humans, particularly in the brain, which is a carbohydrate-dependent organ. In this manner, carbs can be thought of as the storage and transportation form of energy. Carbohydrates, however, are more than simply energy. Carbs also play major roles in our immune system, reproductive system, blood clotting, and cell structure; DNA and RNA are carbohydrate-based chains of molecules. The chemistry behind the structure of sugars is extremely complicated, and some have maintained that the genome is simple compared to the "glycome." The study of the glycome is referred to as *glycomics*, and the science of carbohydrates' role in life is termed *glycobiology*.

Carbohydrates are often referred to as sugars, or *saccharides*. Naturally-occurring saccharides are produced by photosynthetic plants. Unnatural sugars (eg, processed sugars, refined sugars, artificial sweeteners) are simply chemical compounds made in a lab and lack vitamins and minerals; they are referred to as "empty calories." The body digests most carbohydrates in the diet into glucose ($C_6H_{12}O_6$; ie, blood sugar). Glucose is then used in two ways: either it is used as a source of energy via cellular respiration, or it is stored as glycogen in the liver, skeletal muscle, and other tissues (excess glucose can also be stored as fat).

A *monosaccharide* is a carbohydrate in its elemental form, with one sugar unit. When two monosaccharides, or sugar units, combine they form a *disaccharide*. When 3 to 10 monosaccharides join, they form *oligosaccharides*, which have complex, varied, and critical biological functions. *Polysaccharides* are built from any combination of monosaccharides and disaccharides; examples of polysaccharides are glycogen, the storage form of glucose, and starch.

Carbohydrates come in two types—simple or complex—with the difference being their underlying chemical structure. *Simple carbohydrates* are sugars in their simplest form, either one (monosaccharides) or two (disaccharides) sugars. Examples of monosaccharides include glucose, fructose (ie, fruit sugar), and galactose; examples of disaccharides include sucrose (ie, table sugar) and lactose (ie, milk sugar).

Complex carbohydrates are made up of three or more simple carbohydrates bonded together into one larger compound; polysaccharides and oligosaccharides are complex carbs. Complex carbs come in two dietary forms: starch and dietary fiber. *Starches* are digested into sugars for energy; in addition to providing kilocalories, starches also contain vitamins and minerals. Complex carb–containing foods are popularly referred to as "starchy" foods.

Dietary fibers (ie, roughage; bulk; nondigestible carbohydrates) are plant-derived complex carbs that the human body cannot digest or absorb, meaning fiber traverses the gastrointestinal (GI) tract without being broken down. The health benefits of fibers are numerous and include helping to control weight by causing satiety, aiding digestion, preventing constipation, attenuating blood glucose levels, and decreasing serum cholesterol.[39] There are two general types of fiber: soluble and insoluble. *Soluble fiber* dissolves in water and forms a gel-like substance in the GI tract that helps to lower blood cholesterol and glucose levels. *Insoluble fiber* does not dissolve in water and therefore promotes movement of material through the GI tract and helps with constipation and laxation.

What is an average requirement for carbohydrates per 24 hours, and how are the nutritional needs for carbohydrates determined? In general, carbohydrate needs are determined as a percentage of 24-hour energy requirements.[11,39]

CARBOHYDRATE REQUIREMENT BASED ON ENERGY NEEDS

The RDA for carbohydrates is based on a minimum amount necessary to cover the glucose needs of the carbohydrate-dependent central nervous system.[11] With this in mind, when the FDA set the DRV for carbohydrates on all food labels in the United States, they used a very conservative value of 60%: 60% of 24-hour kilocalorie energy needs should come from carbohydrates.[42]

A more modern approach to determining daily carbohydrate needs is to consider the IOM's AMDR for carbohydrates.[11] The AMDRs delineate upper and lower bounds for the percentage of daily calories provided from all macronutrients; these safe ranges recognize the interrelation between the macronutrients and allow flexibility in creating customized diets to individual patient needs.

For carbohydrates, the AMDR ranges from 45% to 65% of total daily kilocalorie requirements[39] (see Table 62-2). This means that carbohydrate-derived energy can safely make up anywhere from 45% to 65% of total energy needs. The calculation for determining 24-hour carbohydrate requirements is based on 4 kcal of energy being produced from every gram of carbohydrate consumed (note that for parenteral nutrition calculations, the conversion is 3.4 kcal/g). For example, using the FDA's DRV of 60%, the equation is as follows:

$$\text{24-hour carbohydrate requirement (in grams)} = (\text{24-hour kcal energy needs} \times 0.60)/4 \text{ kcal/g}$$

To determine other values, one simply substitutes for any percentage, from 45% (use 0.45 in the equation) to 65% (use 0.65 in the equation).

Fat

Fats are an essential nutrient and a key part of our diet. They are characterized by being insoluble in water, nonvolatile, and greasy to touch. Fats are sometimes referred to as lipids, although technically speaking, fats are a member of the lipid family.

Lipids are a group of naturally occurring molecules that are derived from one of two common biochemical subunits (ketoacyl or isoprene). Lipid compounds include *fatty acids* (from which fats are derived); *glycerolipids* (triglycerides; diglycerides; monoglycerides; collectively glycerides); *glycerophospholipids* (ie, phospholipids); *sterol lipids* (eg, cholesterol and steroids); *saccharolipids* (eg, lipopolysaccharides in gram-negative bacteria); and others (see IOM Standing Committee on the Scientific Evaluation of Dietary Reference Intakes[11] for more details).

Fats provide a needed source of energy for the human body. As an energy source, fat produces 9 kcal of energy per gram, which is over twice as many kilocalories as can be derived from carbohydrates (4 kcal/g enterally; 3.4 kcal/g parenterally) and protein (4 kcal/g). For this reason, fat is referred to as nature's storehouse of energy. Fats are necessary for the body to absorb the fat-soluble vitamins A, D, E, and K. Fats help insulate the body and keep skin and hair healthy.

Fats also provide humans with the *essential fatty acids*: linoleic acid and linolenic acid (note that linoleic acid is the

precursor to arachidonic acid, so technically, arachidonic acid is not considered essential). Humans can synthesize all but these two essential fatty acids. Fats can be synthesized from the breakdown products of proteins, carbohydrates, or other fats (using acetate as an intermediate metabolite).

The essential fatty acids are crucial for membrane structure lipids, cell signaling pathways, brain development, controlling inflammation, and blood clotting. Prostaglandins are hormone-like compounds derived from arachidonic acid and are involved in many vital functions in the human body.

As a chemical compound, fats contain carbon, hydrogen, and oxygen, with the defining feature that they are arranged as a hydrocarbon chain skeleton, with a carboxyl group (-COOH) at one end and a methyl group (CH_3-) at the other. Fats are made from various fatty acids, which contribute approximately 95% of the total weight to various fats; the other 5% is from a backbone molecule to which the fatty acids bond, glycerol (and other occasionally attached molecules). Fatty acids are differentiated by the number of carbon atoms in their carbon skeleton as well as the number of carbon-to-carbon (C=C) double bonds. These differences lead to variations in structure and function. There are more than 100 different fatty acids in the human body, although less than 20 contribute to the majority of fats.

Fats are classified as either unsaturated or saturated. *Unsaturated fats* have at least one C=C double bond in the carbon skeleton, which gives them a low melting temperature. They are often liquids at room temperature, known as oils. There are two types of unsaturated fats: monounsaturated and polyunsaturated. *Monounsaturated fats* have only one C=C double bond in the carbon skeleton. *Polyunsaturated fats* have two or more C=C double bonds in the carbon skeleton. Polyunsaturated fats include the two *essential fatty acids*: omega-3 polyunsaturated fats (linolenic fatty acid) and omega-6 polyunsaturated fats (linoleic fatty acid).

Synthetic fats are unnatural, unsaturated fats created in an industrial lab when hydrogen is added to liquid vegetable oil (a natural unsaturated fat) to create solid fat. These fats are used mainly as preservatives for food and to add texture. Synthetic fats come in two types: *hydrogenated fats* and *partially hydrogenated fats* (ie, trans fats; trans fatty acids). Trans fats have been proven to increase cholesterol and the risk for heart disease[49,50] and have a detrimental effect on the brain and nervous system.[51] In short, they have no benefit to human health.[11] It should be noted that there are some trans fats that are naturally occurring, found in animal fats.

Saturated fats are so named because the carbon skeleton in these fats is saturated with hydrogen bonds, and therefore they have no C=C double bonds. These fats are solids at room temperature, indicating a high melting temperature. They are generally referred to as the solid fats and come from two general sources. The primary source is animals, including meats and dairy products (all animal-based saturated fats also contain cholesterol). The second source is certain plants. Saturated fats were once thought to be linked to coronary heart disease and increased cholesterol levels, although that is being questioned by more recent data.[52]

Cholesterol is an organic sterol lipid molecule synthesized by all animal cells. Cholesterol is an essential component of animal cell membranes and is the precursor to steroid hormones, bile salt (it was first discovered in gallstones), and vitamin D. It is found in all foods containing animal fat; cholesterol is not found in significant amounts in plant sources.

Triglycerides are lipid compounds derived when one molecule of glycerol combines with three fatty acids. Triglycerides are the major storage form of fat in human adipose tissue; the hydrolysis of triglyceride ester bonds is the first step in fat metabolism.

What is an average requirement for fat per 24 hours, and how are nutritional fat needs determined? Neither an adequate intake (AI) level nor an RDA exists for total fat. This is because there are not sufficient data to determine a level below which intake is inadequate or above which chronic diseases are prevented.[11] The AMDR for fat for healthy adults is 20% to 35% of the total daily kilocalorie requirement.[39] Accordingly, fat needs are determined as a percentage of 24-hour energy requirements.

FAT REQUIREMENT BASED ON ENERGY NEEDS

The AMDR for fat is 20% to 35% (see Table 62-2). This range was set to ensure that the essential fatty acids were consumed in adequate amounts. The FDA has based its DRV for fat on a value of 30%: 30% of the 24-hour energy needs (as measured in kilocalories) should come from carbohydrates.[42] The equation to calculate 24-hour fat requirements (using 30%, which can change depending on the percentage desired) is as follows:

$$\text{24-hour fat requirement (in grams)} = (\text{24-hour kilocaloric needs} \times 0.3)/9 \text{ kcal/g}$$

To ensure intake of adequate dietary amounts of the essential fatty acids, approximately 10% of total daily kilocalorie intake should come from longer-chain polyunsaturated fats[39] (see Table 62-2):

- Omega-3 polyunsaturated fat (linolenic fatty acid) intake should be in the range of 0.6% to 1.2% of 24-hour kilocalorie needs.
- Omega-6 polyunsaturated fats (linoleic fatty acid) should be in the range of 5% to 10% of 24-hour kilocalorie needs.

Current dietary recommendations also maintain that humans should consume less than 10% of total energy from saturated fats.

Water

The human body is made up of 60% water, and on average, 60% of an adult's total body weight is water.[53] Water is the basis of all fluids in our body: for example, bile is 90% water; blood is 92% water; and cerebrospinal fluid is 99% water. Water is also the basis of all organs and tissues in our body:

bone is 31% water; the brain and heart are 73% water; muscles and kidneys are 79% water; and lungs are 83% water.[54] Total body water (TBW) is distributed between the intracellular fluid (65% TBW) and extracellular fluid (35% TBW); of the TBW in the extracellular fluid, 79% is in the interstitial space and 21% is intravascular in plasma.

Water is made up of three atoms: two hydrogen and one oxygen. The simplicity of the water compound belies its importance, its versatility, and its complexity, in terms of both its physical and chemical properties. Water is the solvent, the medium, and the participant in most biochemical and physiologic reactions occurring in our bodies; it absorbs and releases metabolic heat; it is attracted to itself and many other substances; and it has tremendous surface tension and strength.

Human life and cellular homeostasis depend on water: we could live roughly a month without macronutrients; we can live only a few days without water. Once reaching 10% to 14% dehydration, risk of death increases rapidly, approaching irreversibility.[53] It is via water that carbohydrates and proteins are metabolized, Aqueous solutions are the universal transporter of macronutrients, oxygen, and waste. Cellular hydration is a crucial signal regulating cell metabolism and gene expression. Water aids in digestion, is a lubricant for joints, and is a shock absorber for the brain and spinal cord; and water helps regulate body temperature through sweating and respiration.[53,54]

What is an average requirement for water per 24 hours, and how are the nutritional water needs determined? There is no RDA for water as there are not sufficient data to determine a level above which chronic diseases are prevented.[53] The major risk associated with low intake of total water is dehydration, primarily in the acute setting, which can lead to metabolic and functional abnormalities. Accordingly, an AI has been established for water below which intake is inadequate. These AIs were defined to cover minimal losses from temperate climates for a sedentary individual.

The AI for total water per 24 hours to prevent dehydration is 3.7 L in adult men and 2.7 L in adult women[53]; 80% of this is typically consumed by liquids, meaning healthy adult men should drink 3.0 L (13 cups) per day and women 2.2 L (9 cups); the remaining balance of water comes from food. This intake of water will replace respiratory, urinary, fecal, and insensible fluid losses. Higher intakes should be achieved in physically active people or those exposed to hot environments.

Daily consumption of water below the AI may not translate into an added risk of dehydration because normal hydration can be achieved and maintained over a wide range of intake. Importantly, therefore, the AI is not a specific requirement.[53] In healthy adults, fluid intake, driven by consumption of liquids and food at meals as well as by thirst, maintains TBW at normal levels, preventing dehydration. Body water balance is achieved when water gain and water loss are equal. Water gain occurs from consumption (sources of water include drinking water, water in beverages, and water that is part of food) and production (metabolic water). Water loss occurs from respiratory loss, urinary/renal loss, fecal/GI tract loss, skin loss, and insensible loss.

The interrelationship between the macronutrients, other substances we consume, and water demonstrates the interconnectedness of homeostatic processes in humans. Increased or decreased intake of macronutrients as well as these other substances (eg, caffeine, alcohol, and sodium) can and will affect water requirements.[41]

For example, for dietary proteins and amino acids, the major end product of their metabolism is urea. Urea requires water for excretion by the kidneys. Therefore, increased protein intake requires increased water intake. For dietary carbohydrates, 100 g/d are required to prevent ketosis; consuming fewer carbs can increase ketone bodies, which require water to be excreted. Therefore, increased ketosis requires increased water. Finally, fecal water losses are increased with higher loads of dietary fiber; with increased fiber intake, more water needs to be consumed to prevent dehydration.

Micronutrients: Vitamins

The term *micronutrients* is used to refer to both vitamins and minerals. Vitamins are organic substances made by plants or animals; they are essential for growth and development. Vitamin deficiencies can be seen in the elderly (especially frail or institutionalized people with malnutrition), alcoholics (with associated malnutrition), illicit drug users, impoverished populations, and those in developing countries.

There is a long list of vitamins that humans need[41,55] (Tables 62-3 and 62-4), and they can be grouped together as follows:

- Fat-soluble vitamins:
  - Vitamin A (retinol, including the carotenoids)
  - Vitamin D
  - Vitamin E
  - Vitamin K
- Water-soluble vitamins:
  - B vitamins
    - Biotin
    - Folate (folic acid)
    - Niacin (nicotinic acid)
    - Pantothenic acid
    - Riboflavin (vitamin B_2)
    - Thiamin (vitamin B_1)
    - Vitamin B_6 (pyridoxine)
    - Vitamin B_{12} (cobalamins)
  - Vitamin C (ascorbic acid)
  - Choline

Micronutrients: Minerals

Minerals, on the other hand, are inorganic elements that come from the earth, soil, and water; all minerals are found in the periodic table of elements.[56] Minerals are absorbed by pants from the ground, and humans consume minerals from eating these plants. Minerals are essential for human homeostasis, as the body uses them for normal bone, muscle, heart, and brain function as well as for making hormones.[41]

TABLE 62-3: Vitamins: Functions, Deficiencies, and Toxicities[a]

Nutrient	Vitamin functions	Effect of deficiency	High risk deficiency patients and notes	Effect of toxicity
Fat-soluble vitamins				
Vitamin A (retinol)	Important for vision (formation of rhodopsin, a photoreceoptor in the retina), gene expression, reproduction, embryonic development, growth, immune function. Also integrity of epithelia; lysosome stability; glycoprotein synthesis.	Xerophthalmia (an irreversible drying of the conjunctiva and cornea) leading to night blindness; perifollicular hyperkeratosis; keratomalacia; increased morbidity and mortality in children.	People with high alcohol intake, preexisting liver disease, hyperlipidemia, or severe protein malnutrition may not be protected by the UL set for the general population, because the requirements for vitamin A are based on the assurance of adequate liver stores of vitamin A.	Hypervitaminosis A may be acute or chronic: headache; peeling of skin; hepatosplenomegaly; bone thickening; intracranial hypertension; papilledema; hypercalcemia; teratogenicity
Vitamin D	Involved in bone health (mineralization and repair). It aids in the absorption of calcium and phosphorus in the tubules of the kidneys, thereby helping maintain normal serum levels of these minerals. Also insulin and thyroid function, improvement in immune function, reduced risk of autoimmune disease.	Impair normal bone metabolism, which may lead to rickets in children and osteomalacia in adults. It is also implicated in osteoporosis in adults.	Older adults, especially those who live in northern industrialized cities of the world, are more prone to developing vitamin D deficiency (due to lack of sunlight).	Hypervitaminosis D: Hypercalcemia, hypercalciuria, and calcification of soft tissues, such as blood vessels and certain organs
Vitamin E	Functions as a chain-breaking antioxidant in the body by preventing the spread of free-radical reactions. Is an intracellular antioxidant; scavenger of free radicals in biologic membranes.	Peripheral neuropathy.	Generally occurring only as the result of genetic abnormalities of vitamin E metabolism, fat malabsorption syndromes, or protein-energy malnutrition.	Hemorrhagic toxicity (tendency to bleed)
Vitamin K	Functions as a coenzyme for biological reactions involved in blood coagulation (formation of prothrombin, other coagulation factors) and bone metabolism.	Classic sign of vitamin K deficiency is a vitamin K–responsive increase in prothrombin time and, in severe cases, bleeding; osteopenia.	Clinically significant vitamin K deficiency is extremely rare in the general population, with cases being limited to individuals with malabsorption syndromes or those treated with drugs known to interfere with vitamin K metabolism.	
Water-soluble vitamins				
B Vitamins				
Biotin	Functions as a coenzyme in bicarbonate-dependent carboxylation reactions.	Dermatitis, alopecia, conjunctivitis, and abnormalities of the central nervous system.	Individuals consuming raw egg whites over long periods and in patients receiving total parenteral nutrition (TPN) solutions that do not contain biotin.	NA

(*continued*)

TABLE 62-3: Vitamins: Functions, Deficiencies, and Toxicities[a] (*Continued*)

Nutrient	Vitamin functions	Effect of deficiency	High risk deficiency patients and notes	Effect of toxicity
Folate (folic acid)	Functions as a coenzyme in the metabolism of nucleic and amino acids (purines, pyrimidines, and methionine); maturation of red blood cells; development of fetal nervous system.	Decreased erythrocyte folate concentratin leads to macrocytic anemia (first evidenced by a low erythrocyte count and eventually by a low hematocrit and hemoglobin); neural tube birth defects; confusion.	Coexisting iron or vitamin B_{12} deficiency may interfere with the diagnosis of folate deficiency.To reduce the risk of neural tube defects, women able to become pregnant should supplement folic acid.	NA
Niacin (nicotinic acid)	Involved in many biological reactions (oxidation-reduction reactions), including intracellular respiration and fatty acid synthesis; carbohydrate and cell metabolism.	The classic disease of severe niacin deficiency is pellagra (dermatitis, glossitis, GI and CNS dysfunction), which in industrialized nations generally only occurs in people with chronic alcoholism or conditions that inhibit the metabolism of tryptophan.	People with an increased need for niacin include those with Hartnup disease, liver cirrhosis, carcinoid syndrome, and malabsorption syndrome, as well as those on long-term isoniazid treatment for tuberculosis or on hemodialysis or peritoneal dialysis. Also, pregnant females who are carrying more than one fetus or breastfeeding more than one infant may require additional niacin.	Flushing, nausea and vomiting, liver toxicity, and impaired glucose tolerance; however, most of the data on adverse effects has come from research with patients with special conditions who were treated with pharmacologic preparations.
Pantothenic acid	Functions as a component of coenzyme A (CoA), which is involved in fatty acid metabolism.	Irritability and restlessness, fatigue, apathy, malaise, sleep disturbances, hypoglycemia; neurobiological symptoms, such as numbness, paresthesias, muscle cramps, and staggering gait.	Pantothenic acid deficiency is rare and has only been observed in individuals who were fed diets devoid of the vitamin or who were given a pantothenic acid metabolic antagonist.	NA
Riboflavin (vitamin B_2)	Functions as a coenzyme in numerous oxidation–reduction reactions in several metabolic pathways (especially carbohydrate and protein metabolism) and in energy production; integrity of mucous membranes.	Sore throat, hyperemia and edema of the pharyngeal and oral mucous membranes, cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, and normocytic anemia associated with pure erythrocyte cytoplasia of the bone marrow.	Riboflavin deficiency is most often accompanied by other nutrient deficiencies, and it may lead to deficiencies of vitamin B_6 and niacin, in particular. Diseases such as cancer, cardiac disease, and diabetes mellitus are known to precipitate or exacerbate riboflavin deficiency.	NA
Thiamin (vitamin B_1; aneurin)	Functions as a coenzyme in the metabolism of carbohydrates, fat, branched-chain amino acid, glucose, and alcohol metabolism; central and periphera nerve cell function; myocardial function.	Beriberi (peripheral neuropathy, heart l failure); Wernicke-Korsakoff syndrome.	The classic disease of thiamin deficiency is beriberi, which is sometimes seen in developing countries. Severe thiamin deficiency in industrialized nations is often associated with chronic heavy alcohol consumption and presents as Wernicke-Korsakoff syndrome.	NA

(*continued*)

TABLE 62-3: Vitamins: Functions, Deficiencies, and Toxicities[a] (*Continued*)

Nutrient	Vitamin functions	Effect of deficiency	High risk deficiency patients and notes	Effect of toxicity
Vitamin B_6 (pyridoxine)	Functions as a coenzyme in the metabolism of amino acids (protein, nitrogen), glycogen, and sphingoid bases (transaminations, porphyrin and heme synthesis, tryptophan conversion of niacin).	The signs and symptoms of vitamin B_6 deficiency are seborrheic dermatitis, microcytic anemia, epileptiform convulsions, and depression and confusion.		Sensory peripheral neuropathy and dermatologic lesions.
Vitamin B_{12} (cobalamins)	Functions as a coenzyme for a reaction that converts homocysteine to methionine and for a separate reaction in the metabolism of certain fatty acids and amino acids; maturation of red blood cells; neural function; DNA synthesis; myelin synthesis and repair.	Macrocytic anemia; neurologic deficits (confusion, parethesias, ataxia).	The major cause of vitamin B_{12} deficiency is pernicious anemia, a condition in which the gastric mucosa of the stomach does not produce intrinsic factor. The hematologic effects that occur with this deficiency are identical to those observed in folate deficiency.	NA
Vitamin C (ascorbic acid)	Acts as an antioxidant and a cofactor in enzymatic and hormonal processes. It also plays a role in the biosynthesis of carnitine, neurotransmitters, collagen, and other components of connective tissue (bone and blood vessel health and wound healing), and modulates the absorption, transport, and storage of iron.	The classic disease of severe vitamin C deficiency is scurvy (follicular hyperkeratosis, petechiae, ecchymoses, coiled hairs, inflamed and bleeding gums, perifollicular hemorrhages, joint effusions, arthralgia, and impaired wound healing).	Severe vitamin C deficiency is rare in industrialized countries, but it is occasionally seen in people whose diets lack fruits and vegetables or in those who abuse alcohol or drugs.	Diarrhea and other gastrointestinal disturbances.
Choline	Required for the structural integrity of cell membranes. It is also involved in methyl metabolism, cholinergic neurotransmission, transmembrane signaling, and lipid and cholesterol transport and metabolism.	Liver damage.	Few data exist on the effects of inadequate dietary intake in healthy people.	Fishy body odor (trimethylaminuria), sweating, salivation, hypotension, and hepatotoxicity in humans.

SIX MACROMINERALS

These are needed in large amounts (in the range of grams per day) and are usually simply referred to as *electrolytes* (will be discussed in a later section). The four cation electrolyte macrominerals are as follows: sodium (Na; element 11; an alkali metal); potassium (K; element 19; an alkaline earth metal); calcium (Ca; element 20; an alkaline earth metal); and magnesium (Mg; element 12; an alkaline earth metal).

The two anion electrolyte macrominerals are as follows: chloride (Cl, chlorine; element 17; a nonmetal halogen gas) and phosphorus (P; element 15; a nonmetal solid).

TABLE 62-4: Vitamin Dietary Reference Intakes by Life Stage Group[a]

[a]Sources referenced in text.
[b]UL, tolerable upper intake level; ULs are the largest amount of a nutrient that most adults can consume without risk of adverse health effects. If blank, data were insufficient to set a UL.
[c]Values represent Recommended Dietary Allowance (RDA); RAE, retinol activity equivalent. Note that food and supplement labels usually state vitamin A levels in international units (IUs). One IU of retinol = 0.3 mcg retinol = 0.3 mcg RAE. Further note that 1 mcg RAE = 1 mcg retinol = 12 mcg beta-carotene = 24 mcg alpha-carotene or beta-cryptoxanthin. The RAE for dietary provitamin A carotenoids in foods is twofold greater than retinol equivalents (RE), whereas the RAE for preformed vitamin A in foods is the same as RE.
[d]Values represent adequate intake (AI) level; when data to calculate an RDA are insufficient, AIs are determined based on the intake of healthy people.
[e]Values represent RDA; RDAs are set to meet the needs of 97% to 98% of healthy people.

NINE TRACE MINERALS (TABLES 62-5 AND 62-6)[41,57]

Nine trace minerals, which are needed in small amounts (in the milligram or less per day range), are as follows: chromium (Cr; element 24; a transition metal); copper (Cu; element 29; a transition metal); fluoride (F, fluorine; element 9; a nonmetal halogen gas); iodine (I; element 53; a nonmetal halogen); iron (Fe; element 26; a transition metal); manganese (Mn; element 25; a transition metal); molybdenum (Mo; element 42; a transition metal); selenium (Se; element 34; a nonmetal solid); and zinc (Zn; element 30; a transition metal).

OTHER MINERALS

Other minerals used by the body (not discussed in depth in this chapter; for more information, see IOM report referenced here[41]) are as follows: sulfate (S, sulfur; element 16; a nonmetal solid); arsenic (As; element 33; a metalloid); boron (B; element 5; a metalloid); nickel (Ni; element 28; a transition metal); silicon (Si; element 14; a metalloid); and vanadium (V; element 23; a transition metal).

NUTRITIONAL SUPPORT: ABNORMAL STATE OF HEALTH

Just as dietary factors contribute to increasing the risk for certain diseases, the reverse is also very true: disease processes can have a profound impact on nutritional status and needs. The optimal dietary requirements for a normal healthy adult (and thus the trauma patient with minor injuries), as discussed in the last section, may need to be adjusted for both acute and chronic conditions, in both the inpatient and outpatient setting, and for both medical and surgical disease.

TABLE 62-5: Trace Minerals: Functions, Deficiencies, and Toxicities[a]

Nutrient	Function	Effect of deficiency	Effect of toxicity
Chromium	Promotes glucose tolerance	Possibly impaired gluocse tolerance	NA
Copper	Enzyme component, hematopoiesis, bone formation	Anemia in undernourished children, Menkes syndrome	Wilson disease, copper poisoning
Fluorine	Bone and tooth formation	Predisposiiton to dental caries, possibly osteoporosis	Fluorosis mottling and pitting of permanent teeth, exostoses of spine
Iodine	Thyroxine (T_4) and triiodothyronine (T_3) synthesis, development of fetus	Simple goiter, cretinism, deaf-mutism, impaired fetal growth and brain development	Hyperthyroidism or hypothyroidism
Iron	Hemoglobin and myoglobin formation, cytochromc enzymes, iron-sulfur proteins	Anemia, pica, glossitis, angular cheilosis	Hemochromatosis, cirrhosis, diabetes mellitus, skin pigmentation
Manganese	Healthy bone structure Component of manganese-specific enzymes: glycosyltransferases, phosphoenolpyruvate carboxykinase, manganese-superoxide dismutase	NA	Neurologic symptoms resembling those of parkinsonism or Wilson disease
Molybdenum	Component of coenzyme for sulfite oxidase, xanthine dehydrogenase, and one aldhyde oxidase	Tachycardia headache nausea obtundation (sulfite toxicity)	NA
Selenium	Component of glutathione peroxidase and thyroid hormone iodinase	Keshan disease (viral cardiomyopathy), muscle weakness	Hair loss, abnormal nails, nausea, dermatitis, peripheral neuropathy
Zinc	Enzyme component, skin integrity, wound healing, growth	Impaired growth and delayed sexual maturation, hypogonadism, hypogeusia	Red blood cell microcytosis, neutropenia, impaired immunity

[b]UL, tolerable upper intake level. If blank, data were insufficient to set a UL.
[c]Values represent adequate intake level.
[d]Values represent Recommended Dietary Allowance.

This necessary alteration to nutritional needs occurs because in a state of abnormal health there can be a profound imbalance among the metabolic regulatory mechanisms that act to keep the body in a condition of normal physiologic function. The imbalance in metabolic and physiologic processes leads to changes in energy expenditures and thus energy requirements, driven by complex feedback mechanisms.[11] These changes to energy balance, triggered by metabolic and behavioral responses to disease, are crucial since bodily function depends on energy transformations. As such, changes to energy metabolism can profoundly alter baseline dietary requirements in an effort to return the body to normal function.

A body in homeostasis implies there is balance of physiologic function, and the body has adequate energy reserves and nutrients. Mild disturbances in homeostasis lead to *adaptation*, defined as a process by which a new or different steady state is reached, without loss of function.[24] An example is the increase in hemoglobin concentration that occurs when individuals live at high altitudes.[11] Another example, in response to a change or difference in the intake of food and nutrients, is the decrease in REE during starvation. Adaptation therefore involves changes in body composition that occur over a more extended period of time, without any discernible detriment to health.[11,24]

More severe disturbances in homeostasis may be detrimental if they exceed adaptive capacity; these severe alterations to optimal function lead to *accommodation*. Accommodation involves relatively short-term adjustments, with the loss of less vital physiologic function and attempts by the body to preserve and maintain the most essential functions, all in an effort to achieve homeostasis.[10] Accommodation is therefore an adaptive response to a disturbance that allows survival but results in some degree of serious consequences to health or physiologic function.[11,24] An example of accommodation, with a resultant initial breakdown in homeostatic mechanisms, is the hypermetabolic state, which can be induced by major trauma and injury.

The Stress Response to Trauma and Injury

In addition to the anatomic injuries produced by a traumatic accident, injured patients are susceptible to developing a profound and systemic physiologic inflammatory response. This is known as the stress response to trauma and can last for days to months after the initial injury. The stress response is multifaceted, driven by metabolic changes as well as alterations to the nervous, endocrine, and immune systems.[58,59] These changes can have severe negative downstream consequences, including inflammatory, immunologic, hematologic, and hemodynamic effects.[59,60] These changes can catalyze the systemic inflammatory response syndrome (SIRS), multiple organ dysfunction syndrome, the postinjury multiple organ failure (MOF), and, at its worst, death.[61] The stress response can also affect protein, carbohydrate, and fat metabolism throughout the body,[62] which impacts the nutritional needs for both macronutrients and micronutrients.[63]

The metabolic response to trauma was first described in the early 1930s by a Scottish veterinarian-physiologist named Dr. David Cuthbertson (he was later knighted for his work).[64,65] Cuthbertson showed increased protein metabolism after injury and demonstrated that this was due to increased muscle catabolism. This hypercatabolic state was most pronounced from postinjury days 2 to 8 and, in some patients, lasted up to 2 months. The hypermetabolism was associated with corresponding physiologic changes to heart rate, body temperature, and oxygen consumption.[64,65]

The systemic stress response to trauma is extremely complex and driven by both the primary injury (tissue ischemia/reperfusion and tissue disruption) as well as secondary insults (blood transfusions, delayed operative procedures, infection), and is further compounded by innate gene expression and genetic polymorphisms.[66] Traditionally, the posttraumatic metabolic response is divided into two phases: an ebb phase and a flow phase, with the flow phase having both a catabolic period and an anabolic period.[67] These phases define the metabolic shifts after a major injury, define the deleterious systemic effects a local injury can produce, and define the alterations to energy requirements and nutritional needs after an injury.[67]

The Ebb Phase

The ebb phase is the body's short-term attempt to preserve energy after an injury. This period is marked by depressed cellular metabolism, with decreased body temperature and oxygen consumption.[67] This stage is the period of traumatic shock, dominated by circulatory fluctuations that require resuscitation with fluids and blood products.[67,68] It represents the immediate consequences of the inciting injury and can lead to whole-body ischemia/reperfusion injury and activation of a nervous system response with neuronal and humoral mediators.[66] The ebb phase of the stress response is also known as the nervous system phase, the ischemia/reperfusion phase, the immediate or first phase, and the resuscitation phase.[58,66]

As an example of the profound neuroendocrine changes during the ebb phase, alterations occur to thermoregulatory capacity of the hypothalamus, leading to a drop in core body temperature. The neuroendocrine-driven hypothermia from an overwhelming traumatic injury does not induce shivering, as would normally occur in environmentally driven hypothermia; it has therefore been compared to hibernation.[58] This is indicative of the protective *hypometabolism* of this resuscitation phase, as the body conserves energy to increase the chances of cellular survival.[69]

The ebb phase is typically measured in hours, usually from 8 to 24 hours.[60] The variable intensity and duration of the ebb phase are related to the severity of the injury[69]: the more severe the injury, the shorter the ebb phase and the quicker the onset of the flow phase. Before returning to a normal

metabolic state after an injury, the body must pass through the flow phase.

The ebb phase can be so severe as to overwhelm the body's adaptive mechanisms to a point beyond which the body cannot recover. This terminal ebb phase is simply referred to as irreversible shock. Physiologic mechanisms at work include profound hypothermia, depressed oxygen consumption below BEE, fall in cardiac output, vasoconstriction, increased blood viscosity, intravascular coagulation, profound buildup of lactate due to anaerobic metabolism, failure of buffering capacity and concomitant acidosis, and eventual death.

TARGETED METABOLIC THERAPY FOR THE EBB PHASE

Reducing initial damage caused by the early postinjury pathophysiologic processes in the ebb phase could determine a more favorable outcome,[58] especially for patients with evidence of postinjury early MOF.[70] The overall goal of targeted metabolic and nutritional therapy in this phase is to diminish the deleterious effects related to ischemia/reperfusion. Interestingly, the link between the hypermetabolic response and the postinjury MOF is evidenced by the fact that postinjury MOF was once referred to as the "hypermetabolism organ failure complex."[71] Concepts such as damage control surgery[72] and damage control resuscitation[73] have evolved as therapeutic stopgaps to improve survival during this phase.

Although the one-hit model of MOF (examples of "one hits" are severe organ and soft tissue injury, hemorrhagic shock, and profound hypoxia) stresses the importance of an overwhelming initial insult that precipitates severe SIRS and then MOF, there is also a two-hit model. In the two-hit hypothesis for the development of MOF, the first hits are less severe than in the one-hit model (examples are milder hypotension, ischemia, and resuscitation), leading to a whole-body proinflammatory reaction, but not SIRS. A second hit then occurs (eg, sepsis, blood transfusion, second operation, mechanical ventilation), leading to SIRS and MOF.[61]

The first hits in both models occur during the ebb phase. Initial targeted treatment goals are to dampen the impact of the second hits.[59] For example, global hypoperfusion during the ebb phase can cause GI tract hypoxia, which primes the intestinal microvasculature, rendering it more susceptible to a secondary challenge.[58,74] Once that secondary challenge occurs in the form of reperfusion during resuscitation, the ischemic gut releases cytokines and proinflammatory mediators. This eventually leads to mobilization of neutrophils and possible MOF,[61,75] as they cause direct tissue damage as well as systemic damage via release of cytokines.

Theoretically, identification of patients at high risk for MOF could facilitate institution of early metabolic and/or nutritional therapies to dampen the proinflammatory response.[61] Supplementation with intraluminal glutamine has proved controversial,[66,76] and pulse steroids have been unsuccessful.[77] Evidence of the benefits of early β-blockers is mainly for burn patients.[66]

Catabolic Flow Phase

What follows the ebb phase is the postshock, postresuscitation catabolic flow period, defined by systemic posttraumatic inflammation and increased metabolism as the body tries to repair itself.[68] These integrated metabolic, inflammatory changes occur in virtually all organs and tissues in the body.[62] The need for injury repair stimulates the hypercatabolic state, driven by cytokine mediators released from lymphocytes and macrophages, dominated by interleukin (IL)-6.[60,62] This leads to a functional redistribution of body cell mass to provide amino acids for gluconeogenesis and protein synthesis[60,62,78] (Fig. 62-1). The catabolic state is maintained by proinflammatory cytokines and catabolic hormones for periods long after the acute trauma.[79]

The hypermetabolic changes are associated with neuroendocrine and immune system reactions.[58,59] The neuroendocrine component of the hypermetabolic response includes raised blood concentrations of stress hormones: the glucocorticoid cortisol (also a catabolic hormone/steroid; released from adrenal cortex) and the catecholamine epinephrine (from the adrenal medulla).[60,62] The immune component is multifaceted and diffuse, with a variety of hormones and proinflammatory cytokines bridging the innate and adaptive immune response.[80] Over time, the immune-inflammatory response can lead to SIRS and, if severe enough, postinjury MOF and compensatory anti-inflammatory response syndrome.[59,61,80,81]

This phase's collective actions are characterized by a hyperdynamic, hypermetabolic response, with increased oxygen consumption (Fig. 62-2), increased energy expenditure, increased body temperature, and increased heart rate as well as proteolysis, glycogenolysis, and lipolysis.[58,67] The resultant accelerated catabolism causes breakdown of skeletal muscle, with negative nitrogen balances and loss of body weight (referred to as auto-cannibalism).[60,82] There is mobilization of stored carbohydrate (glycogen via glycogenolysis) and peripheral insulin resistance leading to hyperglycemia.[66,69] Additionally, there is mobilization of fat (triglyceride via lipolysis) with resulting increase in the plasma concentration of fatty acids and triglycerides[66,69]; the rate of fat oxidation is twice that in a normal human.[78]

Overall, it is the initiation of the innate cellular immune system (monocytes, macrophages, neutrophils, endothelium) coupled with other immunologic changes (activation of complement and coagulation cascades, with resultant release of myriad mediators, including cytokines) that feed the hypermetabolic process.[63] In addition to driving the metabolic response, these factors also drive microvascular thrombosis, mitochondrial dysfunction, cellular necrosis and apoptosis, and secondary remote organ dysfunction (Fig. 62-3).[66]

The catabolic flow period lasts for at least 7 days and, at its most severe, up to 3 weeks or longer (note that in burn patients the hypermetabolism can last up to 2 years).[63,69] The proportion of this inflammatory response is directly related to the intensity of the injury. This intermediate phase is also known as the immune phase (due to activation of the innate immune system) or the leukocytic phase.

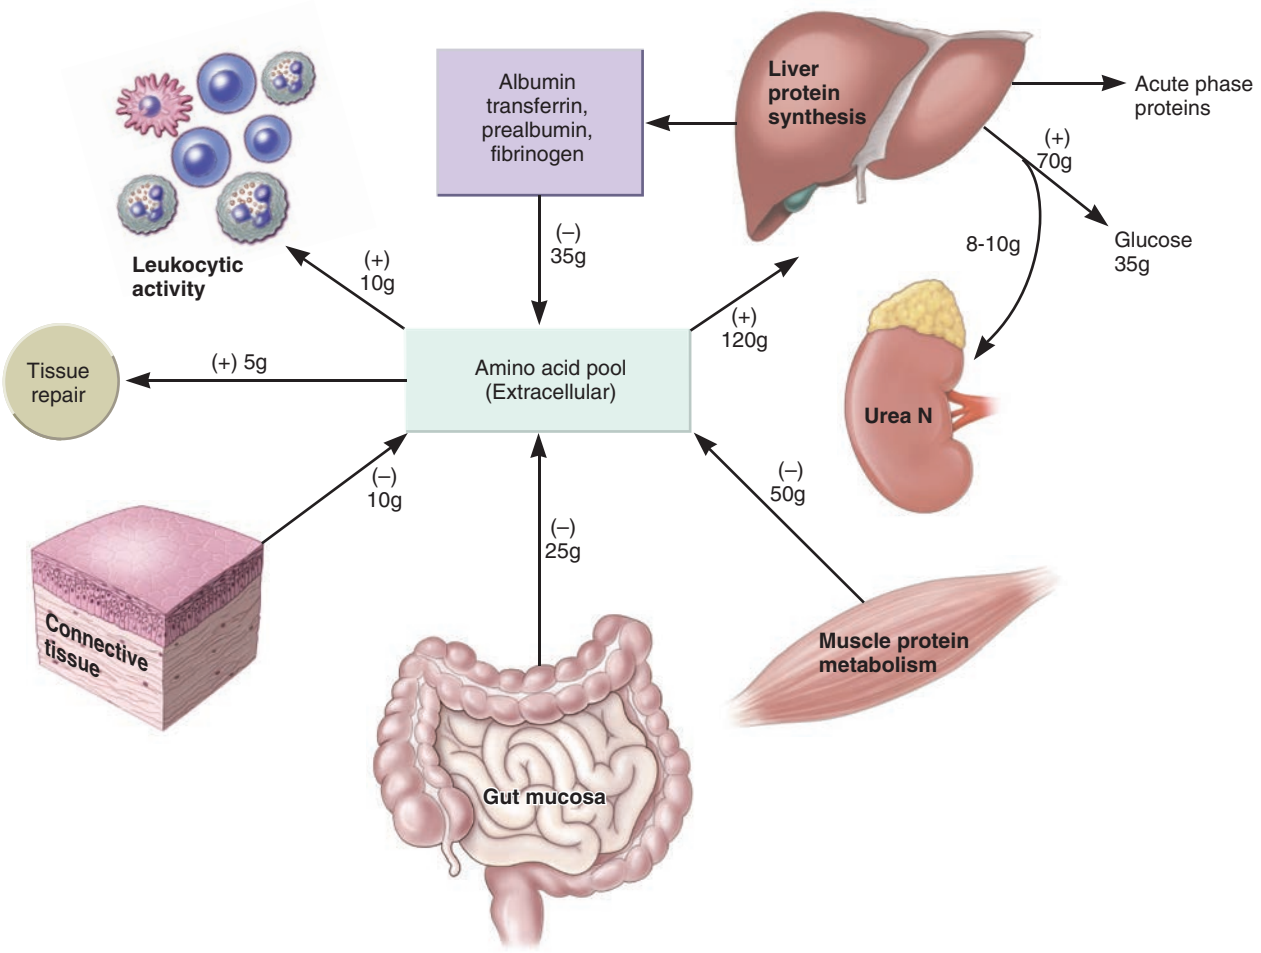

FIGURE 62-1 Functional redistribution of body cell mass after injury provides nitrogen for protein synthesis. Arrows reflect the net release (–) in grams from connective tissue, gut mucosa, and muscle as well as uptake (+) of amino acids into tissues whose net metabolism is associated with survival. The conversion of protein into glucose and urea is a minor source of energy but an important part of the role of the liver to produce the heat necessary to maintain core temperature. TARGETED METABOLIC THERAPY FOR THE CATABOLIC FLOW PHASE

The metabolic changes during this catabolic flow phase catalyze a redistribution of macronutrients and micronutrients (see Fig. 62-1). Labile reserves of protein (skeletal muscle) and fat (adipose tissue) are broken down to provide energy to more active tissue (liver and bone marrow) for host defense, visceral protein synthesis, and heat production.[60] These metabolic alterations in the severely injured patient need to be recognized and addressed during their initial and acute stages.[66,82] The hypermetabolic state increases overall kilocalorie energy requirements, and the increased catabolism with skeletal muscle breakdown increases dietary protein requirements. Early enteral or parenteral nutrition has proven beneficial in this regard (discussed in detail later).

Given the importance of the immune system in driving and maintaining the catabolic flow phase, nutritional therapies to directly alter and target immune function and immune mediators are in theory both logical and possible. Recommendations for glutamine, omega-3 polyunsaturated fatty acids, and other immune-enhancing supplements for trauma patients have been supported in the past. However, new data are changing the landscape of immunonutrition (discussed in detail later), and there is now true clinic equipoise with regard to its use.

This phase's hypercatabolic state is associated with severe complications related to hyperglycemia, hypoproteinemia, and immunosuppression.[60,66] These processes can lead to multisystem organ dysfunction, SIRS, and postinjury MOF.[61] For these reasons, early initiation of glucose protocols with sliding scale insulin is essential, as is attention to nutritional therapy.

Anabolic Flow Phase

The anabolic flow phase gradually occurs as the patient's posttraumatic metabolism shifts from catabolism to synthetic

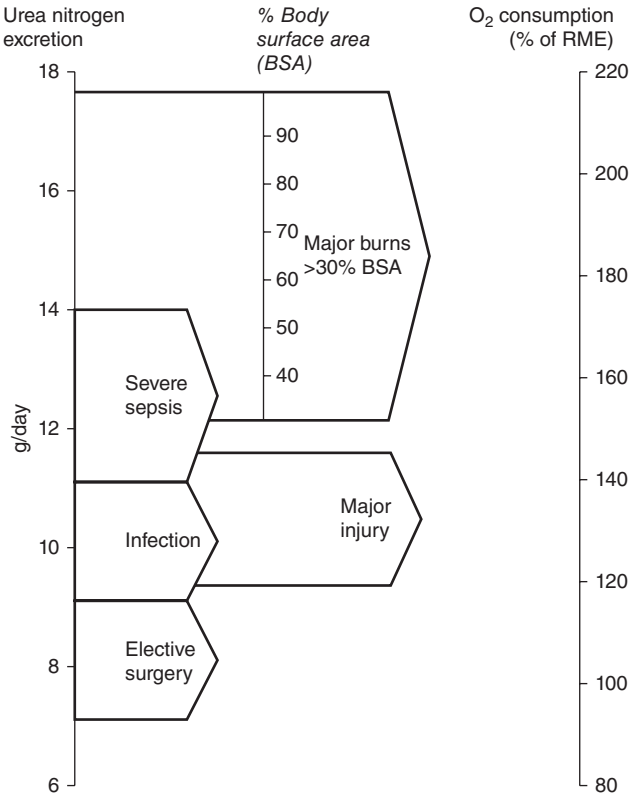

FIGURE 62-2 Rates of hypermetabolism estimated from urinary urea nitrogen excretion. Degree of hypermetabolism differs greatly: for elective surgery, ~100%–110% of resting energy expenditure (REE); for infection and major injury/trauma, ~120%–145% of REE; for severe sepsis, ~140%–170% of REE; and for major burns (>30% total body surface area), ~150%–220% of REE. REE concept explained in the text. RME, resting metabolic expenditure. (Reproduced with permission from Blackburn GL. Metabolic considerations in management of surgical patients. *Surg Clin North Am*. 2011;91(3):467-480. Copyright © Elsevier.)

activities and reparative processes.[63] This phase reprioritizes protein synthesis in the liver, known as the acute phase response. Mediating this phase is increased adrenal cortical hormone secretion as well as a variety of cytokines (IL-1, IL-6, tumor necrosis factor-α), which stimulate the liver's synthesis of the acute phase reactants, including fibrinogen and C-reactive protein,[69] initially at the expense of constitutive proteins such as albumin.[60]

Eventually a convalescence is achieved, as the hypercatabolic syndrome is progressively downregulated with reduction of catabolic hormones (catecholamines, proinflammatory cytokines, cortisol, glucagon) and increase of anabolic hormones (insulin, growth hormones, insulin-like grown factor 1, anabolic steroids).[58] With time, there is an exponential increase in the levels of positive acute phase proteins and a decrease in levels of negative acute phase proteins.[63]

This phase is also characterized by a return of oxidative metabolism, leading to angiogenesis in the injured tissues and organs, facilitating tissue repair and regeneration.[66] For this reason, the phase is also known as the angiogenic phase or the endocrine phase, as it is the endocrine functional system that facilitates oxygen transport.[58] With time, there is full recovery of the endocrine system (hypothalamic-pituitary-organ-hormonal axes), the nervous system (autonomic nervous systems), and the immune system (innate and adaptive).[58] These responses make possible the complex process of resolution of inflammation as well as a return to normal homeostasis.

Nutrient Utilization and Needs After Trauma and Injury: Seven Key Questions

Depending on the severity of the injury, traumatically injured patients are at risk for developing a hypermetabolic posttraumatic stress response (discussed in the last section). If the metabolic insults persist, the body goes into a hyperdynamic state, with breakdown of skeletal protein and rapid loss of lean body mass. Potential complications from this state of hypercatabolism associated with posttraumatic hyperglycemia, hypoproteinemia, immunosuppression, and the multitude of other effects include onset of protein-calorie malnutrition, infectious morbidity, multiorgan dysfunction, prolonged hospital stays, postinjury MOF, and disproportionate death.[34,35,61,83-86]

The inflammatory stress response can be broken down into three phases: ebb, catabolic flow, and anabolic flow. Each of these phases induces distinct pathophysiologic changes that can require interventions to eliminate or minimize their untoward consequences.[63] One of the most fundamental and important interventions is nutrition.[63,82,83,87-90]

WHY IS NUTRITIONAL SUPPORT IMPORTANT?

Early recognition of the hypermetabolic state and adequate early nutritional support are essential to not only meet the patient's increased nutritional needs (and thus preserve lean body mass), but also to facilitate recovery and healing, restore the body's capacity for optimal immune function, prevent oxidative cellular injury, attenuate the inflammatory stress response, and prevent complications.[83] In this sense, early nutrition has gone from supportive care to outright therapeutic care[35] and can be thought of as "metabolic control."[83,84,88]

WHO NEEDS POSTINJURY NUTRITIONAL SUPPORT?

All trauma patients will benefit from nutritional support, especially early in the hospitalization in those who are severely injured or those with baseline malnutrition prior to the injury. Severely injured patients are at highest risk for developing a hypermetabolic state and subsequent malnutrition.

The metabolic response to trauma in clinical terms is an "all-or-none" response: the patient with an Injury Severity Score (ISS) of 18 is metabolically similar to the patient with an ISS of 50.[78] For this reason, some have advocated using an ISS of greater than 16 to identify severely injured patients who are at risk for hypercatabolism and malnutrition.[36] Although this is certainly possible, more often identifying a severely injured patient is done by clinical judgment. It is

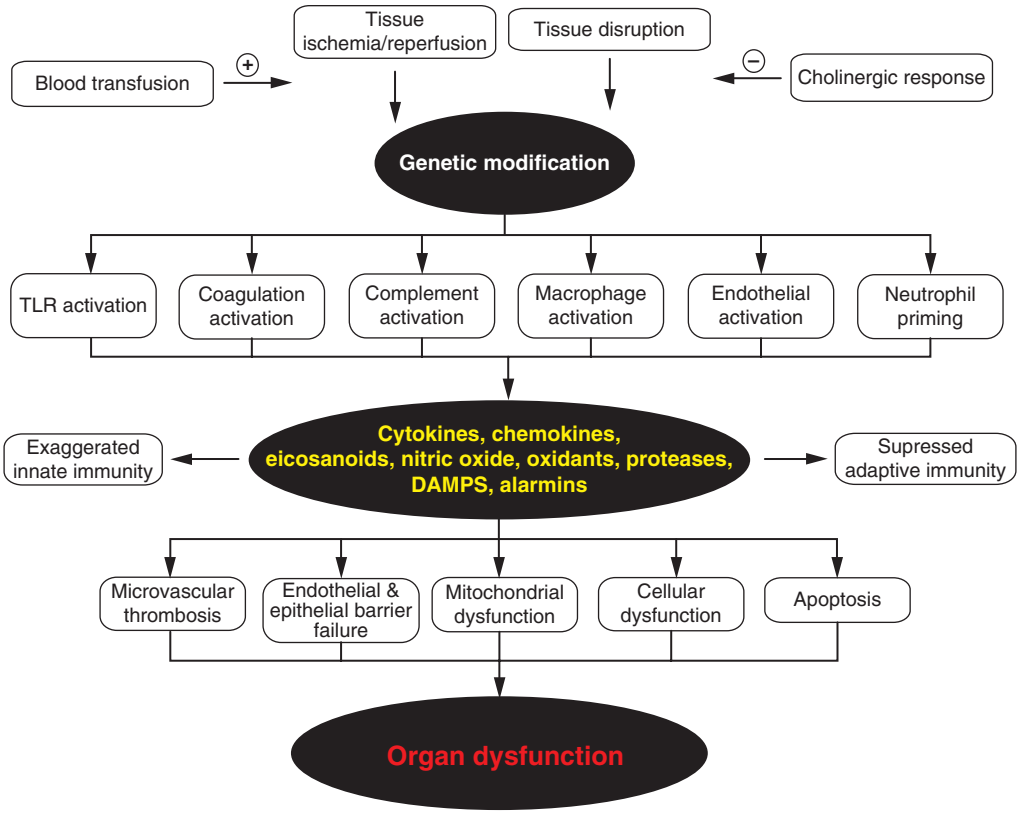

FIGURE 62-3 Simplified schematic representing the current understanding of the pathophysiologic reactions to major trauma. These reactions lead to secondary remote organ dysfunction, as outlined in the text. DAMPs, damage-associated molecular patterns; TLR, Toll-like receptor. (From Stahel PF, Flierl MA, Moore EE. "Metabolic staging" after major trauma: a guide for clinical decision making? *Scand J Trauma Resusc Emerg Med.* 2010;18:34. Reproduced with permission.)

these patients who need to be assessed for specific nutritional formulations with higher protein intake.

There are some unique trauma patient populations with unique nutritional needs and requirements. These include traumatic brain injury patients, burn patients, and others. Please see the Special Patient Populations section later for details and recommendations. This section also has details on how to perform a nutritional assessment to identify patients with baseline malnutrition.

WHEN TO IMPLEMENT NUTRITIONAL SUPPORT?

Prior to starting any nutritional support, the end points of traumatic shock resuscitation should be achieved and the patient stabilized.[32,35,83,91] Once achieved, *early* (within 24–48 hours of injury) enteral nutrition should be started as soon as possible.[32,35] While there are different definitions of early (within 12 hours,[92] within 24 hours,[93] or within 48 hours[32,94] of injury or admission to intensive care unit [ICU]), in general, within 48 hours or earlier is accepted. Early enteral nutrition is so fundamental to good patient management that it should be the final component of traumatic resuscitation.[94]

The severely injured polytrauma patient who does not receive nutritional support in the first few days after the injury can develop worsening energy and protein deficits, which contribute to risk of complications.[83-85,95] Multiple prospective randomized controlled trials have shown that early nutrition can decrease infection rates, hospital lengths of stay, and cost, and improve outcomes.[95-98] Trauma patients with an open abdomen without an associated bowel injury who were started on enteral nutrition once resuscitation was completed had decreased complications and improved survival[99] (Fig. 62-4).

WHAT SHOULD BE USED AS NUTRITIONAL SUPPORT?

Choosing the ideal nutrient formulations for injured and/or critically ill patients is increasingly complex. There are many options for both enteral nutrition (EN) and parenteral nutrition (PN), from the basics to specialized formulations. Please see the sections on nutrition intervention for details and specifics.

WHERE IN THE BODY TO FEED: GI TRACT OR PARENTERALLY?

Patients who have an injury, disability, or critical illness that will preclude their ability to initiate oral feeding (ie, feed themselves) beyond hospital day 5 should be started on enteral tube feedings as soon as safely possible, once resuscitated and stable.[35,36,83,99]

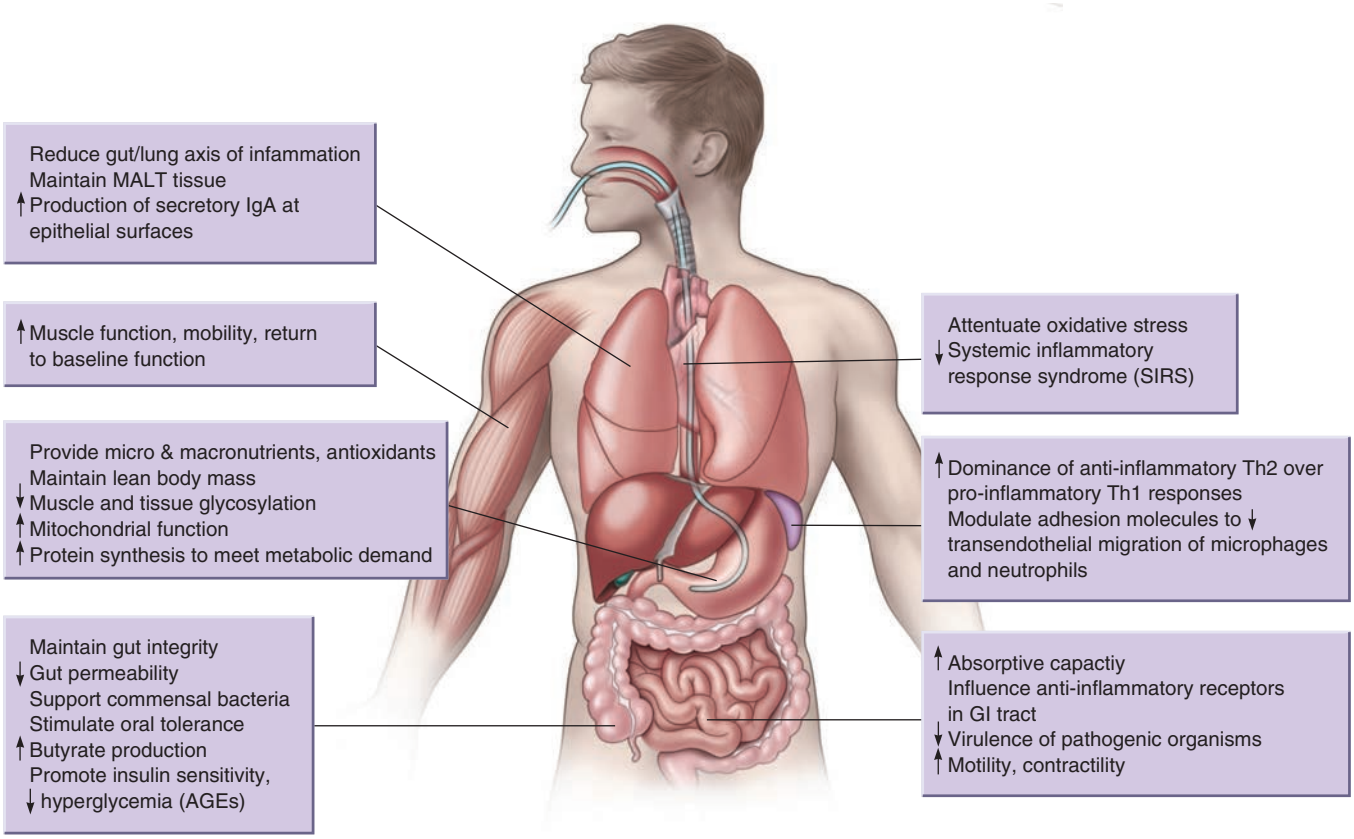

FIGURE 62-4 Nutritional and nonnutritional benefits of early enteral nutrition. AGE, advanced glycolytic end products; GI, gastrointestinal; MALT, mucosal-associated lymphoid tissue. (Reproduced with permission from McClave SA, Martindale RG, Rice TW, Heyland DK. Feeding the critically ill patient. *Crit Care Med*. 2014;42(12):2600-2610.)

Early EN via either gastric feeds or postpyloric feeds is acceptable.[32,34,35,92,97,100-103] In the largest multicenter randomized controlled trial to compare gastric versus small bowel EN in critically ill patients, there was no difference in clinical outcomes between groups, including length of stay, mortality, nutrient delivery, and incidence of pneumonia.[103a] For this reason, our practice is to start with gastric feeds, if possible. This can be achieved through either continuous or intermittent tube feeds, as discussed later in the chapter. The benefits of the enteral route as compared to the parenteral route include fewer infections (eg, pneumonia, catheter-related bloodstream infection), decreased possibility of bacterial translocation, prevention of gut mucosal atrophy, avoidance of complications of PN, avoidance of complications of intravenous access for PN, and reduced cost.[32,35] There is no morality benefit to EN over PN.

Although the enteral route is preferred, there are situations when PN is indicated. If enteral feeds are contraindicated, have failed, or are not expected to be started for 3 days, then *exclusive* PN should be considered.[33,36,104] Note that the 3-day cutoff for initiating exclusive PN is now more widely accepted, and has become a practice when EN is not able to be started. For many years, the European Society for Clinical Nutrition and Metabolism (ESPEN) has used a cutoff of 3 days.[33] The American Society for Parenteral and Enteral Nutrition (ASPEN) and the Society of Critical Care Medicine (SCCM) guidelines, however, use a cutoff of 7 days to start PN in previously healthy patients (prior to their critical illness and injury)—though the evidence to support this stance is reported as "very low."[35] The most recent SCCM/ASPEN guideline does recommend *early* exclusive PN (meaning as soon as possible after admission to the ICU) in patients with baseline protein-calorie malnutrition and when EN is not feasible.[35]

If enteral feeds will be inadequate for the first 3 to 10 days (inadequate defined as achieving only 25% of 24-hour kilocalorie goal), then one option is use of *complementary PN*, meaning the use of PN in addition to EN (complementary PN is also referred to as supplemental PN, dual-modality therapy, or top-off total PN). This topic is somewhat controversial. In 2011, a large, prospective randomized controlled trial found no benefit to early (day 3 of ICU stay) versus late (day 8) initiation of complementary PN.[105] For this reason, ASPEN/SCCM guidelines recommend the use of supplemental PN starting on surgical ICU day 10 only if the patient is unable to meet greater than 60% of their nutritional needs by enteral route alone.[35]

The need for supplementary PN must be interpreted with data demonstrating that trophic EN feeds (which by definition have a negative nitrogen balance) for 7 days in critically ill nontrauma patients have outcomes equivalent to goal tube feeds over the same time period.[106-108] Therefore, if a patient can tolerate even trickle tube feeds, achieving nitrogen balance with complementary PN is not needed. While somewhat controversial (ASPEN/SCCM cite data demonstrating higher infectious morbidity and rates of ARDS when using complementary PN in patients already receiving 1000 kcal/d of EN,[109] and ESPEN cite data demonstrating a strong correlation between negative nitrogen balance and morbidity and mortality in critically ill patients[110,111]), at present, there is not sufficient evidence to make a best recommendation on complementary PN[36,112] beyond the fact that it should not be started before hospital day 10.[105]

Enteral or parenteral modes of nutritional therapy are different means to the same end. In this manner, attention must be paid to the patient's tolerance of one route and, if necessary, switching to the other route.

HOW TO DELIVER NUTRITIONAL SUPPORT?

Please see section on nutritional intervention for details and specifics on the delivery and administration of EN, including access choices, monitoring, and complications.

HOW MUCH ENERGY AND MACRONUTRIENTS ARE REQUIRED?

Energy. Most critically ill trauma patients have in common an increased metabolic rate. The hypermetabolic response coupled with increased protein catabolism create an amplified energy requirement in the severely injured patient. The increase in energy requirements may range anywhere between 30% and 70% above normal, although even the most experienced clinicians are unable to predict the extent to which trauma or injury will amplify an individual's energy requirements.[60]

Based on studies calculating nitrogen losses, needs are increased approximately 30% in major injury, 50% in sepsis, and 75% to 100% with severe burns[60] (see Fig. 62-2). Translating these increased metabolic rates into higher kilocalorie requirements is a bit more nuanced. This is because increasing evidence suggests that critically ill patients have lower energy requirements than expected. For example, while injury and infection increase REE, in most cases, the increase is modest and largely offset by immobility.[10]

Therefore, the old strategy of meeting or exceeding energy requirements after a major trauma compounds the metabolic alterations of the stress response and worsens outcomes.[113] A more modern nutritional doctrine is that overnutrition has detrimental complications.[32-36,114] For this reason, the use of injury factors for the HBE to calculate EER is not recommended (an old dogma was to multiply the 24-hour kilocalorie HBE BEE by factors for postoperative and/or injured patients, such as 1.20 if elective surgery, 1.35 if trauma, 1.60 if major sepsis, or 2.1 if major burn).[115]

A nutritional support goal of 20 to 25 kcal/kg IBW/d is enough to be beneficial during the acute and initial stress response in the critically ill trauma patient.[32,113] This is in keeping with guidelines that highlight reaching at least 50% of total daily goal kilocalories over the first week of the hospitalization, if goal nutrition cannot be achieved.[35] During the anabolic recovery phase (ie, anabolic flow period; convalescence), the aim should be to provide slightly more energy, from 25 to 30 kcal/kg IBW/d.[32] Other guidelines recommend a daily kilocalorie increase of 40% above BEE, which translates into a nutritional support goal of 25 to 30 kcal/kg IBW/d.[32,33,35,36]

The ASPEN/SCCM guideline endorses both predictive equations as well as indirect calorimetry for calculating target energy goals, as does ESPEN. If these goal values cannot be achieved, trophic enteral feeds at lower rates (ranging from 10–30 mL/h) have huge benefits over starvation and have outcomes that are as good as EN at goal.[106-108]

Finally, the question arises regarding which body weight one should use in nutritional calculations in polytrauma and critically ill patients: IBW, actual body weight, LBW, or ABW. This was briefly mentioned in the first section of the chapter. The ESPEN guidelines strongly recommend using IBW for all weight-based calculations ("it is therefore wise to consider ideal body weight when calculating energy requirements").[32,33,91,116] Using IBW avoids the pitfall of overfeeding patients. The ASPEN/SCCM guidelines use the actual body weight for patients with a body mass index (BMI) less than 30, and both the actual body weight and the IBW for those with a BMI of 30 or greater (see Special Patient Populations section later for nutritional requirements in obese patients). Note that in patients with an actual body weight BMI of less than 30, that approximates to the IBW, and thus IBW can be used without dire consequences.

Protein Needs After Trauma. Protein is thought to be the most important macronutrient for wound healing, immune function, and preventing loss of lean body mass in the injured and critically ill patient.[35] The hypermetabolic, hypercatabolic state of posttraumatic stress induces a profound breakdown and redistribution of body protein (see Fig. 62-1); protein needs to be replenished and levels maintained.[60] If such needs are not appropriately addressed, it can lead to ongoing erosion of lean body mass and negative nitrogen balances.

In the midst of a severe inflammatory stress response, once-normal synthetic reactions may require substantially different patterns of amino acid usage: proline for collagen synthesis, aromatic amino acids for synthesis of antibodies and acute phase proteins, and glutamine for rapidly dividing cells.[10] In such conditions, amino acids that are not usually essential can become conditionally essential due to limited synthetic capacity.[10] The amount and composition of protein required to maintain nitrogen balance in postinjury critically ill polytrauma patients may differ substantially from that in healthy subjects. For example, if loss of LBW is severe, adults can have a requirement for essential amino acids resembling that of a growing child due to the needs for tissue rebuilding.[10]

During the acute stress response, a nutritional support goal ranging from 1.2 to 2.0 g protein/kg IBW/d will decrease the

loss of LBW and prevent negative nitrogen balances.[32,33,113] The ESPEN guidelines specifically recommend 1.3 to 1.5 g/kg IBW/d in critically ill trauma patients.[32,33] The latest ASPEN/SCCM guidelines recommend "an ongoing evaluation of the adequacy of protein provision be performed."[35] This amounts to protein of 1.5 g/kg body weight/d if BMI is less than 30; 2.0 to 2.5 g/kg IBW/d if BMI is 30 to 40; and 2.5 g/kg IBW/d if BMI is 40 or greater.[35]

Note that some guidelines use a nitrogen-based recommendation, and the conversion is that 1 g of nitrogen is equal to 6.25 g of protein. Some critically injured polytrauma patients will demonstrate such significant and rapid muscle losses that they have protein requirements three times the normal level, meaning closer to 2.5 g/kg/d.[63] The desire to simply add supratherapeutic levels of protein must, however, be buffered with the fact that it will not prevent the hypercatabolic state in critically ill trauma patients.[117]

The distribution of nutrition kilocalories among the macronutrients during the stress response is not firmly established. It should be adjusted to particular circumstances and for individual patients, keeping in mind the AMDR (see Table 62-2).

Standard recommendations call for calculation of protein kilocalories first based on a protein requirement of 1.3 g/kg IBW/d.[32,33] Then calculate the carbohydrate and fat energy distribution (see later). When calculating energy provision for artificial nutrition support by either EN or PN, do not consider energy provided as protein as separate from energy given as nonprotein calories.

Carbohydrate Needs After Trauma. Carbohydrates should constitute 50% to 70% of nonprotein calories.[36] See specifics on EN and PN later in this chapter.

Fat Needs After Trauma. Fat should constitute 20% to 30% of nonprotein calories.[36] See specifics on EN and PN later in this chapter.

Water Needs After Trauma. The impacts of dehydration are amplified in the critically ill and postinjury patient.[53] Dehydrated trauma patients (those who have lost 7%–10% of body weight as water) are more susceptible to fever, have increased cardiovascular strain and reduced tissue perfusion, and are at increased risk of death.[53] Euvolemia should be maintained as discussed in the healthy adult section.

NUTRITIONAL INTERVENTION: GENERAL

Choosing and constructing the ideal nutritional therapy for injured and critically ill patients is increasingly complex. Expanded knowledge of the pathophysiology of the posttraumatic stress response as well as critical illness and the growing field of nutritional sciences have made the possibility of disease-targeted nutrition a near reality. Enteral and parenteral formulas today are not only expected to provide balanced nutrients to meet energy requirements, but are also supposed to modulate the immune system, enhance neuroendocrine function, mitigate the hypermetabolic response to injury, and offset postinjury catabolism.

In metabolically stressed polytrauma patients, the anabolism-catabolism balance becomes severely weighted toward catabolism, leading to rapid depletion of body tissue stores and critical protein elements, such as immunoglobulins. This is characteristic of protein-calorie malnutrition. The primary goal of nutritional intervention is therefore to minimize the net negative energy and protein balances and their negative downstream consequences, while appreciating that lean tissue loss is unavoidable in severe trauma patients even with aggressive nutritional therapy. The secondary goal, which is increasingly controversial, is to target immune and neuroendocrine function via pharmaconutrition.

Before reading further, please ensure you have read the last section entitled Nutrient Utilization and Needs After Trauma and Injury: Seven Key Questions, which addresses the why, who, when, what, where, how, and how much of trauma patient nutritional support. For additional resources, multiple medical, surgical, trauma, and critical care organizations have developed and published nutrition guidelines which are of benefit, as are their websites:

- SCCM and ASPEN[35]
- ESPEN[32,33,91,116]
- Canadian Critical Care Society[93]
- Eastern Association for the Surgery of Trauma[87]
- Spanish Society of Intensive Care Medicine and Coronary Units–Spanish Society of Parenteral and Enteral Nutrition[36]
- German Association for Nutritional Medicine[118,119]

If nutritional requirements are properly attended to, the polytrauma patient should get the right type of nutritional substrate, in the right amounts, at the right time. This is easier said than done, however, as nutrition and nutritional science is a modern, complex, and ever-changing field of medicine. Nutrition, after all, is not intuitive,[120] and nutritional assessments and interventions demand that one's clinical knowledge is up to date.

NUTRITIONAL INTERVENTION: ENTERAL NUTRITION

Meeting the increased energy requirement with early EN is essential to the adequate care of the injured patient.[66] Prospective, randomized controlled trials have clearly proven the positive effect of early EN in the polytrauma patient, with decreased posttraumatic infection rates, a shorter hospital length of stay, and improved morbidity and mortality (Fig. 62-5).[95-98]

Patient Selection

All patients should ideally receive nutritional support within 24 to 48 hours of injury. Before starting enteral feeds, a thorough history (including past medical and surgical history)

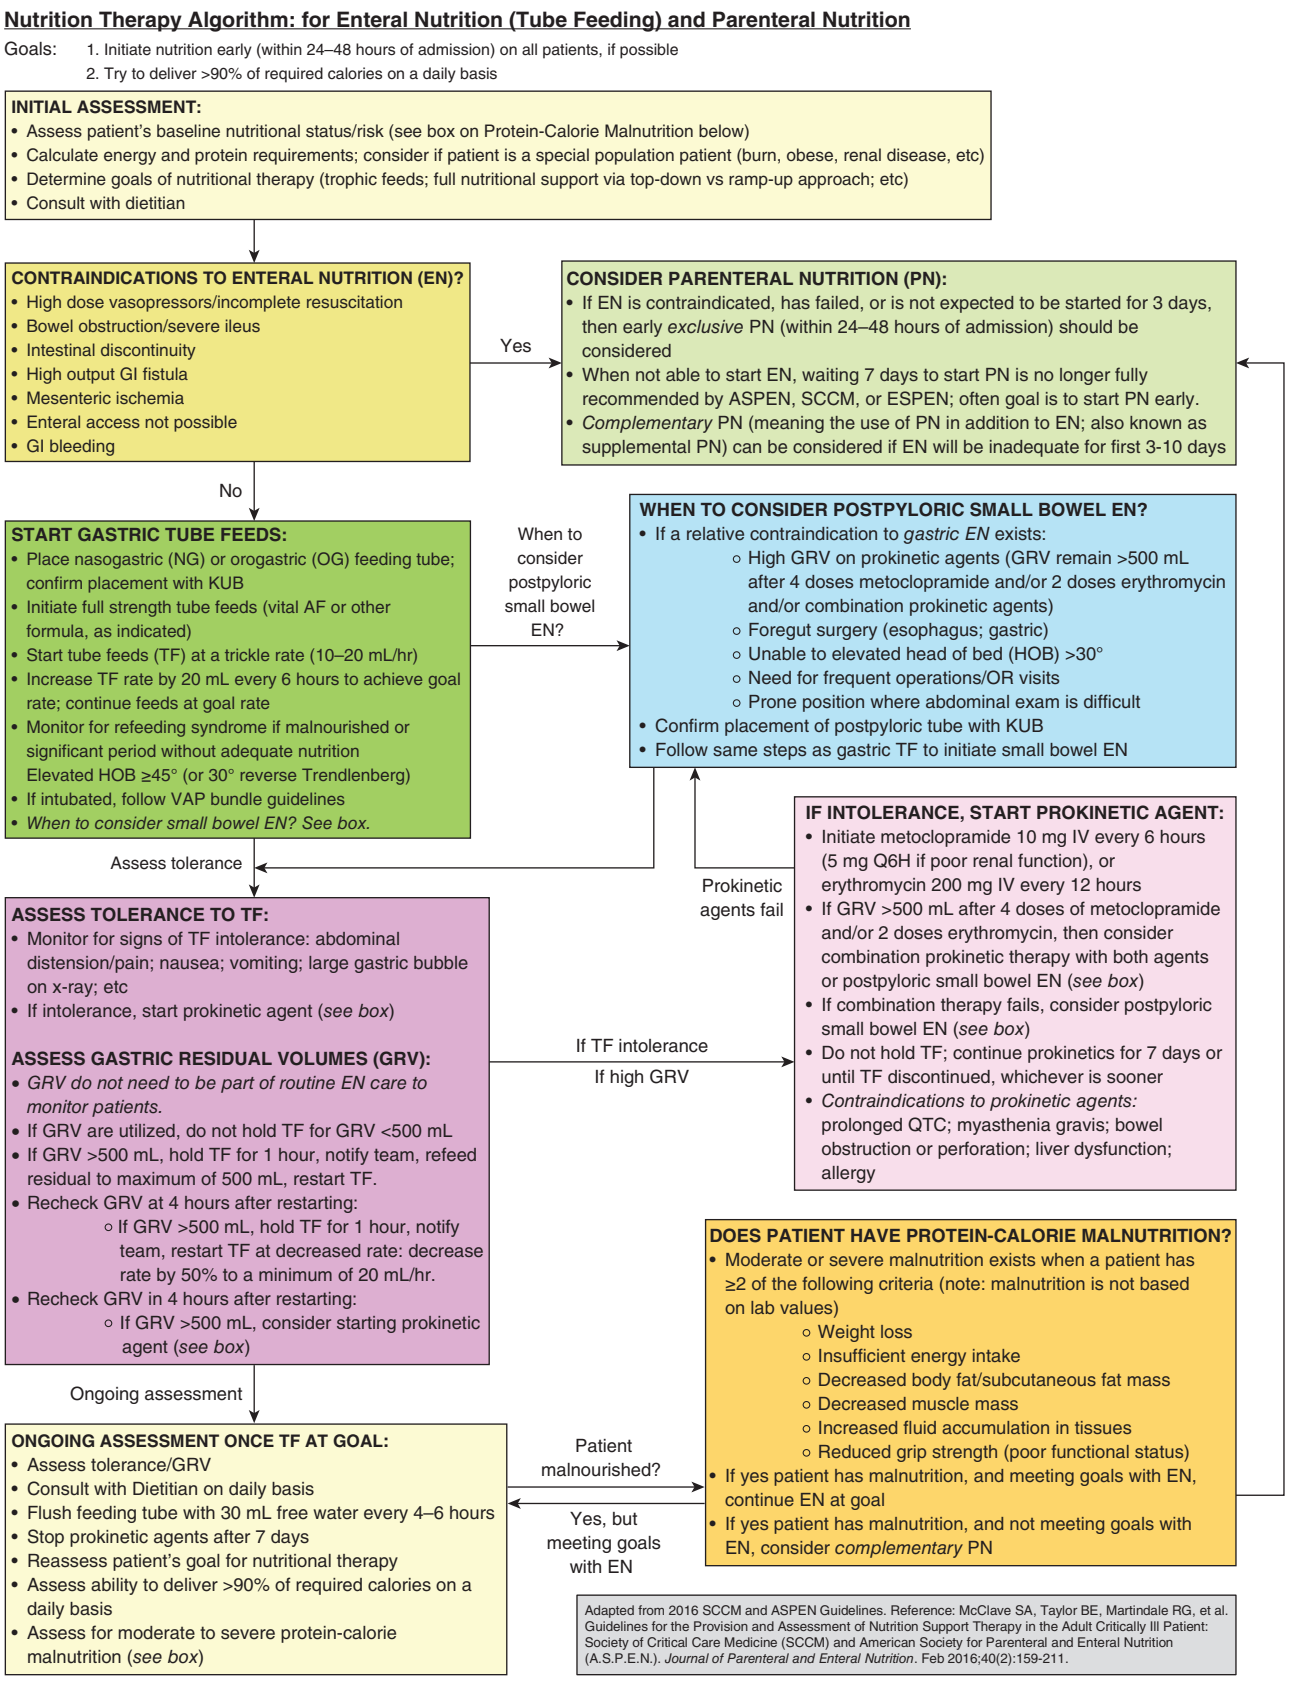

FIGURE 62-5 Clinical algorithm for initiating nutritional therapy.

and physical exam should be completed. Conditions such as heart, liver, and/or kidney disease as well as alcoholism and malnutrition will impact the approach to enteral feeding, as will key operative history such as short gut or gastric bypass. Please see the later Special Patient Populations section for more specifics; particularly important is the section titled Patients with Baseline Malnutrition or High Nutritional Risk.

Meeting Nutritional Requirements by Enteral Route

How to meet the macronutrient and micronutrient requirements of both healthy and critically ill, hypermetabolic trauma patients was discussed earlier in the chapter.

Enteral Formulas and Choices

Highly sophisticated enteral nutritional formulas were developed long ago as part of NASA's space program.[121] Back then, the goal was to develop a diet that would leave no fecal residue. Such enteral formulas eventually became known as elemental diets, and although astronauts rejected them as tasteless, medicine has embraced them as revolutionary. And it is clear why: they can be given in defined concentrations, they contain all macro- and micronutrients, and some require very little enzymatic activity on the part of the GI tract. Enteral nutritional formulas (ie, artificial nutrition, chemically defined diets) today cover a full spectrum of products, many claiming pharmacologic effects in addition to standard nutrient delivery; hundreds are available.

Choosing an appropriate enteral formula is mostly based on meeting the energy (kilocalorie) and protein requirements of the patient (these requirements are discussed at length earlier in the chapter). Other considerations include baseline nutritional status, electrolyte balance, digestive and absorptive capacity, disease and inflammatory state, ongoing or completed resuscitation, and comorbidities including cardiac, pulmonary, hepatic, and renal function.

Enteral formulas are classified in three ways: standard, predigested, or specialized. There are many choices within each category. In general, if patients have normal GI function, they can get standard formulas. If their GI function is compromised, then one should consider the predigested formulas. If they have significant baseline comorbidities, then a specialized formula can be considered; the specialized formulas are for both normal and abnormal GI function.

STANDARD FORMULAS

Standard formulas (ie, polymeric formulas) have intact protein with balanced amounts of macronutrients. Their nutrient compositions are meant to match what is recommended in healthy individuals (within the AMDR; see Table 62-2). They come in various kilocalorie concentrations (called kilocaloric density, ranging from 1.0–2.0 kcal/mL), which translate into higher or lower water content formulas. They are made with and without fiber supplementation; the fiber can be soluble and/or insoluble. The sources of carbohydrates, proteins, and fats are variable. Standard formulas require complete digestive capacity, as they have proteins in their original, natural form. These formulas are often much cheaper than others.

For stressed polytrauma patients with systemic inflammation, high-protein (ie, high-nitrogen) formulas are necessary, meaning they usually have a nonprotein calorie–to–nitrogen ratio of 70:1 to 100:1 (much lower than the usual 150:1 ratio).[35] Additionally, two sources of energy are believed to benefit high-stress situations: medium-chain triglycerides (MCT) and branched-chain amino acids (BCAA).

PREDIGESTED FORMULAS

Predigested formulas are designed for patients with decreased absorptive capacity who need predigested nutrients, thus requiring less enzymatic activity by the GI tract and leaving no residue behind. The protein source in these formulas has already been broken down into either free amino acids (in the case of elemental formulas) or short peptides (in the case of peptide-based formulas, with either dipeptides or tripeptides). These formulas are also called hydrolyzed or partially hydrolyzed formulas, as well as elemental or semi-elemental formulas.

SPECIALIZED FORMULAS

Specialized formulas are designed for a variety of clinical situations and conditions. These formulas can be generally categorized as either disease-specific formulas or immune-modulating formulas (IMFs), although there is overlap. The latest fad in specialized EN is "natural formulas."

SPECIALIZED DISEASE-SPECIFIC FORMULAS

The disease-specific formulas are specially designed for renal disease, liver disease, diabetes/hyperglycemia, pulmonary disease (eg, chronic obstructive pulmonary disease, acute respiratory distress syndrome), and hypoallergenic patients. They can be useful for the stressed polytrauma patient with significant comorbidities.

SPECIALIZED IMMUNE-MODULATING FORMULAS

Pharmaconutrition is the practice of using both nutrition and nutritional supplements as pharmaceuticals, with the intention of improving an outcome or curing a disease. An arm of pharmaconutrition is *immunonutrition*: the practice of using the diet to affect both the nutritional and the immune status of a metabolically stressed patient.[60]

The role of IMFs (ie, immune-enhanced nutrition) was, in the recent past, considered routine clinical care for critically ill trauma and surgery patients.[32,91] Today, however, it is more controversial,[63] as the data on the true benefits of immunonutrition are changing rapidly. Part of the difficulty in interpreting this literature is that supplement dosing, timing, and route of administration are not standardized, the supplements can be given alone or as part of a combination

therapy, and the patient populations are heterogeneous.[122] In short, at present, there is true clinical equipoise with regard to immune-enhanced nutrition.

The latest 2016 guideline from ASPEN/SCCM[35] supports the use of IMFs in trauma patients with a traumatic brain injury as well as in perioperative surgical ICU patients, noting, however, that the evidence for the use of IMFs is very low. In several meta-analyses, adding immunomodulating nutrients to enteral feeding formulas was associated with reduced infectious complications and improved recovery compared with standard EN. IMFs have therefore gained widespread use in severely injured polytrauma patients. Supplements that have been researched include arginine,[123-125] glutamine,[76,126] omega-3 polyunsaturated fatty acids,[125] nucleic acids,[127] and micronutrient antioxidants (eg, selenium),[76] among others.

The most recent ESPEN guideline, on the other hand, has concluded there is no general indication for administering immune-modulating nutrients to critically ill patients.[32] Two recent studies support the ESPEN stance: both the 2013 REDOX study of glutamine and antioxidants[76] and the 2014 MetaPlus Trial of high-protein IMF[128] show an increased risk of mortality with IMFs compared to standard high-protein formulas. Although in theory glutamine, arginine, nucleic acids, omega-3 polyunsaturated fatty acids, selenium, and antioxidants should help as immunonutrition, in practice, their use may be harmful.

"NATURAL FORMULAS"

EN is big business. The global enteral feeding formulas market size was valued at $4.39 billion in 2016 alone[129] and is only expected to get bigger in time. Out of this large corporate market has grown a small, boutique industry for "natural" and "real food" enteral formulas. These new formula companies offer everything from organic to plant-based to vegan EN options. Examples include "Liquid Hope," "Kate Farms," and "Orgain."

Enteral Access

Multiple access options exist for the administration of EN. They can generally be divided into either temporary (ie, short term) or long-term feeding access devices.

Temporary access devices are one of two types: prepyloric or postpyloric. Prepyloric options include simple nasogastric tubes or smaller-diameter feeding tubes placed into the stomach. Postpyloric tubes are also inserted through a nostril, although they are placed past the pylorus and into the duodenum or jejunum.

Long-term access devices are also one of two types: prepyloric or postpyloric. Prepyloric tubes are gastrostomy tubes; they mainly differ by their physical characteristics and the method by which they are inserted (percutaneously, laparoscopically, or open) (see Atlas Figure 68). Postpyloric tubes can originate in the stomach (combination gastric-jejunostomy tube) or in the jejunum (jejunostomy tubes).

In general, there are few contraindications to feeding the stomach. There are no good data to advocate for postpyloric feedings as the delivery option of choice in polytrauma patients. Although it makes sense that postpyloric feeds would decrease the risk of aspiration and pneumonia, this has not been proven[130,131] (please see later in chapter for in-depth discussion on gastric residual volumes). Do not delay the initiation for EN because of a lack of postpyloric access.

The major indication for long-term access (gastrostomy or jejunostomy tubes) is the anticipated inability of a patient to tolerate oral feedings beyond 1 month after the time of injury.

Mechanically ventilated critically ill patients should have the head of the bed elevated to at least 30° when receiving EN[34] to decrease risk of aspiration and pneumonia.

Delivery and Administration of Enteral Nutrition

The delivery of enteral nutritional is achieved by either continuous or intermittent tube feeds. There are no data to support one method of delivery as superior to the other.

Goal-directed continuous tube feeds (with a target goal of full kilocalorie nutritional support) are initiated by one of two strategies: the top-down approach (ie, aggressive approach) or the ramp-up approach.[132] The *top-down aggressive approach* is akin to an hourly volume-based approach: immediately start the rate of tube feeding right on the maximal hourly goal and deescalate if needed. The *ramp-up approach* is more traditional and involves initiation of tube feeds at a lower rate (often 15–25 mL/h) and increasing to the goal rate over a period of time.[83]

More recently, a third strategy has been espoused: trophic feeds. *Trophic feeds* do not target full kilocalorie support, but rather a lower level of both kilocalories and protein to provide the GI tract the benefits of nutritional support (improved gut integrity, better contractility, increased brush border enzymes, restoration of the commensal bacteria[100]) without putting the patient at risk for aspiration, GI intolerance, or other complications of higher volume feeds. With trophic feeds, the rate is set low (10–20 mL/h, representing only 15%–25% of goal kilocalories) and kept low for days; it can be thought of as a very delayed ramp-up to goal.

Studies comparing these methodologies of continuous tube feeds have failed to demonstrate improved outcomes with increased amounts of enteral kilocalories via the aggressive approach compared to underfeeding with a trophic approach.[106-108] Trophic feeds, however, were not shown to be superior to a regimen of full target feeding. Additionally, these methods have not been studied in trauma patients, meaning patients with a hypermetabolic response getting trophic feeds may have ongoing erosion of lean muscle mass, resulting in impaired recovery and worse clinical outcomes.[100] As such, iatrogenic underfeeding with trophic feeds appears to be safe in the very short term, although timely advancement to goal remains the aim of early nutritional therapy in polytrauma patients.

Trophic feeds by definition mean that the patient is getting less than goal energy requirements and less than goal protein requirements (typically 15%–25% of goal). A fourth strategy is *permissive underfeeding*, when the patient gets goal rates of protein requirements but restriction of nonprotein kilocalories. Recent studies have shown promise with permissive underfeeding in comparison to full feeding in critically ill patients,[133] although earlier studies lack both internal and external validity.[100]

From a practical standpoint, there are key considerations to choosing a strategy. One is that hypertonic enteral formulas will not be well tolerated if started at full volume and full concentration. A gradual buildup is necessary (over days) for the GI tract to accept this unnatural source of energy without severe diarrhea (and thus risk of dehydration). Another is that the jejunal route may require more patience before full strength is tolerated, as the jejunum can be sensitive to tonicity, fat concentrations, and protein sources. Additionally, gastric feeds can be higher tonicity, with higher administration rates, and given as bolus feeds, thus giving the provider more options for nutritional support.

It is not natural for the GI tract to be exposed to food/nutrition continuously for 24 hours a day. For this reason, there is a school of thought that interrupting continuous tube feeds for 4 to 6 hours a day makes them better tolerated by patients and is healthier for the GI tract. In this manner, the full kilocalorie feeding regimen would be given continuously for only 18 to 20 hours per day. There are at present no data to support this practice.

Intermittent infusions (ie, bolus feeds) are delivered at intervals (every 4–6 hours), with a large volume given at each interval (often 200–500 mL). Bolus feeds are well tolerated with a prepyloric feeding tube, especially in the outpatient setting. Most inpatients are administered tube feeds continuously. Jejunostomy tube feeds are not well tolerated as intermittent feeds (due to abdominal pain, distention, and diarrhea) and therefore must be given continuously.

PROKINETIC AGENTS

Prokinetic drugs, such as erythromycin and metoclopramide, can be used to promote motility to achieve effective administration of EN.[34-36,134] These agents help in emptying the stomach and in tolerating EN but have not been shown to improve or change outcomes.[35]

GASTRIC RESIDUALS

The practice of regularly holding or interrupting prepyloric EN for elevated gastric residual volumes (GRV) in mechanically ventilated patients has long been used. The rationale is that if, during the initiation or maintenance of enteral feeding, a threshold GRV was reached (anywhere from 200–500 mL has been used), this was proof of gastroparesis, delayed gastric emptying, or GI dysfunction, and warranted stopping the EN. Recent randomized controlled trials have questioned this practice.[130,131] However, checking GRV is by no means a dead practice, especially in a surgical/trauma ICU with patients at high risk for GI dysfunction.[132] The latest ASPEN/SCCM guideline[35] strongly recommends against checking GRV as part of routine care to monitor EN. They instead recommend monitoring for tolerance ("by physical examination, passage of flatus and stool, radiologic evaluations, and absence of patient complaints such as pain or abdominal distention") versus intolerance ("defined by vomiting, abdominal distention, complaints of discomfort, diarrhea, reduced passage of flatus and stool, or abnormal abdominal radiographs").[35] However, in the surgical ICUs that do still use GRV, the guideline recommends a GRV of greater than 500 mL to hold EN.

MONITORING

Once tube feeds are initiated, patients need to be closely monitored. Monitoring for fluid balance and losses, metabolic and inflammatory status, positioning (of both patient and tube), and early detection of complications is required. Blood glucose should be checked at least every 6 hours. Electrolytes should be checked daily, especially with increased GI tract losses. Trace element and vitamin levels should be checked only as clinical concern warrants.

During acute illness, the short-term goals of feeding are to restore and maintain function while limiting further loss of lean tissue. During the weeks of convalescence, the aim is to restore lean mass as well as function Nitrogen balance may be indicative of loss or gain of body protein but is not a goal in itself. Nonetheless, in the absence of specific tests for adequacy of protein intake, some measure of nitrogen balance is useful in various clinical settings, since a prolonged state of negative nitrogen balance is not compatible with life.[10]

COMPLICATIONS

Although in general EN is extremely safe, there are potential complications. The complications fall into one of two categories: access complications (either during insertion or mechanical) or diet-related complications.

Insertion-Related Complications. Feeding tubes of various types can be placed at the bedside, by interventional radiology, by gastroenterologists, and surgically. Each of these methodologies has inherent complications. These include bleeding, infection, nasal damage, intracranial insertion, pulmonary insertion, and perforation. While real and significant, we will not highlight the multiple potential surgical complications of gaining feeding access (these operations include percutaneous endoscopic gastrostomy tubes, laparoscopic and open gastrostomy tubes, and placement of jejunostomy tubes).

Mechanical Complications. Various mechanical complications relating to the tube itself can occur. The lumen of tube can get obstructed. This is often the result of poor

maintenance or lack of tube hygiene. Obstruction can be prevented with free water flushing protocols and ensuring no crushed medications are administered through the tube. Tubes can also be accidentally dislodged or removed, and they can migrate. Over time, tubes can cause discomfort, erosions, fistulae, and strictures.

Diet-Related Complications. Diet-related complications (ie, formula related) are specifically associated with the enteral formula itself (including a host of metabolic issues) or to the unnatural process of being fed via a tube. These include aspiration, diarrhea, GI intolerance, electrolyte disturbances, micronutrient deficiencies, hyperglycemia, hypertriglyceridemia, refeeding syndrome, malabsorption, hypertonic dehydration, hyperosmolar nonketotic coma, liver dysfunction, renal dysfunction, overfeeding, infection, bacterial translocation, pneumatosis intestinalis and necrosis, fluid overload, and hypoprothrombinemia (from vitamin K deficiency), among others.

NUTRITIONAL INTERVENTION: PARENTERAL NUTRITION

In 1968, Wilmore and Dudrick[135] proved—first in beagles and later in a newborn girl with intestinal atresia[135]—that patients could grow and meet their nutritional needs by receiving exclusive intravenous nutrition. Their discovery of what is now known as PN (ie, total PN [TPN]; formerly referred to as hyperalimentation or hyperal) has greatly expanded the ability of physicians to treat malnutrition in patients who were otherwise not candidates for enteral feeds. In this section, we discuss when to use PN, who will benefit from PN, how to order and initiate the use of PN to meet the needs if the patient, and how to monitor patients on PN to ensure few complications with good nutritional support.

Patient Selection

All patients should ideally receive early nutritional support within 24 to 48 hours of injury. As discussed in detail previously in this chapter, PN should be prescribed if:

- Enteral feeds are contraindicated (usually due to nonfunctional GI tract from dysmotility, discontinuity, ischemia, fistula, or obstruction)
- Enteral feeds have failed (either because of nonfunctional GI tract or because EN is not adequately or consistently achieving nutritional goals)
- Enteral feeds are not expected to be started for 3 days in the postinjury, inflammatory stress response patient or patient at high nutritional risk

Contraindications to starting PN, even if one of the above requirements is met, are ongoing resuscitation, shock, and/or high-dose vasopressors. Nutritional therapy is vitally important, but it is never an emergency.

Meeting Nutritional Requirements by Parenteral Route

How to meet the macronutrient and micronutrient requirements of the polytrauma patient with PN is discussed in the following sections.

CENTRAL VENOUS ACCESS

Central venous access, with a dedicated line not to be used for anything else, is fundamental to PN administration. Compulsive attention to sterile technique for both placement and maintenance will prevent complications. Parenteral nutritional preparations have very high tonicity (often >1000 mmol/L, and usually close to 2000 mmol/L) and are better tolerated centrally.

PARENTERAL NUTRITION PRESCRIPTION

There are five steps to writing orders for PN. Figure 62-6 provides an example of PN calculations.

Step 1: Total Kilocalories and Fluid Volume Over 24 Hours. Total energy requirements for the critically ill polytrauma patient were outlined in the last section, specifically the 24-hour kilocalorie requirement and the distribution between the macronutrients. The one major difference between EN and PN in terms of nutritional support is that a strategy of "permissive underfeeding" should be pursued at first with PN; to do this, 80% of total daily nonprotein energy requirement should be given at first.[35]

Total fluid volume of PN preparations will vary depending on the patient's clinical condition, with patients in the immediate postresuscitation hypercatabolic phase needing more. In general, patients need a minimum of 30 to 50 mL fluid/kg of actual body weight to maintain hydration; as discussed earlier in the chapter, in adult men, this is 3.7 L, and in adult women, it is 2.7 L. Additionally, when initially starting PN delivery, volumes may be lower over the first few days (please see later Administration and Delivery section) (Fig. 62-6).

Step 2: Amino Acids and Protein. The next step is to calculate protein requirements and their contribution to total energy requirements. As noted earlier, 1.3 g/kg IBW/d is recommended in critically ill trauma patients,[32,33] and no more than 2.0 g protein/kg IBW/d.[32,33,113] Simply adding huge levels of protein will not prevent the hypercatabolic state in critically ill trauma patients.[117]

With PN, protein is delivered in the form of a balanced amino acid mixture of both essential and nonessential amino acids. The contributions of these amino acids, including BCAA, is variable. In septic patients, for example, TPN fortified with BCAA at high concentrations (0.5 g/kg/d or higher; up to 45% of total protein) has been shown to lower morbidity and mortality when compared to standard TPN.[136]

Supplementation of PN solutions with immune-enhancing amino acids is controversial and in flux. Although at one point it was considered standard of care, more recent data

Calculating Parenteral Nutrition Formulations

(Assuming normal renal, hepatic, and cardiac function)

STEP 1: TOTAL KILOCALORIES AND FLUID VOLUME OVER 24 HOURS

Determine dosing weight:

a. If BMI 18.5–25, using actual weight
b. If BMI 25.1–29.9, use Hamwi equation
    1. Male: 48 kg (for first 5 feet) + (2.72 kg × each inch over 5 feet)
    2. Female: 45.5 kg (for first 5 feet) + (2.27 kg × each inch over 5 feet)
c. If BMI <18.5, use Hamwi equation –10%
d. If BMI 30–39.9, use Hamwi equation +10%
    - *Example:* 60 kg patient with BMI of 23, dosing weight = 60 kg

Determine energy needs:

a. If BMI ≤39.9, use 30 kcal/kg dosing weight
b. If BMI 40–49.9, use 11–14 kcal/kg actual weight
c. If BMI ≥50, use 25 kcal/kg dosing weight
    - *Example:* 60 kg dosing weight × 30 kcal/kg = 1800 kcal/day

Determine PN volume:

a. 25–35 mL/kg dosing weight or 1 mL:1 kcal fed
b. Divide total mL/day by 24 hours to determine hourly rate
c. Divide total mL/day by 1000 mL to determine PN volume in L
    - *Example:* 1800 kcal/day = 1800 mL/day ÷ 24 h/day = 75 mL/h x 24 h/day = 1.8 L/day

STEP 2: AMINO ACIDS AND PROTEIN

Determine protein/nitrogen requirements:

a. If BMI ≤39.9, use 2 g/kg dosing weight
b. If BMI 40–49.9, use 2–2.5 g protein/kg dosing weight
c. If BMI ≥50, use 2.5 g/kg dosing weight
    - *Example:* BMI = 23 → 2 g/kg × dosing weight

Determine protein provisions:

a. Multiple protein dose/kg × dosing weight = grams of protein/day
b. Multiple grams of protein/day × 4 kcal/g = kcal from protein
    - *Example:* 2 g/kg × dosing weight (60 kg) = 120 g/day protein × 4 kcal/g = 480 kcal/day

STEP 3: AMOUNTS OF DEXTROSE AND LIPIDS

Determine lipid dosing:

a. Multiply total energy needs × 0.3 or ≤30% of total kcal = total kcal from lipids
b. Divide total kcal from lipids by 10 kcal/g = grams of lipids/day
c. Divide grams of lipids/day by dosing weight to determine final lipid dosing = g lipid/kg
    - *Example:* 1800 kcal/day x 0.3 = 540 kcal/day from lipids ÷ 10 kcal/g = 54 g/day ÷ dosing weight of 60 kg = 0.9 g/kg

Determine dextrose dosing:

a. Subtract kcal from proteins and kcal from lipids from daily energy requirement = kcal from dextrose/day
b. Divide kcal from dextrose/day by 3.4 kcal/g = grams of dextrose/day
c. Divide grams of dextrose/day by PN volume in L = grams of dextrose/L
d. Calculate percent dextrose concentration by dividing grams of dextrose/L by 10 to = % dextrose concentration
e. Determine final dextrose provisions by multiplying grams of dextrose/L × PN volume × 3.4 kcal/g
    - *Example:* 1800 kcal – 480 kcal – 540 kcal = 780 kcal/day from dextrose ÷ 3.4 kcal/g = ~230 g/day dextrose ÷ total volume of 1.8 L = 128 g/L dextrose × 10 = 12.8% dextrose; 128 g/L × 1.8 L = 230.4 g dextrose × 3.4 kcal/g = 783 kcal/day

STEP 4: ELECTROLYTES, VITAMINS, AND TRACE ELEMENTS

STEP 5: MEDICATION ADDITIVES

LASTLY: Write PN order

- *Example:* P2g/kg D12.8% L0.9 g/kg at 75 mL/h → based on dosing weight of 60 kg provides 1.8 L, 1803 kcal, 120 g protein

FIGURE 62-6 Clinical calculations for parenteral nutrition.

are questioning that practice (see earlier section on EN for detailed discussion). For example, TPN solutions enriched with glutamine have been shown to increase jejunal mucosal weight and nitrogen levels, decrease atrophy of intestinal villi, reduce hepatic steatosis, reduce pancreatic atrophy, and decrease gut bacterial translocation.[63] However, two large multicenter randomized controlled trials published in 2013 and 2014 found that ICU patients with multisystem organ failure receiving immunonutrition had significantly increased risk of death.[76,128]

Step 3: Amounts of Dextrose and Lipids. The next step is to outline the nonprotein kilocalorie distribution between the two major energy sources with PN: dextrose and fat (note that protein as amino acids also provides an energy source but at much lower amounts). Most kilocalories will come from carbohydrates, which are convenient and safe,[33] with only a small amount of fat emulsion to provide the essential fatty acids (Fig. 62-6).

The protein:fat:glucose kilocaloric ratio in surgical patients should approximate to 20%:30%:50%, respectively.[32,33] The common three-in-one or two-in-one formulations will therefore need to be modulated. The three-in-one PN regimen contains all three macronutrients: typically 10% to 15% energy as protein, 30% to 45% as fat, and 35% to 55% as carbohydrate. A two-in-one regimen contains no fat (fat is given separately) and has 15% to 25% energy as protein and 75% to 85% as carbohydrate.

Dextrose in PN should provide 50% to 70% of the daily energy requirements. A basal requirement is estimated to be roughly 2.0 g dextrose/kg IBW/d,[33] much of this for brain metabolism, which oxidizes glucose at a rate of 100 to 120 g/d. During the stress response, the hypermetabolic state creates oxidative limits of energy utilization; for this reason, dextrose should not exceed 5 g/kg IBW/d.[87] If exceeded, this can lead to overfeeding and fatty liver. One method to monitor overfeeding is to check a respiratory quotient (RQ) by indirect calorimetry. The RQ is the ratio of carbon dioxide (CO_2) production to oxygen consumption. Excessive CO_2 production is evidence of overfeeding with carbohydrate and will drive the RQ to be greater than 1. With an elevated RQ, increased kilocalorie contributions from fat should be considered (as can happen in patients with pulmonary failure as well) as fat metabolism generates less CO_2.

Fat emulsions in PN should provide 30% to 50% of the daily energy requirement; total dose of PN fat should be in the range of 1.0 to 2.0 g/kg IBW/24 h.[33] Fat emulsions are usually in the form of long-chain triglycerides (LCT), although in the polytrauma patient, it is best to use a mixture of both LCT and MCT.[33] As discussed previously, during the stress response, MCTs are preferred because they do not exert negative effects on neutrophil and macrophage function or hinder the reticuloendothelial system.

During the systemic inflammatory stress response, the addition of intravenous fish oil to the lipid emulsion, which provides omega-3 fatty acids (both eicosapentaenoic acid and docosahexaenoic acid), has been shown to mitigate multiple aspects of the inflammatory response.[33] Much has been written about the metabolic benefits of omega-3 polyunsaturated fatty acids in fish oils[137,138]; they have been shown to decrease ICU length of stay and have been recommended in Europe since 2005.[33] Although they have long been recommended for and available in EN,[32,34,35] only in July of 2016 did they become FDA approved for PN in the United States. Known here as "Smoflipid," it is an alternative injectable lipid emulsion composed of four different oil sources that spell "smof": soy oil 30%; MCT 30%; olive oil 25%; and fish oil 15%.

If central access is not possible, PN preparations with very limited kilocaloric intake, primarily derived from fat, can be given into the peripheral vasculature. This is known as peripheral PN.

Step 4: Electrolytes, Vitamins, and Trace Elements. The major issue in specifying amounts for electrolytes, vitamins, and trace elements is their contribution to osmolar load. While daily requirements should be met,[33] amounts should not exceed that level unless indicated for other reasons.

Supplementation of PN solutions with immune-enhancing and antioxidant micronutrients is also controversial and in flux. During the hypermetabolic stress response, there is an increased need for vitamins and trace elements, but just how much of an increase is not well defined.

Step 5: Medication Additives. Certain medications can be added to parenteral nutritional formulations to simplify what is often a long list of intravenous and enteral medications in the critically ill patient. Examples include proton pump inhibitors and insulin.

Administration and Delivery

PN cannot be started at full goal intake from day 1; rather, the rate of administration must be gradually increased over a few days to ensure tolerance. The factor limiting immediate goal delivery is glucose and the risks of hyperglycemia.

Monitoring and Complications

Following a patient on PN involves monitoring the metabolic response to the infused nutrients and anticipating or preventing such complications. The major complication is hyperglycemia, and therefore glucose control and monitoring blood sugar levels are of paramount importance.[33,35] A high-risk period is while the volume and glucose load are being increased, before steady levels of administration have been reached. Glucose management can be compounded in diabetics, septic patients, or those on steroids. Hyperglycemia can lead to a hyperosmolar coma, which should

be avoided at all costs. Insulin administration may be necessary.

By its very nature, the aim of PN is to induce an anabolic state (occurs eventually in the hypermetabolic, hypercatabolic polytrauma patient). As such, serum electrolytes will need regular daily monitoring. Patients are at high risk for hypokalemia, as well as alterations in phosphate, calcium, and magnesium. Micronutrient and essential fatty acid deficiencies can also develop. Tonicity and acid-base balance need monitoring as well; TPN solutions have a pH of 4 to 5 and can be balanced by the addition of more base, such as sodium or potassium acetate. Bloodstream infection and complications from venous access (eg, venous thromboembolism) are always a threat. Lastly, although not major issues in the short term, over the long term, liver dysfunction and hypertriglyceridemia are major concerns.

In time, the goal is to transition the patient off of the PN and onto EN. While patients are on PN, EN can be gradually introduced. Once greater than 60% of total daily kilocalorie requirements are being delivered enterally, PN can be stopped.[35]

SPECIAL PATIENT POPULATIONS

Obese Patients

The energy requirement for critically ill and injured obese patients (BMI >30) is lower than that for a nonobese patient and should not exceed 70% of total daily 24-hour energy requirements. The rationale behind this is to achieve some degree of weight loss in this patient population, which may in turn increase insulin sensitivity and reduce the risk of comorbidities.[35] This translates into target kilocalorie requirements of 22 to 25 kcal/kg IBW/d.[35,36,114] Protein requirements for BMI of 30 to 40 are in the range of 2.0 to 2.5 g protein/kg IBW/d; if BMI is greater than 40, then greater than 2.5 g protein/kg IBW/d is required.[35]

Patients with Baseline Malnutrition or High Nutritional Risk

Malnutrition is common: it is estimated that up to 40% of hospitalized patients fit the diagnosis.[8,9] It occurs for two major reasons: because of a patient's primary underlying baseline condition (before they were admitted to hospital, such as alcoholism or malignancy) or because they do not receive adequate nutritional intake for prolonged periods of time (typically while patients are hospitalized, such as after injury or postoperatively). Malnutrition is associated with worse outcomes, including infection (eg, pneumonia, abscess, sepsis), respiratory failure, poor wound healing and pressure ulcers, increased length of hospital stay, and death. These patients are at huge risk for complications if they become critically ill and often need slightly increased energy requirements, especially in the initial and acute phase of their injury.

A baseline nutritional risk assessment must be made and subsequently used to guide nutritional therapy. Randomized controlled trials have shown that nutritional intervention in patients identified to be undernourished or at high nutritional risk improves outcomes.[139,140] Determining the nutritional status of trauma and critically ill patients can be challenging, but knowledge of baseline malnutrition and malnourishment is exceptionally valuable[141,142]: those patients at moderate to severe nutritional risk are most likely to benefit from early nutrition and most likely to be harmed by iatrogenic underfeeding.[35]

Validated scoring systems for nutritional risk include the NUTRIC score (Nutrition Risk Score in ICU[143,144]) as well as the NRS 2002 (Nutritional Risk Screening 2002 tool).[141] The ASPEN/SCCM guideline[35] identifies patients as high nutritional risk if the NUTRIC score is 5 or greater or the NRS 2002 score is 5 or greater. The guideline's section on nutritional assessment is worth reading, as is the consensus statement[145] from the Academy of Nutrition and Dietetics and ASPEN on identifying malnutrition (Fig. 62-7).

Alcoholism

Alcohol use is a major cause of malnutrition; 20% to 60% of patients with alcohol dependence will be malnourished. This has major implications for the polytrauma patient population. These patients often need significantly increased energy requirements, especially once stabilized: kilocalorie goals are 35 to 40 kcal/kg IBW/d with protein intake of 1.2 to 1.5 g/kg IBW/d.

Spinal Cord Injury Patients (See Chapter 26)

Please see Chapter 26 for full specifics on meeting the nutritional needs of the patient with spinal cord injury. In quadriplegic patients, daily energy requirements are met with 20 to 22 kcal/kg IBW/d; in paraplegic patients, it is a bit higher at 23 to 24 kcal/kg IBW/d.[36,146]

Renal Patients (See Chapter 61)

In patients with acute kidney injury, there are multiple adjustments that should be considered to daily nutrition, especially PN. These include decreasing the grams of protein if blood urea nitrogen is greater than 100 mg/dL; decreasing magnesium, potassium, and phosphorus; increasing acetate; decreasing overall kilocalories if on peritoneal dialysis; decreasing fat kilocalories if triglycerides levels are high; and maximally concentrating all solutions.

Intubated Patients (See Chapter 59)

In intubated patients, avoid overfeeding to prevent excessive CO_2 production (which will make weaning off of the ventilator difficult) and try to maximally concentrate all solutions.

Nonsevere Malnutrition/Malnutrition of a Moderate degree in Adults			
	Acute Illness/Injury	**Chronic Illness**	**Social/Environmental**

In patients with overfeeding, indirect calorimetry will demonstrate an RQ of greater than 1.

Low-Flow States and Hypoperfusion (See Chapters 15 and 58)

Historically, EN has been avoided in patients in low-flow states because of the risk of worsening intestinal mucosal ischemia during periods of hypoperfusion. This practice is evolving, as there is evidence to support the safe and beneficial use of trophic feeds even when a patient is in nonrefractory shock on low to moderate dose vasopressors.[107,147]

Hepatic Patients (See Chapter 60)

In patients with liver dysfunction, there are multiple adjustments that should be considered to daily nutrition, especially PN. These include decreasing protein levels in patients with encephalopathy; using BCAA if encephalopathy is unresponsive to medical treatment or is worsening; using both carbohydrate and fat to meet energy requirements; providing 150 g of carbohydrate per day; and maximally concentrating all solutions.

Preoperative Patients and Holding Tube Feeds

For critically ill patients receiving EN, stopping tube feeds at midnight prior to operative interventions and diagnostic tests is unfortunately a routine practice. It is thought to decrease the risk of aspiration when the patient is in the supine position during the operation, and therefore at risk for aspiration. This is of particular concern in the polytrauma patient, as they are frequently in the operating theatre for a multitude of reasons at the start of their hospitalization, and thus tube feeds are frequently interrupted.

Perioperative management of EN should be evidence-based, and established guidelines for preoperative fasting guidelines should be followed.[148-154] For patients who are not intubated, solid foods should be stopped 6 hours prior to an operation, and clear fluid/EN should be stopped 2 hours prior to an operation; nil per os (NPO) beginning at midnight prior to an operation is no longer recommended or justified.

For patients who are intubated with a protected airway, tube feeds (whether gastric or small bowel EN) can safely be stopped just prior to transport to the operating room, ensuring that the tube is placed to suction and/or aspirated immediately before transport. Established exceptions to this practice are operations with planned airway manipulation (such as tracheostomy), operations requiring prone positioning, and operations on the upper intestinal tract.

Regularly stopping tube feeds at midnight leads to patients receiving at most 50% of goal energy requirements from one day to the next.[148] One study in burn patients found that those randomized to have tube feeds continued during their operative debridement (as compared to those who had EN stopped at midnight) had statistically fewer wound infections and reduced caloric deficits.[149] The ESPEN guideline for enteral nutrition in surgical patients does not endorse stopping liquid diet or tube feeds until 2 hours prior to operation.[91]

ELECTROLYTE MANAGEMENT

Most feeds contain adequate electrolytes to meet the daily requirements of sodium, potassium, calcium, magnesium, and phosphate, although specific requirements can vary enormously. Malnourished or metabolically stressed individuals often develop electrolyte derangements.

Sodium and Disorders of Water Balance

Sodium and chloride are necessary to maintain extracellular fluid volume and plasma osmolality.[41,53] The most common electrolyte problems noted in trauma patients are derangements in sodium. While diabetes insipidus or inappropriate antidiuretic hormone (ADH) may occur with head injuries, producing hypernatremia and hyponatremia, respectively, the most common cause for abnormalities in sodium levels is an excess in sodium administration, fluid restriction in patients with traumatic brain injuries, or administration of large volumes of fluid containing low sodium. In the first case, prolonged use of normal saline or lactated Ringer's as a maintenance fluid in association with other hidden sources of sodium administered through multiple antibiotics, H_2-blockers, and so on, in saline produces a gradual and progressive hypernatremia. Many antibiotics contain large amounts of sodium, and since specific admixtures for medications are rarely ordered, intravenous "piggybacks" can reach 2 to 2.5 L/d in some patients. If this is administered in normal saline, hypernatremia develops. Likewise, if medications are mixed in 5% dextrose and water, significant hyponatremia develops.

Assessment of volume status in concert with the low serum sodium concentration will usually identify the patient as hypovolemic, isovolemic, or hypervolemic. Hypovolemic patients usually respond to normal saline or lactated Ringer's infusions. If losses of fluid are chronic and similar to serum (eg, ileostomy losses), additional sodium may be needed in the nutrient solutions. Isovolemic, hyponatremic patients often need little treatment beyond increasing the sodium content in intravenous fluids. In severe cases where urine sodium is elevated at 100 to 200 mEq/L, restriction of free water is necessary by decreasing fluid administration and concentrating the nutrient solution. This problem is most commonly seen with severe head injury or pneumonia and resolves as the patient recovers. Hypervolemic, hyponatremic patients should have nutrient formulas concentrated as much as possible. Other therapy such as diuretics may occasionally be needed.

A less common cause of hyponatremia after trauma is inappropriate ADH secretion. It is usually associated with central nervous system effects induced by head injury, meningitis, subarachnoid hemorrhage, anesthetics, meperidine, carbamazepine, or tricyclic drugs. In addition, a decrease in the vascular volume, secondary to use of diuretics in patients who are on high levels of positive end-expiratory pressure or have large fluid losses from the GI tract, open abdominal wounds, and so on, can also lead to increased ADH secretion and increased sodium loss. Typically, serum chloride concentrations decrease with the hyponatremia, and a hypokalemic metabolic alkalosis with a high serum bicarbonate occurs, especially when diuretic induced. The diagnosis of inappropriate ADH is made by a combination of hyponatremia, a decrease in serum osmolality, a urine osmolality that is elevated relative to serum osmolality, a urine sodium greater than 20 mmol/L, and, if measured, an increase in ADH. Because of the effect of ADH on the kidney, water is absorbed without sodium so that urine sodium and tonicity are high relative to serum. The appropriate therapy is water restriction.

Hypernatremia is also relatively common in the critically ill trauma patient, especially in patients with severe head injury, where a mild hyperosmolar state is often used to decrease intracranial pressure. After bedside assessment, most of these patients can be categorized as hypovolemic, isovolemic, or hypervolemic. Patients with hypovolemic hypernatremia are usually treated with lactated Ringer's solution first to ensure adequate organ perfusion, and then with solutions containing substantial free water (eg, dextrose 5% in water, 0.22% or 0.45% sodium chloride injection). During free water administration, it is appropriate for the sodium to be reduced in the nutrient solution. Patients with isovolemic hypernatremia usually need free water, and sodium should be removed from the PN. Patients with hypervolemic hypernatremia should have intake minimized by concentrating the nutrient formula. Exogenous sodium should be eliminated from PN, medications, and other infusions to the extent possible.

Potassium

Potassium is the main intracellular cation in the body and is required for normal cellular function.[41,53] Hypokalemia is very common after trauma, especially in patients with normal renal function who require aggressive resuscitation with crystalloid. Loss of GI fluids rich in hydrogen and chloride aggravates this hypokalemia. Patients with prolonged nasogastric suction will lose considerable HCl, resulting in metabolic alkalosis and substantial renal wasting of potassium. Drug therapy with loop diuretics, amphotericin B, antipseudomonal penicillins, and corticosteroids has been reported to aggravate renal wasting of potassium. Other drugs, such as inhaled β-agonists (eg, albuterol) and insulin, drive potassium into the cell, also resulting in hypokalemia in some patients. All these conditions will require additional potassium added to the nutrient solution above the standard of 30 to 40 mEq/L that is commonly used in PN or present in enteral formulas. Occasionally, up to 120 mEq of potassium/L must be added to nutrient solutions of patients who were receiving three or four of the previously mentioned drugs to keep them in potassium balance.

Body potassium needs are not proportionate to serum levels. Each 0.25-mEq drop in serum potassium levels between 3.0 and 4.0 mEq/L represents a 25- to 50-mEq deficit in total body potassium. Between 2.5 and 3.0 mEq/L, each 0.25-mEq drop represents an additional 100- to 200-mEq deficit, which must be replaced to avoid precipitous drops with refeeding.

Hyperkalemia is less common than hypokalemia after trauma and is usually associated with compromise in renal function. In general, hyperkalemia from acute renal failure warrants potassium removal from the nutrient solution. Once levels have decreased to 4.0 mEq/L, potassium should be added back in modest doses (eg, 10 mEq/L). Other causes of hyperkalemia are hemolysis of the blood sample and drugs known to cause this disorder, even when renal function is normal. Most laboratories will identify hemolyzed samples that do not require treatment other than repeat analysis. Heparin and trimethoprim have been reported to cause hyperkalemia in patients. Heparin is an aldosterone antagonist that causes sodium wasting and potassium retention. This drug–nutrient interaction occurs with both systemic and low-dose heparin, especially in patients with diabetes and chronic renal dysfunction. Trimethoprim is a component of the combination product of trimethoprim/sulfamethoxazole used frequently for gram-negative systemic infections. It is a weak diuretic with potassium-sparing activities. Patients who experience these interactions should have potassium decreased in the nutrient solution, even when renal function is normal.

Phosphorus

Phosphorus helps maintain a normal pH in the body and is involved in multiple metabolic and homeostatic processes.[41,53] Hypophosphatemia is a common metabolic complication of critically ill patients receiving nutritional support. While most practitioners add phosphorus to PN solutions routinely, several patient populations require greater amounts, including patients with a history of alcohol abuse, poor nutritional status before injury, or chronic use of antacids or sucralfate. Even when serum phosphorus concentrations are monitored closely, hypophosphatemia occurs in approximately 30% of patients receiving PN. Treatment of hypophosphatemia is dictated by the severity, and intravenous replacement doses are most frequently used. The enteral route should be considered in mild cases of hypophosphatemia by adding 5 to 10 mL of Fleet's phosphosoda to each liter of the enteral formula in patients requiring additional phosphate. In patients requiring both potassium and phosphate, potassium phosphate (usually 15–22.5 mmol/L) can be added to the formula. For isolated potassium depression, potassium chloride can be added to the enteral formula.

Hyperphosphatemia is much less prevalent than hypophosphatemia in trauma patients and is usually associated with renal compromise when it does occur. Phosphorus should be decreased or removed from the nutrient solution.

Magnesium

Magnesium is involved in more than 300 enzymatic processes in the body, as well as bone health and the maintenance of intracellular levels of potassium and calcium.[41,53] The development of hypomagnesemia is underappreciated. Magnesium is rapidly depleted in stress, particularly when diuretics and antibiotics such as aminoglycosides are administered. Dysrhythmias, hypocalcemia (an unusual problem in trauma patients), and irritability are avoided with magnesium monitoring and appropriate treatment. Patients with a history of alcohol abuse or lower GI losses, such as diarrhea, are particularly prone to develop hypomagnesemia. Amphotericin B, aminoglycosides, and loop diuretics (and in addition cisplatin and cyclosporine) have all been reported to cause renal wasting of magnesium. Intravenous magnesium replacement therapy is usually necessary in patients with moderate to severe magnesium deficiency due to poor absorption of oral magnesium salts. Magnesium has a renal tubular threshold similar to glucose, so rapid administration over a short period of time will invariably result in high urinary losses.

Magnesium status should also be considered in evaluating a hypokalemic patient, as magnesium is an important cofactor for the Na/K-ATPase pump. It may be necessary to administer magnesium replacement therapy for low-normal serum magnesium concentrations in the presence of hypokalemia, because magnesium is an intracellular cation and serum concentrations may not accurately reflect intracellular status.

Hypermagnesemia usually occurs in association with renal dysfunction or failure. Magnesium should be removed from the PN of these patients.

Postinjury Inflammation and Organ Dysfunction

Benjamin Moran • Samuel A. Tisherman

KEY POINTS

- Multiple organ failure (MOF) is defined as dysfunction of greater than one organ system.
- Although multiple scoring systems of MOF exist (Marshall, Sequential Organ Failure Assessment, Denver), there is no gold standard.
- MOF accounts for approximately 50% of delayed deaths in trauma.
- The pulmonary, cardiac, and renal systems are affected first, usually within 3 days, followed later by derangements in hepatic function (>3 days).
- Fifty percent of MOF mortality occurs within 3 days, with 80% of mortality occurring within 7 days.
- Traumatic injury and resuscitation from hemorrhagic shock result in proinflammatory and anti-inflammatory responses, which affect multiple organ systems and can contribute to sequential organ dysfunction.
- Prevention of MOF is directed at early resuscitation, avoidance of hypotension, protective lung ventilation, renal protection, and prevention of secondary infection.

HISTORICAL PERSPECTIVE ON MULTIPLE ORGAN FAILURE

With advances in emergency medical services, pharmacology, technology, surgical techniques, and other treatment modalities, the ability of the physician to keep a severely injured patient alive is ever increasing. As more patients have survived initial resuscitation, more patients potentially develop postinjury multiple organ failure (MOF), which has emerged as the leading cause of late trauma deaths.[1-3]

Many advances in trauma care, treatment modalities, and shock were initially stimulated by military need and experience only to be later refined in civilian trauma centers. In World War I, late battlefield casualties were attributed to the release of toxins from dead or dying tissue. Physicians during this time period, particularly Walter B. Cannon, first proposed the concept that hypovolemia is the inciting event that results in organ failure.[4] This concept of hypovolemic shock was not expanded until many years later. In the 1930s, Alfred Blalock demonstrated that reduced circulating blood volume was the main cause of shock and mortality.[5] This knowledge drove treatment modalities toward the restoration and normalization of blood pressure through volume expansion. Patients were resuscitated with freeze-dried plasma and later with stored whole blood. With early restoration of blood pressure, the rate of cardiac arrest observed in World War I decreased, but survivors more frequently developed renal failure. This practice of plasma and blood resuscitation continued into the Korean War, where additional advances in rapid battlefield transport helped improve overall battlefield survival. Patients who once died from hemorrhagic shock now survived initially, although many patients succumbed to late deaths from oliguric renal failure.

These late deaths led G. Tom Shires and others in the 1960s to propose that not only did hypotension lead to shock, but also extracellular or third space fluid deficits compounded the magnitude of traumatic shock. He demonstrated improved survival in animals with the addition of balanced salt solutions to shed blood during resuscitation.[6] From this point until recently, crystalloids were used liberally in addition to blood and plasma resuscitation with the end points of resuscitation focused on maintaining adequate urine output. During this time period, advancements in helicopter evacuation in the Vietnam War enabled rapid transport of the severely injured patient, further decreasing battlefield mortality but resulting in the emergence of more organ failure. Prevention of oliguric renal failure with greater fluid administration, particularly crystalloids, however, presented a new challenge of late deaths from "shock lung." The concept of the acute respiratory distress syndrome (ARDS) was thus born.[7]

During the 1970s, improvements in organ support, specifically mechanical ventilation, vasoactive drugs, parenteral nutrition, and hemodialysis, gave physicians the tools to further sustain the critically ill. Death from isolated single-organ failure became rare, and a new syndrome of "multiple, progressive, or sequential systems failure" emerged.[8] By 1977, the term *multiple organ failure* was coined by Ben Eiseman, who provided the first clinical description of patients with progressive organ dysfunction.[9] Initially the cause of MOF was thought to be the "fatal expression of uncontrolled infection."[10] Concurrent studies at the time pointed toward organ failure as a bimodal phenomenon, with a rapid single-phase MOF from massive tissue injury and shock, or a delayed, two-phase MOF due to moderate trauma and shock followed later by secondary infection and sepsis.[11,12] Clinicians believed that sepsis remained the main culprit of organ failure. By the mid-1980s, however, more evidence demonstrated that organ failure could occur in the absence of infection, and the concept of "generalized autodestructive inflammation" emerged.[13,14]

Noninfectious inflammatory models of MOF, such as trauma or severe pancreatitis, were the focus of investigation in the 1990s. The hypothesis was that patients were resuscitated into an early state of systemic hyperinflammation, the systemic inflammatory response syndrome (SIRS). SIRS is defined clinically by the American College of Chest Physicians/Society of Critical Care Medicine consensus conference as two or more of the following: (1) temperature less than 36.8°C or greater than 38.8°C, (2) heart rate more than 90 bpm, (3) respiratory rate more than 20 breaths/min or P_{CO_2} less than 32 mm Hg, and (4) white blood cell count less than 4000/μL or greater than 12,000/μL or with greater than 10% immature forms.[15]

Like the bimodal distribution of MOF noted earlier, the inflammatory cascade could cause two potential responses to the inciting traumatic event. In a one-event model, a massive traumatic insult overwhelms the ability of a patient to respond to the resuscitative efforts and precipitates early organ failure. In a two-event model, patients may have a moderate response to the initial resuscitation, but this leaves the patient "primed" for a second insult, or "second hit," that dysregulates the immune system, leading to a hyperinflammatory response and sequential organ failure. Examples of second hits include infection, sepsis, abdominal compartment syndrome (ACS), fat embolus, mechanical ventilation, blood transfusions, and subsequent surgical procedures, such as long bone fixation.[16,17] ACS became almost epidemic because of massive fluid resuscitation based on the work of Shires et al[6] and the attempt to achieve supranormal oxygen delivery promulgated by William Shoemaker's group.[18] The administration of massive amounts of crystalloids to achieve supranormal oxygen delivery clearly contributed to the development of ACS.[19,20] Focusing on early, rapid administration of blood products while limiting the amount of crystalloids has led to a decreased incidence of ACS.[20]

By the late 2000s, evidence for the development of two opposite responses to trauma had emerged: a proinflammatory response (SIRS) and its converse, the compensatory anti-inflammatory response syndrome (CARS).[21] Because these responses appear to begin simultaneously, CARS may be a misnomer because it does not seem to be truly compensatory. The *systemic anti-inflammatory response syndrome* may be a better term. The development of MOF is related to the intensity and the balance between pro- and anti-inflammatory states. In severe SIRS, unbalanced early proinflammation from the innate immune system causes early MOF and can result in a fulminant, proinflammatory death. Conversely, early anti-inflammation inhibits the adaptive immune system and creates a preconditioned state in which the patient may be protected against second, inflammatory hits. When the body attempts to counter unbalanced proinflammation, the persistent, severe anti-inflammatory response sets the stage for immune paralysis, impaired wound healing, recurrent infections, and eventual late MOF.[22,23] Current laboratory and translational research provides insights into each specific component and biomarkers of the inflammatory and anti-inflammatory cascades. Thus, each stress, trauma, or septic insult affects cellular functioning and pathways in what has been called the genomic storm.[24] At the cellular expression level, each new gene expression that is decoded adds another potential target for blocking or stimulating agents that may help prevent MOF.

With our current advances in resuscitation and organ system support, we are now observing patients who have survived even these late effects of SIRS and CARS, only to linger for weeks to months in the intensive care unit (ICU) with what has recently been termed the persistent inflammation-immunosuppression catabolism syndrome (PICS).[23] In the next few sections, we will describe more details about MOF, SIRS/CARS, and PICS, including potential mitigating or therapeutic approaches (Fig. 63-1).

DEFINING MULTIPLE ORGAN FAILURE

Simply put, MOF is defined as the sequential dysfunction of multiple organ systems. There is no gold standard scoring system used to identify and measure MOF, particularly the progressive and successive nature of organ dysfunction. Although imperfect, there are a number of scoring systems that measure the total amount and degree of each organ system affected. These scores help establish a baseline degree of organ dysfunction and allow physicians to trend organ dysfunction over time. They also allow stratification of subjects for research purposes.

The most common of these scoring systems are as follows: (1) the Marshall Multiple Organ Dysfunction Score (MODS),[25] first developed in a Canadian ICU; (2) the Sequential Organ Failure Assessment (SOFA),[26] developed by the European Society of Intensive Care Medicine in 1994 and then further revised in 1996; and (3) the Denver Score,[27] developed from a long-term, prospective database from the Denver Health Medical Center. Other intensive care scoring systems exist; however, these often focus on predicting patient

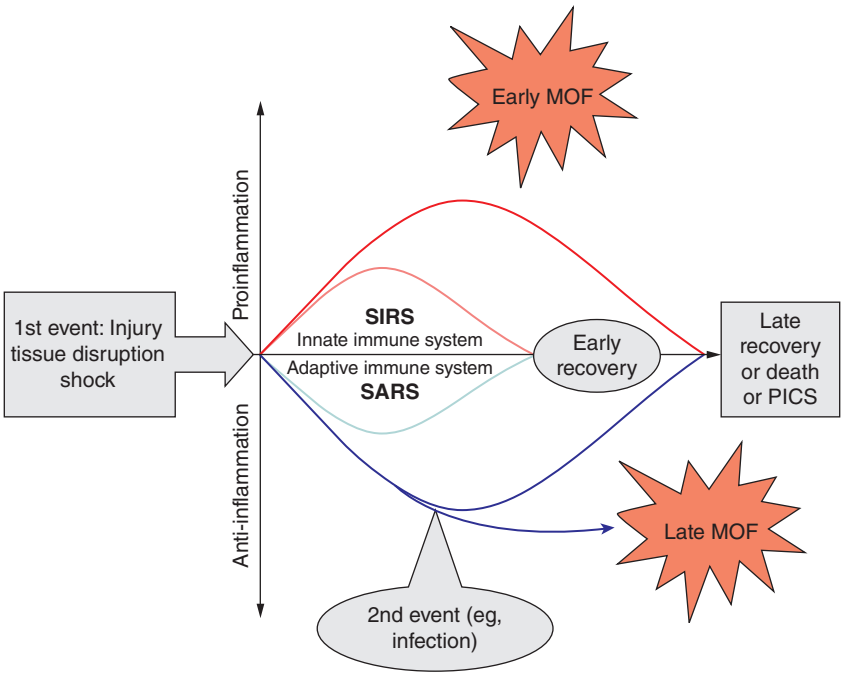

FIGURE 63-1 Theoretical framework for postinjury multiple organ failure (MOF): the synchronous immunoinflammatory model. PICS, persistent inflammation-immunosuppression catabolism syndrome; SARS, systemic anti-inflammatory response syndrome; SIRS, systemic inflammatory response syndrome.

outcomes, length of stay, and overall in-hospital mortality, as opposed to quantifying specific organ failures.

Both the MODS and SOFA scoring systems evaluate the degree of organ dysfunction based on six organ systems. The data of the cardiovascular, pulmonary, hepatic, hematologic, renal, and central nervous system are scored on a scale from 1 to 4. The original Denver Score, based on eight organ systems, was refined to include just four systems, graded 0 to 3, and is assessed every day (Table 63-1).

Multiple analyses of the SOFA score have helped to define and predict outcomes in patients with sequential organ derangement. With MOF defined as dysfunction of two or more organ systems, the lowest rate of mortality is observed in patients with respiratory failure alone. If the respiratory system remains intact but the other organ systems have failed, nearly all potential combinations lead to a mortality between 65% and 74%.[28]

The European Sepsis Occurrence in Acutely Ill Patients (SOAP) multicenter trial examined data from roughly 3100 adult, mixed medical and surgical ICU admissions to evaluate the incidence of MOF. The investigators noted that patients who had severe sepsis and organ failure had the highest mortality. In this group of patients, the highest to lowest mortality groups by system failure were coagulation system (53%), hepatic (45%), central nervous system (44%), cardiovascular (42%), renal system (41%), and respiratory system (35%).[29]

When using SOFA to score patients, the highest, mean, and change in score are useful predicators of outcomes. Higher mean and maximal SOFA scores during the first 48 hours of patient presentation predicted an increased risk for mortality.[30] If the SOFA score increased at 48 hours from presentation, mortality was at least 50%. Conversely, if the score decreased at 48 hours, mortality declined below 27%. If the score did not change over 48 hours, patient mortality remained at 27% to 35%.[31] Cumulative and trending SOFA scores are better at discriminating patient outcome compared to a single organ dysfunction score at one time point.[32]

INCIDENCE

The incidence, presentation, and time course of MOF have changed greatly as new treatment modalities and resuscitation techniques have evolved. Donald Trunkey described a trimodal pattern of death from trauma in 1982.[33] The first peak, which was the tallest, occurred in the first hour following injury and was predominantly caused by severe traumatic brain injury (TBI) and mostly irreparable major cardiovascular injuries. The second peak, over the subsequent 1 to 4 hours, was from ongoing hemorrhage or TBI. The third peak, occurring 1 week or more after injury, was thought to be caused by MOF. Although this peak has significantly decreased over the years, it has not disappeared.[34,35] Despite improvements in resuscitation and critical care, some patients will develop a deranged physiology of inflammation and anti-inflammation, leading to sequential dysfunction of multiple organ systems and late death.

MOF likely accounts for more than 50% of delayed deaths following trauma, although the true incidence and development of posttraumatic MOF are unknown.[36,37]

TABLE 63-1: Denver Postinjury Multiple Organ Failure Score, Sequential Organ Failure Assessment (SOFA) Score, and Marshall Multiple Organ Dysfunction Score

		Score allocation				
Organ system	**Variable (units)**	**0**	**1**	**2**	**3**	**4**
Denver						
Respiratory	PaO_2/FiO_2	>250	250–175	175–100	<100	
Renal	Creatinine, μmol/L	<159	160–210	211–420	>420	
Hepatic	Bilirubin, μmol/L	<34	34–68	69–137	>137	
Cardiac	Inotropes	None	1 inotrope small dose	1 inotrope moderate dose or >1 inotrope small dose	1 inotrope large dose or >2 inotropes moderate dose	
SOFA						
Respiratory	PaO_2/FiO_2		<400	<300	<200 and respiratory support	<100 and respiratory support
Renal	Creatinine, μmol/L		110–170	171–299	300–440	>440
Hepatic	Bilirubin, μmol/L		20–32	33–101	102–204	>204
Cardiac	Inotropes μg/kg per min		Mean arterial pressure <70 mm Hg	Dopamine ≤5 or dobutamine any dose	Dopamine >5 or epinephrine ≤0.1 or norepinephrine ≤0.1	Dopamine >15 or epinephrine >0.1 or norepinephrine >0.1
Coagulation	Platelets, $\times 10^3/mm^3$		<150	<100	<50	<20
CNS	GCS		13–14	10–12	6–9	<6
Marshall						
Respiratory	PaO_2/FiO_2	>300	226–300	151–225	76–150	≤75
Renal	Creatinine, μmol/L	≤100	101–200	201–350	351–500	>500
Hepatic	Bilirubin, μmol/L	≤20	21–60	61–120	121–240	>240
Cardiac	PAR = (HR/MAP) × CVP	≤10.0	10.1–15.0	15.1–20.0	20.1–30.0	>30.0
Coagulation	Platelets, $\times 10^3/mm^3$	>120	81–120	51–80	21–50	≤20
CNS	GCS	15	13–14	10–12	7–9	≤6

CVP, central venous pressure; GCS, Glasgow Coma Score; HR, heart rate; MAP, mean arterial pressure; PAR, pressure-adjusted heart rate; SOFA, sequential organ failure assessment.

This difficulty is due to varying definitions, differences in treatment strategies, and a lack of consensus on a gold standard scoring system. A few studies have attempted to investigate and determine the true incidence of MOF in posttraumatic populations. In a review of 1 million hospital discharges from verified trauma centers, the incidence of posttraumatic MOF varied from 6% to 25%.[36,37] Patients who developed MOF had increased morbidity and were nearly four times as likely to require ongoing assistance with activities of daily living at discharge.[36]

Not all patients who sustain a traumatic injury will develop MOF. There exists a multimodal distribution, with the highest peak of MOF occurring within the first 3 days after injury and a small peak that follows afterward. The organ systems affected most commonly within 3 days are pulmonary, cardiac, and renal systems. Hepatic failure usually occurs after 3 days. Early MOF is associated with worse outcomes. Fifty percent of patient deaths from MOF occur within the first 3 days, and 80% of deaths occur within the first week. Patients who survive MOF have longer clinical courses (mean ICU stays of 18 vs 8 days) and have increased ventilator days (14 vs 5 days) compared to their non-MOF counterparts.[38]

Although mortality would seem to be a straightforward end point, there are important confounders that need to be considered. First, following initial resuscitation and stabilization, patients rarely die while aggressive organ system support is provided. More often than not, late deaths in the ICU occur after the medical team and the family agree to withdraw life-sustaining therapies. Involvement of a palliative care service can facilitate this process when appropriate.[39] Prognostication in the ICU is extremely difficult. It should also be clear that involvement of palliative care services does not change the percentage of patients who die but has been shown to decrease the time to death and ICU length of stay.[40] Second, with the push to transfer patients out of the tertiary or quaternary hospitals to long-term acute care hospitals or rehabilitation centers, patients may still die of their injuries, unbeknownst to the original care team.[41]

PATHOPHYSIOLOGY

Initial Response

Trauma frequently leads to a SIRS response from the combination of tissue injury and ischemia/reperfusion (Fig. 63-2). This response is similar to the generalized inflammatory response observed following infection or nontraumatic, noninfectious conditions such as necrotizing pancreatitis. The SIRS response following trauma is complex but seems to be initiated by a release of endogenous damage-associated molecular patterns (DAMPs).[42] This is similar to the response seen following sepsis, in which microbial products induce a release of pathogen-associated molecular patterns (PAMPs).

Numerous molecules have been identified that activate the inflammatory system after trauma. Hemolysis commonly occurs after trauma, and extracellular hemoglobin can become a redox-reactive DAMP molecule, binding and triggering toll-like receptor–mediated signal transduction leading to increased inflammation.[42-44] Additionally, mitochondrial DNA, which has chemical similarity to bacterial DNA, released from lysed cells can activate circulating neutrophils, worsening organ injury.[42]

Reperfusion injury following hemorrhagic shock–induced hypoperfusion adds to the degree of inflammatory dysfunction. Ischemia/reperfusion induces proinflammatory markers, including cytokines, lipids, and chemokines, which all serve to activate polymorphonuclear neutrophils (PMNs).[17] These factors result in continued activation of the immune system and activation of leukocytes. Smaller studies have shown persistent stimulation of the immune system 28 days after injury in patients without signs of sepsis or a notable second hit.[24]

Polymorphonuclear Response

Patients who develop MOF tend to have a different PMN response to trauma than those who do not develop MOF. Immediately after injury, there is a relatively similar response between MOF and non-MOF patients with regard to total PMN activation. However, as time progresses, patients who go on to develop MOF have increased levels of PMNs.[45] This PMN response occurs as early as 6 hours after the traumatic event. Early demargination, accumulation, and degranulation of PMNs in tissue result in increased local cytotoxic effects by the release of nitric oxide and reactive oxygen species. Degranulation further increases production of systemic proinflammatory cytokines, promoting further inflammation. Early accumulation of PMNs in tissue is facilitated by an increase in endothelial-expressed adhesion molecules allowing for demargination.[46] Interestingly, blockade of the early expression of adhesion molecules significantly reduces

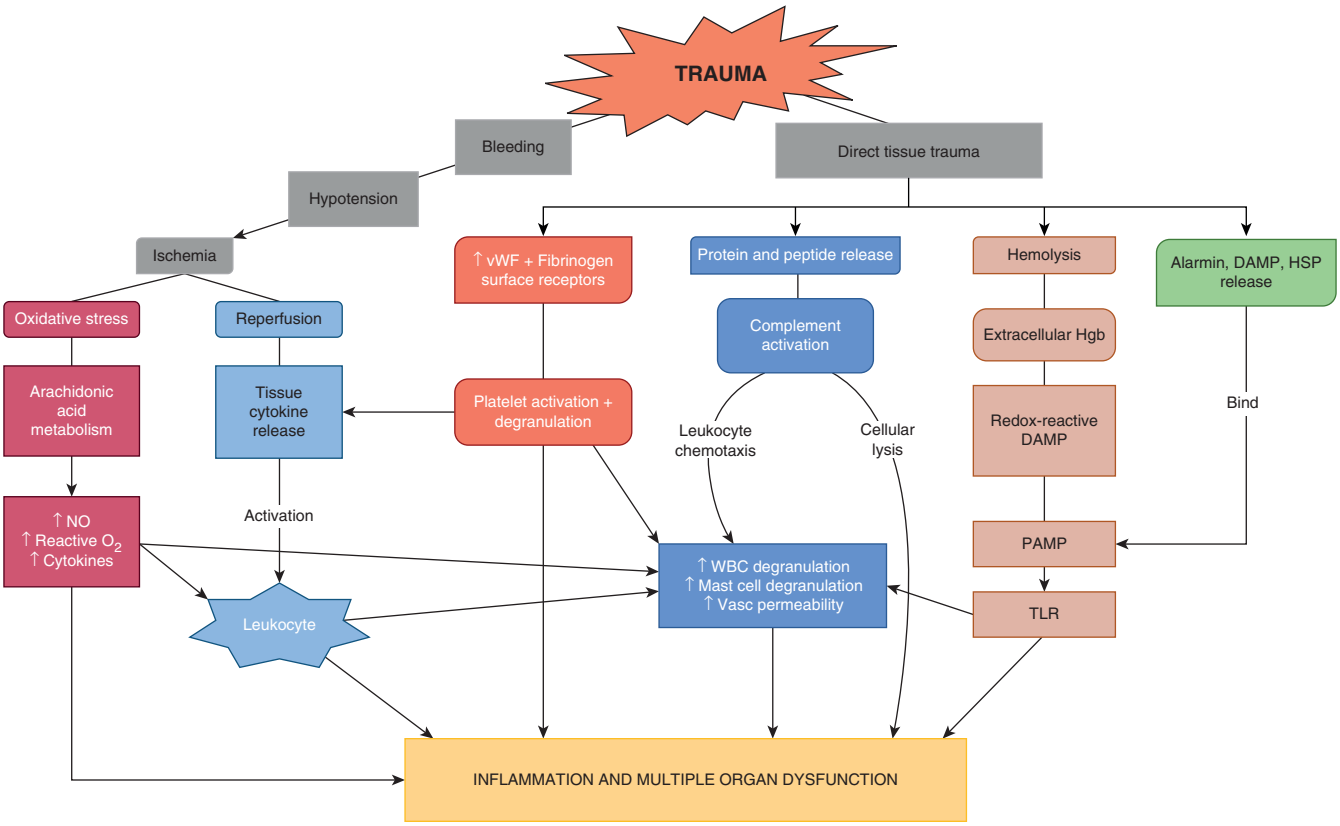

FIGURE 63-2 Pathophysiology of trauma-induced inflammation and development of multiple organ failure. acute lung injury in experimental sepsis models, suggesting that PMN adhesion and demargination is a critical step in tissue injury during inflammation.[46]

Macrophages

Macrophages play an important role in the development of inflammation, contributing to MOF, following trauma or sepsis. As macrophages are activated, they produce key proinflammatory cytokines including tumor necrosis factor-α and interleukin (IL)-2, which contribute directly to inflammation. They also produce large quantities of nitric oxide, which leads to vasodilation and hypotension and contributes to fluid shifts in sepsis.[47,48] Macrophage signaling is affected during periods of sepsis. In sepsis, macrophages are initially activated by bacterial wall proteins (eg, lipopolysaccharides [LPS]). In late stages of sepsis, however, macrophages are less responsive to LPS.[47-49] This tolerance to LPS contributes to the immunosuppressive stage of sepsis, often seen in patients prior to succumbing. Novel therapies targeting epigenetic regulation and other aspects of macrophage metabolism could better control inflammation and decrease MOF.[49]

Cytokines

Cytokines are local and systemic inflammatory mediators produced from systemic immune cells and cells at sites of injury. They help regulate hemodynamic, metabolic, and immune responses through cellular activation. Activation is achieved by binding specific membrane proteins that result in upregulation of gene transcription to ultimately influence activation, differentiation, proliferation, and survival of immune cells. Cytokines are classified into two types: proinflammatory and anti-inflammatory (Table 63-2). Both types have feedback mechanisms that result in downregulation of the respective pro- or anti-inflammatory counterpart.

Timing and degree of the cytokine release are important in the development of MOF. In one study of the temporal cycling of cytokine production in patients who suffered severe torso trauma, proinflammatory cytokine levels were higher at every time point in patients who developed MOF than in those who did not.[50] Peak cytokine production also appeared to separate patients who develop early (<3 days) MOF versus those who develop late (>3 days) MOF, with patients who developed early elevated cytokine levels having worse outcomes.[51] A rapid initial peak of proinflammatory cytokines, specifically those that activate PMNs (IL-6 and IL-8), was seen in patients who developed early MOF. Patients who developed late MOF had a secondary, delayed increase in inflammatory cytokines.[51] Substantial differences in cytokine levels have been seen as early as 90 minutes after injury. These differences may help differentiate patients who go on to develop MOF from those who do not.[52]

TABLE 63-2: Pro- and Anti-inflammatory Cytokines

Anti-inflammatory	Proinflammatory
TGF-β	TNF-α
IL-4	IL-1
IL-5	IL-6
IL-10	IL-8
IL-11	IL-21
IL-13	IL-22
bFGF	IL-26

bFGF, basic fibroblast growth factor; IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor.

Complement

The complement system constitutes a major component of the innate immune system. Complement functions to help mediate inflammation, clear immune complexes and apoptotic cells, and identify and eliminate microorganisms.[53] Complement also enhances the adaptive response, connects the innate and adaptive immune systems, and links the coagulation and immune systems together.[54,55]

Tissue trauma induces the release of proteins and peptides. These peptides activate the alternative pathway of the complement system, which leads to the chemotaxis of leukocytes, degranulation of white blood cells (including mast cells), and increased vascular permeability.[44,53] In addition, complement production and binding of peptides result in the formation of complement complexes that mediate cell lysis and enhance hemostatic capacity. This continues to activate the inflammatory cascade as complement triggers oxygen free radical production, metabolites, and cytokine formation.

Not only does trauma initiate the complement cascade, but it also has an effect on complement regulation. Regulatory proteins usually exist to help modulate and protect against unwarranted complement-mediated tissue destruction. In trauma patients, however, these regulatory proteins are altered, creating a state of complementopathy with increased complement factors, tissue destruction, and inflammation.[56-60]

Pathogen- and Damage-Associated Molecular Patterns and Heat Shock Proteins

Stressed and injured cells play a direct role in activating the immune system by triggering innate and adaptive responses through release of PAMPs, DAMPs, and alarmins. PAMPs, true to their name, are exogenous microbial molecules that trigger intracellular signaling pathways through toll-like receptors that are located on the membrane of the immune cells of the adaptive and innate immune system. Damage to the body's cells causes release of endogenous molecules that act similarly to PAMPs, but are named alarmins due to their endogenous release. Examples of major DAMPs include high mobility group box protein-1 (HMGB1), heat shock proteins, uric acid, and released DNA. DAMPs have been shown to be elevated 30 times above normal in trauma patients

within 1 hour after injury and have been associated with SIRS and end-organ damage in animals.[61-63]

Another important cellular consideration in immune modulation is that of the role of mitochondrial DNA. Mitochondrial DNA arose from endosymbiotic bacteria. Thus, release of mitochondrial DNA from cellular damage may activate the immune system identically to the bacterial pathways signaled through PAMPs, making tissue trauma akin to inflammation and sepsis.[42]

Role of Platelets

Inappropriate platelet activation and degranulation has been implicated in the development of MOF. Worsening thrombocytopenia has correlated with patient deterioration, with a higher likelihood of MOF development.[64,65] In patients who go on to develop MOF, there is upregulation of platelet surface factors for fibrinogen and von Willebrand factor, which leads to activation and degranulation of platelets, promoting microvascular fibrin deposition.[66] Increased degranulation of platelets strongly correlates with increased severity of organ dysfunction. Increased platelet degranulation causes further activation of neutrophils, oxidative stress, and damage to end organs.

The impact of platelet activation on organ dysfunction is quite notable in models of transfusion-related acute lung injury (TRALI). In lung injury, as discussed earlier, platelet activation and degranulation stimulate neutrophils and result in oxidative stress, local tissue damage, and respiratory distress. In rat models, when platelet activation was blocked with aspirin, local tissue damage and acute lung injury were prevented.[67,68] Similarly, targeting and blocking another platelet activating receptor, P2Y12, protected against acute lung injury in another TRALI mouse model.[68] Pretreatment with antiplatelet therapy helped decrease the risk of MOF in high-risk patients with blunt trauma who received blood transfusions.[69] Antiplatelet therapy (aspirin) was additionally associated with a reduction of mortality in ICU patients with ARDS.[70] In contrast, the Lung Injury Prevention with Aspirin Study Group (LIPS-A)[71] found no benefit of aspirin over a placebo in the development of ARDS at 7 days in patients in the emergency department who were at risk for the development of ARDS (defined as a lung injury prediction score >4).

Role of the Gut

The gastrointestinal tract appears to have a significant relationship with the development of postinjury respiratory dysfunction. The gut is the last organ to have restoration of perfusion after an ischemic insult.[22,44] Ischemia and reperfusion promote the disruption of the barrier between enterocytes and intraluminal bacteria. Gut-derived inflammatory mediators are not only released from intestinal bacteria, but are also released from the intestinal cells secondary to ischemia/reperfusion injury. These pathogenic components enter the systemic circulation through the mesenteric lymph via the thoracic duct. The first organ system encountered is the lungs.[72-74] This is a key reason why respiratory failure commonly precedes development of failure in other organs (heart, kidney, liver).[75]

The microbiome of the intestinal tract has emerged as an important contributor to patients' overall homeostasis. During critical illness, the composition of the microbiome changes.[76] For example, in patients with SIRS, the fecal microbiome may change into one of three patterns—a diverse, single, or depleted pattern. These changes are associated with clinical outcomes, as patients with depleted or single patterns have a significantly higher mortality compared to patients who retain diverse patterns.[76,77] With a better understanding of the effect of the microbiome on the development of MOF and even mortality following trauma and critical illness, the microbiome has become one more potential target for therapeutic interventions in the future.

Oxidative Stress

Reactive oxygen intermediates (ROIs) are generated by mitochondrial oxidation, arachidonic acid metabolism, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in phagocytic cells, and, lastly, activation of xanthine oxidase. ROIs serve to function in cellular homeostasis, mitosis, differentiation, and cellular signaling.[44] Excess ROIs can overcome the endogenous antioxidant defenses and lead to oxidative stress.[78] Oxidative stress can lead to injury by disrupting cellular proteins, nucleic acids, and cell membranes.[78,79]

Ischemia and reperfusion injury are seen in nearly every hypotensive and resuscitated trauma patient, leading to increased production of reactive oxygen species. These molecules are generated by shifts in cellular energy generation from aerobic to anaerobic metabolism during periods of hypoxemia and ischemia. As the cell decreases energy production (loss of adenosine triphosphate [ATP]), changes in cell membrane permeability result in increased intracellular sodium, causing resultant cell swelling and membrane damage. Decreased ATP results in increased cytosol calcium levels, which activates phospholipases and proteases that perpetuate cell membrane damage. Lastly, ATP hydrolysis increases cellular adenosine monophosphate (AMP) and purine metabolites.[80] As reperfusion increases the availability of oxygen, the purine metabolites are oxidized into urate and superoxide radicals, which contribute to cellular stress and damage. Additionally, ischemia/reperfusion stimulates ROI secretion from PMNs, which further induces cytokines and chemokines, causing more cell and tissue damage.[44]

PREVENTION AND TREATMENT

Despite decades of experimental studies and clinical trials, there are no specific treatments for preventing and treating MOF in patients. Management consists of supporting physiology and optimizing organ system function. Following severe trauma, the initial insult has occurred and management is focused on controlling hemorrhage, resolving shock, supporting each organ system, and preventing any further secondary insults. This is done by maintaining tissue

TABLE 63-3: Measures to Prevent Multiple Organ Failure

System or condition	Interventions
Pulmonary	Lung-protective tidal volume (6 mL/kg) and plateau pressure (<30 torr)
	PEEP management
	Prevention of cyclic opening and closing of airways
	Fluid-restrictive resuscitative strategies
Renal	Rapidly treat shock
	Avoid nephrotoxic agents
	Appropriate dosing of known nephrotoxic drugs
	Hydration prior to contrast agents
Hospital-acquired infection prevention	
Ventilator-associated pneumonia	HOB >30°, chlorhexidine oral rinse, daily interruption of sedation and aggressive weaning strategies such as daily breathing trials
CLABSI and CAUTI	Sterile technique; removal as soon as possible
Nutritional support	Early enteral feeding
Glycemic control	Blood glucose range 140–180 mg/dL
	Avoid hypoglycemia
	Minimize glycemic variability

CAUTI, catheter-associated urinary tract infection; CLABSI, central line–associated bloodstream infection; HOB, head of bed; PEEP, positive end-expiratory pressure.

oxygenation, preventing and treating infections, adequately resuscitating patients while avoiding overresuscitation, providing early enteral nutrition, and minimizing any iatrogenic complications (Table 63-3).

Resuscitative Strategies

Episodes of hypovolemia are common following trauma and in septic patients, and hypotension or circulatory shock is a common inciting event occurring prior to the development of MOF. Timely restoration of intravascular volume and oxygen delivery is imperative to help prevent the development of MOF. The optimal type and amount of fluid used in resuscitation is constantly under discussion (see Chapter 17).

The ideal fluid choice in patients is replacement of the fluids that have been lost. Thus, in trauma patients, blood products should be used for resuscitation. Fresh whole blood may be the ideal and is now becoming available again in the civilian setting. Traditionally, packed red blood cells (PRBCs) were administered first, followed by fresh frozen plasma (FFP), cryoprecipitate, and platelets (PLT) as needed. More recent studies have demonstrated a benefit of proactive, balanced blood product administration, now termed *damage control resuscitation*. Early blood product administration in a 1:1:1 (FFP:PLT:PRBC) ratio increased the frequency of hemostasis, decreased mortality from hemorrhage within 24 hours of injury, and improved early (<24 hours) survival in patients receiving more than 3 units of blood compared to a 1:1:2 (FFP:PLT:PRBC) ratio.[81,82] Initiating FFP transfusion as soon as possible, even outside the hospital, may be advantageous.[83]

When choosing fluids, other than blood, the initial choices are crystalloids or colloids (starches and albumin). Multiple trials, including the Scandinavian Starch for Severe Sepsis/Septic Shock (6S) and the Crystalloid Versus Hydroxyethyl Starch (CHEST) trial, compared the use of colloids (starches) with that of crystalloid (modified Ringer's lactate).[84,85] Not only did these trials fail to show a survival benefit with starches, but they also demonstrated an increased risk of acute kidney injury. Resuscitation with albumin compared to crystalloid showed no improvements in 28- or 90-day mortality.[86] Dextrans and hetastarches can also alter platelet function and increase renal failure.[87] Solutions containing large chloride concentrations, compared to balanced salt solutions, promote a hyperchloremic metabolic acidosis and have been associated with worsening renal function and increased need for renal replacement therapy.[88,89]

In the 1980s and 1990s, resuscitation of trauma patients was focused on reversing hypovolemia and preventing extracellular fluid loss. Supranormal hemodynamic targets for resuscitation were promoted through the use of pulmonary artery catheters.[90] These practices led to injudicious and often harmful quantities of fluid administration, dilution of coagulation factors, pulmonary dysfunction, worsening MOF, and infectious complications.[6,90,91] Additionally, the association between positive fluid balance and mortality in a range of critical illnesses has been well established.[92]

In general, fluids should be administered if the patient is hypotensive and/or demonstrates evidence of hypoperfusion. They should be administered by bolus infusions in the ICU, so that proper responses can be monitored to assure that therapeutic end points are being achieved. Prolonged maintenance fluid therapies should be avoided to decrease the risk of excess fluid administration, which contributes to worse outcomes of organ failure.

A variety of resuscitation end points have been studied, including normalization of acid-base status (lactate, base deficit, pH) and urine output.[93] Oxygen delivery and cardiac output have traditionally been monitored with pulmonary artery catheters. Two promising, less invasive technologies are focused ultrasound assessment and arterial pulse waveform analysis. Focused ultrasound assessment, although user dependent, allows for real-time assessment of cardiac filling, diameter and collapsibility of the inferior vena cava, cardiac function, and the presence of pulmonary edema. Arterial pulse waveform analysis provides a beat-to-beat estimate of cardiac output and stroke volume variation. These technologies provide real-time analysis of volume status to guide adequate treatment, although further studies are needed to demonstrate efficacy.[91]

Multiple strategies have been adopted for limiting fluid resuscitation, and the notion of "deresuscitation" has been

promoted, particularly in the setting of positive fluid balance.[90] One such study by Silversides et al[92] evaluated 400 patients from 10 mixed ICU sites. The use of deresuscitation techniques, including diuretics and renal replacement therapies, to achieve negative fluid balance on day 3 of ICU stay was associated with improved patient outcomes and a lower mortality.

Although restoration of organ perfusion in trauma patients initially requires fluid resuscitation, there is a role for the judicious use of vasoactive agents (eg, vasopressors or inotropes) in many patients. The use of sedation or anesthesia to facilitate procedures can cause vasodilatation and hypotension. In addition, prolonged shock can lead to vasoplegia. Focused ultrasound, arterial pulse waveform analysis, or pulmonary arterial catheterization can help with titrating these therapies, although early use of vasopressors, especially in the setting of hypovolemia, is associated with increased mortality.[94]

ORGAN SYSTEM SUPPORT

Mechanical Ventilation

Mechanical ventilation, although lifesaving for patients with critical illness, can contribute to worsening lung pathology and organ failure (see Chapter 59). Overdistension of the alveoli, by either high pressures (barotrauma) or high volumes (volutrauma), will lead to direct lung injury and an inflammatory response that can further damage other organ systems.[95-97] A lung-protective strategy of low tidal volumes (6 mL/kg) and low plateau pressures (<30 cm H_2O) for patients with ARDS can increase ventilator-free survival, decrease organ failure, and improve survival.[98] Applying this strategy in patients at risk for ARDS may also be beneficial.[99]

Respiratory cycling of opening and collapsing inflamed airways (atelectrauma) can further precipitate damage to the stressed pulmonary system. Positive end-expiratory pressure (PEEP) has been used to help prevent the cyclic collapse, as PEEP can be adjusted to just above the inflection point where alveoli collapse or de-recruitment occurs.[100] This method of PEEP adjustment has shown some improvement in mortality compared with controls. In patients with moderate to severe ARDS, a higher PEEP was associated with improved survival.[101,102] Lastly, a conservative fluid strategy has been shown to improve ventilator-free days and oxygenation at no risk to increasing other organ failures.[103]

In patients requiring increased ventilatory support with the development of severe ARDS, the early use of short-acting paralytics and prone positioning can improve outcomes.[104,105] Extracorporeal membrane oxygenation (ECMO) may play a role in the management of some patients with refractory hypoxemia.[106]

Renal Support

Acute kidney injury (AKI) commonly develops following trauma and is associated with a mortality rate between 40% and 80% (see Chapter 61).[107] Acute tubular necrosis, stemming from hypoperfusion (a prerenal insult), is the cause of acute renal failure (ARF) in the majority of patients (75%). Knowing this, it is imperative to adequately and expeditiously resuscitate patients. Any use of nephrotoxic drugs during the periods of shock and hypovolemia should be avoided if possible. Dosing should be based on pharmacokinetic principles using drug levels if available.[108,109] This is especially important in patients receiving antimicrobials that have been implicated in AKI, including vancomycin, aminoglycosides, and amphotericin B. It is also worth keeping in mind that some drugs cause direct toxic effects on nephrons and others cause indirect injury (eg, interstitial nephritis from penicillins). The attributable risk of AKI from antimicrobials has been difficult to determine in critically ill patients because sicker patients tend to develop more infections and receive more antibiotics. The impact is likely far less than that of other more definitive risk factors, including shock, sepsis, and prior renal dysfunction.

Once patients develop AKI, the use of any nephrotoxic agent should be reassessed. In addition, dosing of all medications that have any renal clearance should be adjusted appropriately. Renal replacement therapy (RRT), either intermittent or continuous, may be needed for management of fluid overload, electrolyte abnormalities (particularly hyperkalemia), refractory metabolic acidosis (after adequate hemodynamic stabilization), or uremia (particularly pericarditis). Theoretically, high flux RRT or RRT using specifically designed adsorbing materials could remove many of the mediators of MOF. Unfortunately, studies using these approaches have not demonstrated any benefit.[110]

Early Fracture Stabilization

The approaches to operative management of fractures in patients with multiple trauma has involved either early total care (ETC) or damage control orthopedic surgery (DCO). In ETC, patients have definitive fixation of all fractures as soon as feasible. ETC, especially of a femur fracture, has been shown to decrease pulmonary complications and promote early patient mobilization when compared to traditional nonoperative management.[111] When ETC is compared to delayed fixation, ETC is also associated with fewer pulmonary complications plus decreased ICU and hospital lengths of stay.[112] Although early fracture fixation in trauma patients has its benefits, many polytrauma patients are too unstable and cannot undergo early, definitive fixation. The importance of patient selection cannot be overstated, as attempting ETC in unstable or poorly resuscitated patients is associated with high rates of pulmonary complications.[113] In addition, these procedures are often lengthy and associated with a great deal of blood loss, potentially setting up patients for a "second hit" and the development of MOF. This led to the concept of DCO, which includes early abbreviated fracture stabilization, usually with splints and external fixator devices.[114] This provides long bone fixation, allows early mobilization, and helps to prevent the prolonged operative times that can lead to a second hit and precipitate MOF. Because posttrauma days 2 to 4 are "fraught with peril," because patients have immunologic changes, ongoing fluid shifts, tissue edema, and may not have achieved normal physiology,[115] timing of definitive

fixation after DCO is usually performed between posttrauma days 5 and 10. In one study, definitive fixation between days 2 and 4 was associated with more frequent development of MOF compared to fixation between days 6 and 8.[116] If possible, definitive fixation should be accomplished within 2 weeks, as infections in external fixator pin sites increase after this time point.[117]

Prevention of Hospital-Acquired Infections

Patients on mechanical ventilation are at risk for ventilator-associated pneumonia (VAP), which can play a significant role in the development of MOF. Bundled measures aimed at the prevention of VAP include elevation of the head of the bed, optimization of sedation with daily spontaneous awakening trials, daily spontaneous breathing trials, aggressive weaning protocols, and chlorhexidine oral rinse.[118-120]

Central line–associated bloodstream infections and catheter-associated urinary tract infections (CAUTIs) are two catheter-related sources of iatrogenic infection. In order to reduce the risk of central line infection, catheters should be inserted following maximal sterile technique (handwashing, cap, mask, sterile gloves and gown, large sterile drape) and skin preparation with an alcohol-based chlorhexidine solution; femoral insertion should be avoided.[121-123] Use of antibiotic-impregnated catheters and chlorhexidine sponge dressings and expeditious and early removal of catheters help reduce infection risk.

The best prevention for CAUTIs is minimizing the use of urinary catheters. Recommendations include a daily assessment of the need for an indwelling catheter, consideration for alternate urine collection methods, emphasis on sterile technique during insertion, and proper maintenance after insertion.[124]

Nutrition

Trauma and sepsis are prominent stressors and increase the metabolic demand of the patient. This can lead to a state of catabolism, resulting in unwanted tissue breakdown and proteolysis. Malnutrition can further contribute to the morbidity and mortality of MOF. Early nutrition, started within 24 to 48 hours of admission, can help suppress this process (see Chapter 62), shift the body toward anabolism, and decrease the risk of developing MOF.[125] Enteral nutrition, which is more physiologic and helps maintain gut integrity, is preferred over parenteral nutrition. The body's hypermetabolic response to trauma and sepsis is driven by the release of endogenous catecholamines, and early administration of catecholamine blocking agents (β-blockers) has been demonstrated to reverse the hypermetabolic response and protein catabolism in burn patients.[126]

Glycemic Control

Hyperglycemia has reproducibly been associated with worsened outcomes in the critically ill, particularly surgical patients. Intensive glucose control in postoperative populations may impact survival and surgical complications.[127,128] In 2001, Van den Berghe et al[129] compared tight glucose control (blood glucose 80–110 mg/dL) with the common management goal at the time of less than 180 mg/dL in a medical ICU in which many of the patients received early parenteral nutrition. The tighter glucose control reduced hospital mortality by 3% to 4% compared to the control. Tight glucose control was also associated with reductions in bloodstream infections, acute kidney injury, critical illness polyneuropathy, hyperbilirubinemia, anemia, and the duration of mechanical ventilation.[129,130] Subsequent studies have not been able to reproduce these results. The NICE-SUGAR trials, which randomized over 6000 mixed medical and surgical ICU patients to tight (81–108 mg/dL) versus conventional (<180 mg/dL) glucose control, demonstrated a higher 90-day mortality and 13-fold increased risk of hypoglycemia with tight control.[131] Hypoglycemia has been associated with increases in cardiovascular mortality and an increased risk of overall mortality among diabetic and nondiabetic patients.[132-134]

Glycemic variability, defined as acute fluctuations in glucose, is another factor that may be more important than previously thought. These fluctuations are often a direct result of the treatment of hyperglycemia. This leads to increased oxidative stress, causing endothelial dysfunction and vascular damage, and worsens the inflammatory cascade.[133] In nondiabetic, critically ill patients, glycemic variability confers an increased mortality risk of 26%.

The current management of glucose control is aimed at decreasing glycemic variability and stopping episodes of hypoglycemia. For now, the most prudent approach seems to be to maintain the blood glucose below 180 mg/dL by initiating interventions to control blood glucose when the level is 150 mg/dL or higher and to maintain blood glucose above 70 mg/dL.[135,136]

SUMMARY

Patients with severe trauma are at high risk of developing SIRS and CARS following resuscitation, leading to late deaths from MOF or the development of PICS. Currently, there are no specific treatments to prevent or treat SIRS or CARS. Support of failing organs and prevention of secondary insults are the best management strategies.

Trauma and Global Health

Nakul Raykar • Katherine Hill • Jana Macleod • Juan Carlos Puyana

KEY POINTS

- At least 250 million disability-adjusted life-years (DALY) are attributed to traumatic injuries around the world each year.
- In 2018, an estimated 1,350,000 individuals died from road traffic injuries around the world.
- Ninety percent of the world's traffic-related fatalities occur in low- and middle-income countries.
- In 2015, the World Health Assembly passed Resolution 68.15 calling for emergency surgical care as a part of universal health coverage.
- The Residency Review Committee and the American Board of Surgery approved international rotations to fulfill graduation requirements for surgical residents in 2011.
- The "P" values of successful international research collaborations include strong **p**artnerships, knowledge of the **p**eople, requirement for **p**atience and di**p**lomacy to build **p**roductive programs.
- Initiatives from the Global Health Advocacy Incubator have resulted in 11 countries passing new or improved road safety laws, thus protecting over 3.36 billion people

". . . a new and sweeping utopia of life, . . . where the races condemned to one hundred years of solitude will have, at last and forever, a second opportunity on earth."

—Gabriel Garcia Marquez

INTRODUCTION

Trauma is a public health challenge of global proportions. Roughly 5 million individuals lose their lives each year from road traffic collisions and interpersonal violence, and most of these events occur in low- and middle-income countries (LMICs).[1] The challenges of treating traumatic injury are not divorced from the broader challenges of health systems and lack of surgical access. Much of the death and disability is attributed to inadequate prehospital and hospital systems that are understaffed and unequipped to bring patients to receive care or to provide emergent surgical intervention. Comparing mortality rates for Injury Severity Score–matched injuries between high-income countries (HICs) and LMICs suggests that up to 1.9 million (almost 40%) of these lives could be saved with improved health systems.

Acute care surgeons are well positioned to promote improvements in trauma and emergency surgical care, injury prevention, regionalization of acute care, and implementation of data systems to drive process improvement in global surgery.[2] Trauma surgery already has a long history of contributors and beneficiaries of international partnerships.[3]

Dr. Oswaldo Borraez was a young attending surgeon in Bogota, Colombia, in the 1980s when he first thought of using an inexpensive, sterile plastic bag as a means of temporary coverage of the open abdomen. He showed this to a visiting surgeon from the United States, Dr. David Feliciano, who later introduced the technique to the trauma community as the "Bogota bag" in the United States. Variants of this methodology continue to be used worldwide.[4] Similarly, trauma surgeons from LMICs routinely visit major trauma centers in high-resource trauma settings to learn about regionalization and advances in care.[5]

Unfortunately, for too long surgical care has been considered too expensive for provision in the world's poorest regions. Surgeons, too, were largely silent in the debates over investment in health resources. This is beginning to change. Surgical trainees are increasingly seeking meaningful international experiences. Many academic departments of surgery have begun to recognize the value of a variety of global health endeavors.[6-8] The concept of "global surgery" has evolved from simple outreach volunteerism on the part of individuals, nongovernmental organizations (NGOs), and faith-based organizations to a mature academic discipline. This discipline encourages formal postresidency training oriented toward

establishing international partnerships and long-lasting institutional multidisciplinary collaborations.[7] Recent work from the Lancet Commission on Global Surgery, the World Bank's Disease Control Priorities Third Edition (DCP3), and the World Health Organization (WHO) Assembly Resolution 68.15, among others, have framed global surgery as part of worldwide initiatives for health equity. We believe that the term *global surgery* now defines a discipline that seeks to improve the surgical needs of all marginalized and vulnerable populations, irrespective of their regional, national, or subnational geographic location. For the purposes of this chapter, however, we will focus on vulnerable populations in geographic areas of the world with the most disparity (LMICs) as defined by the World Bank.

In this chapter, we will detail the global burden of emergent and traumatic surgical disease, contextualize the recent surge of interest in global surgery, and outline critical areas for collaboration between trauma and emergency general surgeons from across the world.

THE GLOBAL BURDEN OF SURGICAL DISEASE AND TRAUMA

There is an immense need for surgical services worldwide. The *global burden of disease* refers to the total volume of ailments that affect humans, and researchers estimate that between 28% and 32% of it will require surgical expertise for treatment.[9] The AIDS patient who develops an empyema necessitating drainage will require surgical services just the same as the trauma patient with a shattered spleen. At least 15% of pregnancies will result in complications that need emergency obstetric care, including surgical management.[10] The disability-adjusted life-year (DALY) is a composite measure developed to quantify the years of life lost from a premature death or the years of life lived at diminished potential due to morbidity from illness. At least 250 million DALYs are attributed to traumatic injury each year (DCP3, Chapter 2), surpassing the 214 million DALYs per year from AIDS, tuberculosis, and malaria, and the 130 million DALYs per year from ischemic heart disease.[11,12] This is not surprising, as surgery is such an effective treatment modality. The presence of a functional surgical infrastructure including systems-based care for prehospital and posthospital coordination allows for the treatment of a broad range of diseases. Over half of the 45 million deaths in LMICs each year could be potentially averted with improved prehospital or emergency care. This translates into a staggering 1023 million DALYs, or 932 million years of life lost to premature mortality.[13]

In 2018, an estimated 1,350,000 people died from road traffic injuries alone.[14] More than half of these deaths were pedestrians, bicyclists, or motorcyclists. Also, road traffic injuries are the leading cause of death among people in the core years of workforce productivity (ages 15–29 years). Astounding as these numbers are, they represent only a small fraction of the disability generated from road traffic injuries. Roughly fourfold more people are disabled than die from road traffic injuries. As economic development brings more and more people into the middle class, the number of motor vehicles and the number of road traffic incidents are projected to increase.[15] LMICs already are home to 90% of the world's traffic-related fatalities with just about half of the world's vehicles.[16] It is estimated that road traffic injuries will become the seventh *overall* cause of death by 2030, and the economic cost will reach a staggering 3% of the gross domestic product in certain countries.[17]

Crime, drug abuse, alcoholism, and social unrest continue to fuel interpersonal violence in low-income countries and HICs, alike. A population-based survey showed that 10% to 69% of women worldwide reported being physically assaulted by an intimate male partner at some point in their lives.[18] Gun violence, mass shootings, and domestic and international terrorism add additional pressures on training programs both at the residency and fellowship level to ensure proficiency in the management of severe penetrating injuries. In fact, the need may be greater in lower resource settings. The rate of violent death in LMICs is more than twice the rate in middle-income countries.[19] Of the top 50 cities in the world with the highest murder rates excluding current war zones, 17 are in Brazil, 12 in Mexico, 5 in Venezuela, and 5 in the United States (Fig. 64-1).

POOR ACCESS TO TRAUMA CARE IN THE CONTEXT OF POOR SURGICAL ACCESS AND THE RISE OF GLOBAL SURGERY

Most of the world's population does not have access to surgical care when needed. Initial estimates have reported that at least 2 billion people do not have access to surgical care based on operating theater capacity alone.[20] When additionally accounting for timeliness, safety, and affordability, this number rises to more than 5 billion, or 70% of the world's population[21] (Fig. 64-2). In the world's poorest regions, including parts of South Asia and Africa, over 95% of the population are without access. The challenge to improve access is exacerbated by pervasive deficits in the infrastructure, workforce, and financing necessary to provide surgical care (Fig. 64-3).

Aware of the challenges of reaching a surgical hospital with affordable care, many patients delay seeking treatment when faced with illness.[22] Over 90% of deaths from abdominal conditions in India occur in rural areas, with over 70% occurring at home.[23] Unfortunately, too many patients in these environments live hundreds of kilometers away from the nearest surgical hospital.[24] Accessing care will require many hours or days of travel on multiple modes of transportation including bullock carts, bicycle, and on foot. If patients do make it to the hospital, they will likely find equipment and medication shortages; insufficient numbers of physicians, nurses, and

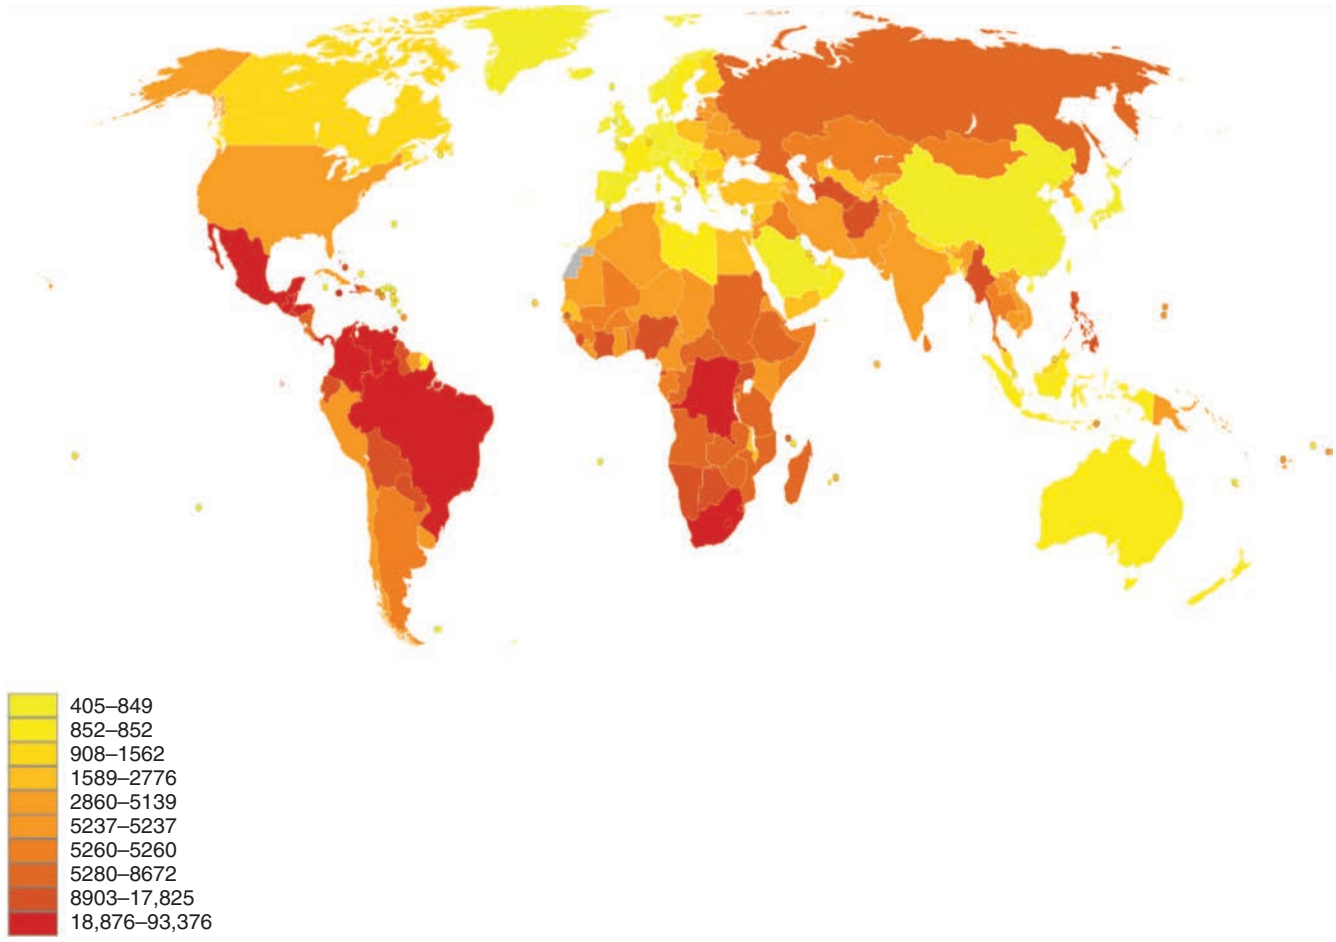

FIGURE 64-1 Disability-adjusted life-years (DALYs) lost from interpersonal violence in 2012 per million males.

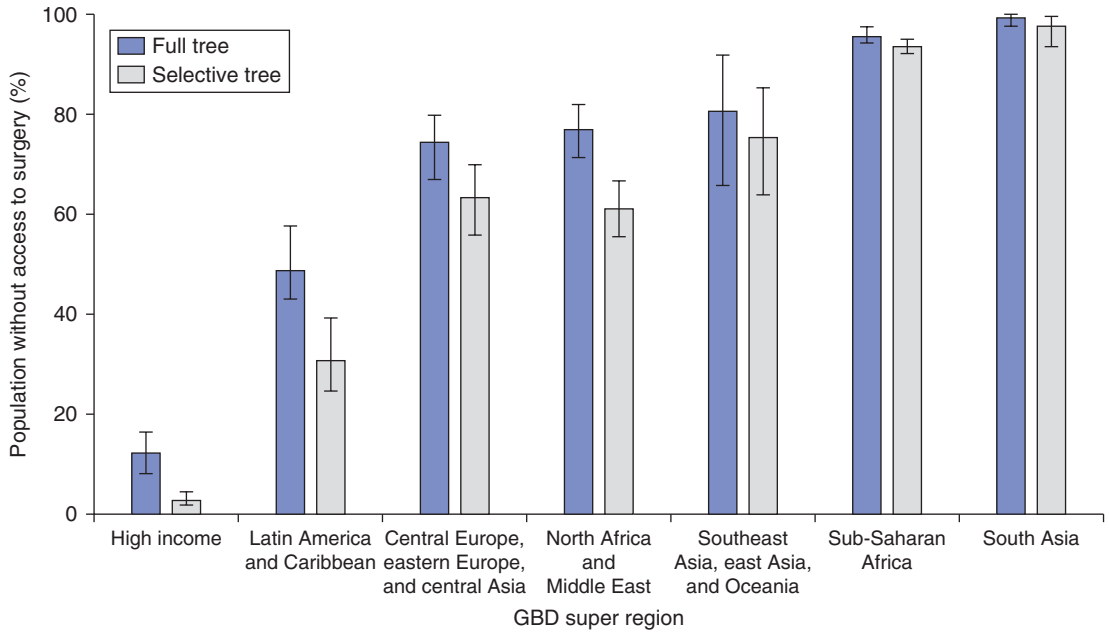

FIGURE 64-2 Over 90% of the populations of sub-Saharan Africa and South Asia do not have access to surgery when taking into account availability, timeliness, safety, and affordability. (Reproduced from Alkire BC, Raykar NP, Shrime MG, et al. Global access to surgical care: a modelling study. *Lancet Glob Health*. 2015;3(6):e316-e323.)

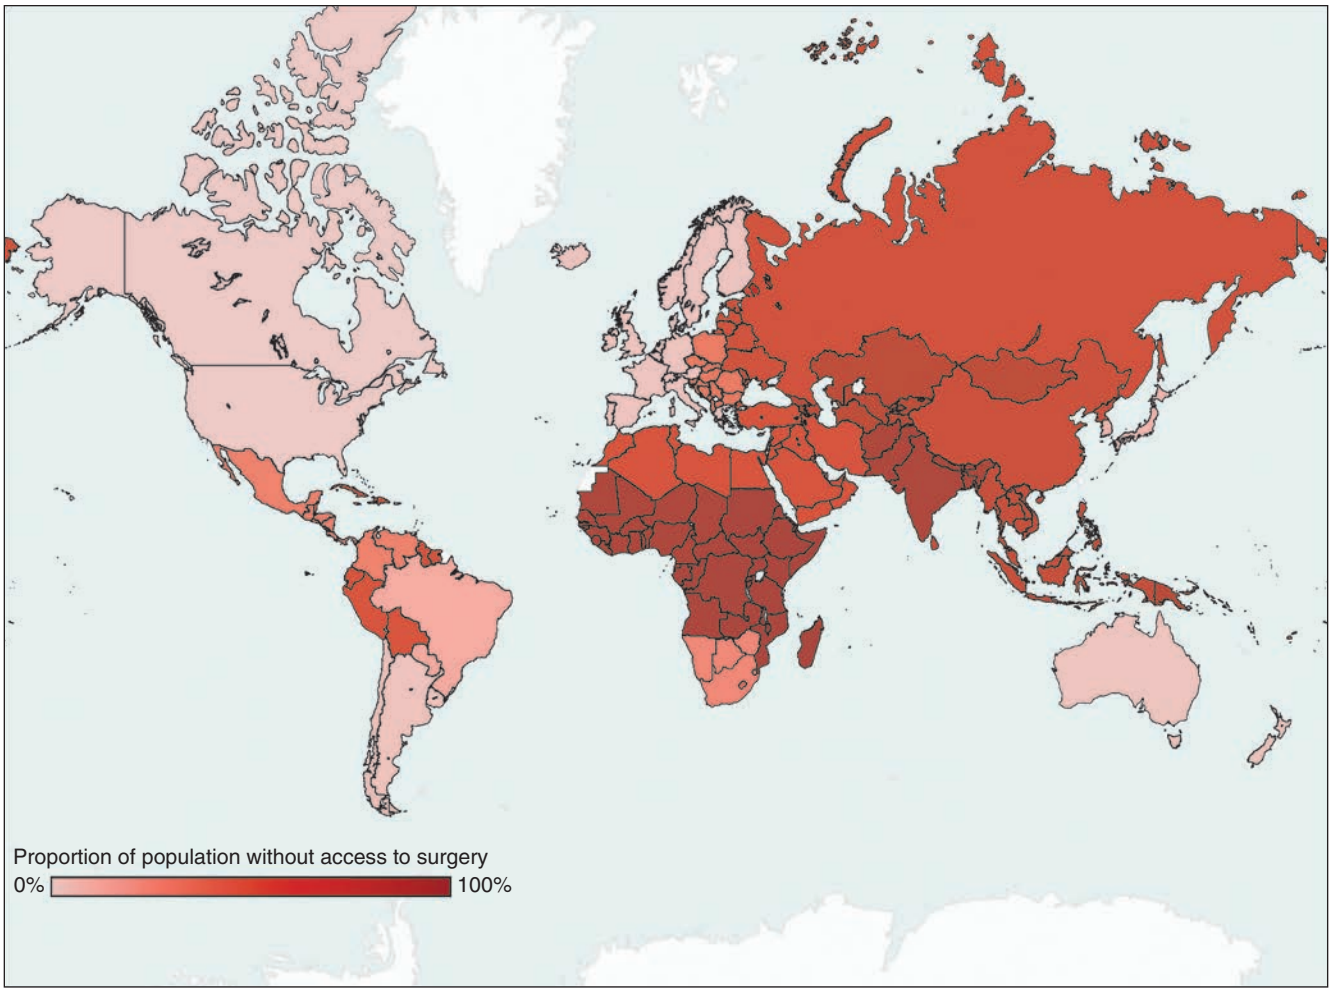

FIGURE 64-3 Unfortunately, the areas of poorest access often overlap with areas of greatest rates of trauma and violence, as depicted in Fig. 64-1. (Reproduced from Alkire BC, Raykar NP, Shrime MG, et al. Global access to surgical care: a modelling study. *Lancet Glob Health*. 2015;3(6):e316-e323.)

staff; and unaffordable costs.[9,25] A quarter of those who successfully obtain surgical care are bankrupted by it.[10]

Accompanying these deficits has been the lack of policy focus. Paul Farmer and Jim Kim famously described surgery as the "neglected stepchild" of the global health community. This alluded to decades of international efforts from the WHO, World Bank, NGOs, and HIC governments prioritizing funds for nonsurgical treatments for AIDS, tuberculosis, malaria, dehydration, and malnutrition.[26] In the United States, the National Academy of Sciences, part of the National Academies of Sciences, Engineering, and Medicine (NASEM), plays a major role in shaping US policy in global health and, for the better part of this century, considered addressing the surgical burden of disease a low priority. As of 2014, less than half of national health strategic plans in sub-Saharan Africa had any mention of trauma, and only 2% of mentioned health targets related to surgical conditions or surgical care.[27] Corruption, violence, and war also threaten the stability of the poorest regions of the world, resulting in the destruction of any existing health system and impeding public health interventions.[28]

The Rise of Global Surgery

Fortunately, there have been recent strides in the prioritization of surgery within the global health landscape. In early 2015, the World Bank released its third iteration of the Disease Control Priorities, dedicating, for the first time, an entire volume to surgical diseases (previous versions in 1999 and 2006 either made no mention or consisted of a single chapter).[29] Also, in 2015, the Lancet Commission on Global Surgery released its seminal report, culminating a 2-year process of data gathering and priority setting involving over 500 experts in 100 countries. There was critical involvement from the World Bank, WHO, and multiple ministries of health.[10] Both the World Bank and WHO revised their core data collection requests from national governments to include surgical indicators from the Lancet Commission's

report. The latest NASEM report, published in May 2017, addresses matters pertaining directly or indirectly to trauma and surgery in 4 of its 14 core recommendations.[30] In 2007, WHO recognized the importance of trauma and emergency care systems with World Health Assembly Resolution 60.22, and in 2015, the World Health Assembly passed Resolution 68.15 calling for emergency surgical care as a part of universal health coverage.[31]

Several national governments have already taken heed of the global drive to strengthen health systems and include surgery. Zambia became the first to undergo a formal national surgical planning process, establishing a National Surgical, Obstetric, and Anesthesia Plan into its national strategic health plan for 2017 to 2021.[32] Ethiopia and Mongolia have embarked on similar processes.[33] Advocates of the rural poor have combined forces with academics, private industry, NGOs, and government officials to drive a grassroots process in India.[34]

THE ROLE OF THE ACUTE CARE SURGEON

Trauma surgeons have had a longstanding record of public health engagement. Never before have the opportunities for the trauma and acute care surgeon interested in global health coincided with the global momentum for surgery. The very nature of combining surgical expertise with the provision of emergency care places the acute care surgeon at center stage to promote appropriate improvements in injury prevention, trauma and emergency care, development of information systems, and workforce training. In fact, continued improvement will require coordinated action led by acute care surgeons in the clinical, training, research, and policy partnerships.

Clinical Partnerships

The massive unmet need for surgery will require a coordinated approach that focuses on enhancing capacity for delivery of surgical care in hospitals and communities worldwide. Hospitals in the health system are usually categorized into first-level (district), second-level (regional), and third-level (tertiary) hospitals. The first level is closest to the communities it serves and is the entry point for the critically ill within the broader health system.[35] Broad consensus exists in the global health community that a functional first-level hospital should be the base for a strengthened surgical system.[36]

The Lancet Commission on Global Surgery has adopted these recommendations and further suggests local clinicians and surgeons stratify priorities for surgical scale into categories of "must do," "should do," and "can do." In fact, it defines abdominal laparotomy, cesarean delivery, and treatment of open fracture as the bellwether procedures, markers of a hospital's surgical functionality.[37] Local clinicians and policymakers and their international partners should focus on context-specific improvements to provide year-round coverage for "must do" and "should do" procedures. In certain hospitals, this may focus on securing a reliable energy source or running water. In other localities, attracting and retaining expert talent including nurses and pharmacists may take top priority. In yet other settings, focus may shift to developing protocols and guidelines dictated by local experts and applicable to the local resources to maximize efficiency in triage or treatment. The specific improvements and priority setting should be left to clinicians and policymakers with a nuanced understanding of local context and disease burden in the community.

Acute care surgeons interested in partnering in these efforts should seek structured, longitudinal collaborations, built through both individual relationships and leveraging institutional resources on both sides. The interest in "surgical volunteerism"—short-term engagements, a staple model for global surgery engagement in the past—should be channeled into structured engagements focused on providing dependable, year-round (long-term) support. Short-term camp-based engagements may continue to have a role, particularly for more specialized, elective "can do" procedures, but the need for and timing of these spurts in surgical activity should be guided by local clinicians so they do not distract from the broader mission of reliably functional first-level hospitals.[38]

Training Partnerships

Educational and training partnerships can present opportunities to enhance provision of care at the first-level hospital with bilateral benefit.[39] International experiences are common among medical trainees worldwide, and recent US medical school curricula have been adapted to include global health and cultural competency.[40] Departments of surgery, however, lag behind other disciplines in offering international experiences for their trainees, with only 34% of US surgical residency programs offering such opportunities, and often they require the use of vacation time.[41] Likewise, acute care surgery programs in the United States are finding increasing difficulty in securing adequate exposure for trainees in penetrating operative trauma. Some programs are actively seeking opportunities for their fellows to travel and participate in clinical rotations where they can be exposed to challenging penetrating caseloads.

Novel partnerships may provide supervised case exposure in low-resource settings for surgical trainees from higher resource settings while coupled with level-appropriate clinical service by advanced trainees or partner faculty.[42] A board-certified American College of Surgeons (ACS) fellow could conceivably provide general surgery support at a first-level institution while gaining operative trauma experience at the trauma center. The Residency Review Committee and the American Board of Surgery (ABS) approved international rotations to fulfill graduation requirements for surgical residents in 2011.[43,44] This approval is contingent on specific requirements, such as Internet access, literary resources, and the supervision of an ABS-certified surgeon. Unfortunately, the regions of the world that will benefit the most from these cultural and educational exchanges are the very regions

that lack the presence of ABS-certified surgeons. Innovative thinking is needed to balance these realities with the need to ensure trainees continue in a safe training environment and are not extended beyond their level of training without adequate supervision. Global health has a complicated history that includes accusations of colonialism. The onus will be on training programs from higher resource partners to ensure trainee presence does not supplant local trainee opportunities or cause disruption without accountability to local partners.[45]

IMPORTANCE OF RECIPROCITY

Opening the doors for surgeons and trainees from the United States to travel to and operate in busy trauma centers in LMICs does require fulfilling several regulatory steps including special permissions and liability protection. In most of these centers, the visiting surgeons and trainees will not be asked to validate their training, although they may need to obtain temporary licenses, often under the purview of the host institution. Regardless, almost universally, they are able to participate in operations and play a pivotal role in the decision making required to provide comprehensive care. Unfortunately, a truly reciprocal experience cannot be offered to foreign medical graduates (surgeons) when invited to visit trauma centers in the United States. Foreign medical graduates specialized in surgery outside the United States and Canada must redo their complete surgical residency in the United States to be able to practice as surgeons, and their interactions in North American trauma centers are subject to regulations from the ABS and state and federal licensing boards.

As international educators whose trainees benefit tremendously from their experiences overseas, we must commit to creating mechanisms to offer valuable experiences for surgeons trained overseas who are invited to the United States. The underlying reason to invite trauma surgeons or residents from LMICs to visit trauma centers in the United States is to provide exposure to mature, academic trauma systems. As long as visitors are supervised and not expected to engage in independent decision making, they should be allowed to participate in clinical rounds and assist in the operating room. Most importantly, they should be provided immersive experiences in the multidisciplinary academic, investigative, and performance improvement efforts that distinguish American academic trauma centers.

Needless to say, most will recognize that the mere technical experience of assisting in a surgical case in isolation from the broader system employed to take care of these patients will be an incomplete strategy.

THE NEED FOR INSTITUTIONAL PARTNERSHIPS IN MEDICAL EDUCATION AND THE ROLE OF PROFESSIONAL SOCIETIES IN SUB-SAHARAN AFRICA

Medical school enrollments are increasing across the African continent. Kenya, for example, had two medical schools for its first 50 years after independence, but the last decade has seen seven more, a 350% increase. Concurrently, the class size for these medical schools has risen annually, with increases of 200% to 300%.[46] The average medical school in Kenya enrolls 80 to 350 students per year.

While this is an encouraging development for a region in dire need of medical professionals, it presents challenges to the medical and surgical community. How will they provide a quality education and postgraduate training with limited faculty already stretched to provide clinical care and administrative duties?

University-to-university collaborations are primed to meet some of these educational challenges.[47,48] Broad collaborations signed at the highest levels between institution leadership can cut across disciplines and provide a steady pool of visiting faculty and leverage resources from online resources to course curricula. Lasting partnerships, after all, mandate that the mechanisms for faculty to participate at partner sites are built into their job descriptions and do not rely solely on volunteerism.

The College of Surgeons of East, Central, and Southern Africa (COSECSA) was formed in 1999 to provide a standard training pathway and internationally recognized surgical qualification, currently in existence across 12 countries in sub-Saharan Africa. COSECSA has graduated over 250 surgeons since 2004 and currently has 575 trainees enrolled across the region. Beyond postgraduate training to scale up the African surgical workforce, COSECSA has also developed initiatives in faculty development, research and peer-reviewed publication, and policy formation in conjunction with national medical boards.[49]

Global partnerships have been critical to COSECSA's successes. The Association of Surgeons of Great Britain and Ireland collaborated with COSECSA for more than 10 years to provide multidisciplinary team training in basic surgical skills and management of surgical emergencies.[50] The Pan-African Association of Christian Surgeons partners with COSECSA, allowing its constituent surgeons and hospitals under faith-based organizations to participate in regional surgical training and leadership while contributing critical additional trainers and training sites.[51] Since 2007, the Royal College of Surgeons of Ireland (RCSI) has collaborated with COSECSA to design and administer examinations (along with a global cohort of expert surgeon-examiners), develop e-learning and logbook resources, and manage administration and business of the college. The RCSI-COSECSA partnership has also cooperatively collected and published data on the surgical needs of the region.[52,53] The ACS has also initiated a scholarship program to support the training of women surgeons through COSECSA.[54]

Research Partnerships

Clinicians in the frontlines often lament that they are both literally and figuratively "operating in the dark." Faced with overwhelming patient loads and working in remote hospitals, providers and administrators rarely receive feedback to assess benchmarks or drive process improvement. Unfortunately, not only is the data void demoralizing, but it also leads to ineffectual choices with investment for scale-up.

Well-intentioned initiatives based on successes in one part of the world do not necessarily transfer well. Ambulance systems, for example, a hallmark of high-income prehospital trauma systems, have failed to improve outcomes in lower-resource settings where injury patterns, traffic and population density, and hospital capabilities may differ.[55]

In fact, organized trauma systems require robust data collection (trauma registries) for optimization of the system. The establishment of the ACS National Trauma Data Bank in the United States continues to enhance trauma care and direct resources toward high-efficiency interventions. Benchmarking trauma systems in the low-resource world will require novel methodology for data collection and new scales to identify system deficiencies.[56] Unfortunately, policymakers and clinicians in most low-resource environments are unable to direct significant investment toward data/informatic systems.

Academic partnerships capitalizing on the expertise of high-income universities in creating, financing, and sustaining trauma registries with electronic injury surveillance applications may provide a hard reset. Such research relationships may also serve as an avenue for reciprocity in global health, leveraging the strong traditions of academic medicine in higher resourced settings with the strong clinical expertise of surgeons from LMICs. As more surgeons-in-training gain valuable surgical experience in low-resource countries, mechanisms must be developed to provide a commensurate experience in high-income institutions for partner surgeons from low-resource settings. Providing immersive learning opportunities in research and quality improvement, with degree opportunities and full access to learning materials, research groups, and faculty typical of academic centers in the United States and Europe, may not only provide benefit to the visiting physician, but must also serve as a longer term investment in research infrastructure in LMICs.

Unfortunately, funding for international trauma research has traditionally been scarce. Several academic surgical departments in the United States have used clinical revenue to support a diversity of international endeavors, particularly at the level of midterm surgical residents or junior faculty.

A few developments, however, offer hope. Since its inception in 1968, the National Institute of Health's international health coordinating entity, the Fogarty International Center, has promoted international collaborations built in the United States by funding research training grants and capacity building in international/global health. The Fogarty International Collaborative Trauma and Injury Research Training Program was designed in 2005 and awarded in 2006 to foment relationships between universities in the United States and medical schools in LMICs, which are reissued in 5-year cycles.[7] Similar programs have been established in Europe and Australia, with direct eligibility linked to research in specific partner countries. The Australia–India Trauma Systems Collaboration is a multiyear partnership funded by a diversity of donors with aims to improve trauma systems through data systems in both countries.[57]

With newfound recognition of the importance of this research within the global health community, investigators will need to employ creativity in responding to dissimilar but related funding requests for applications, in government and nongovernmental sectors, and create new opportunities through advocacy.

CASE EXAMPLE OF CAPACITY BUILDING FOR TRAUMA RESEARCH: FOGARTY INTERNATIONAL CENTER, D43 TRAINING GRANTS

The University of Pittsburgh was awarded a D43 training grant in 2006 in collaboration with the Universidad del Valle in Cali, Colombia. Under this grant, Colombian trainees engage in research training at the University of Pittsburgh. They are offered several short-term research capacity rotations, as well as long-term training in master's and PhD programs in clinical research and clinical translational sciences. This academic training has been pivotal in creating a new culture of trauma research in Colombia, a country where trauma surgeons had developed astonishing clinical proficiency but did not have the opportunity to examine this experience or submit it in a rigorous academic format required for international scientific forums.

Since inception of the program, Colombian trauma research participation has surged at the American Association for the Surgery of Trauma, the Clinical Congress of the American College of Surgeons, and the European Society of Trauma and Emergency Surgery. Colombian trauma surgeons have become independent clinical investigators and regional leaders, collaborating with faculty from other countries in the region including Guatemala and Paraguay. Studies have been diverse and varied, ranging from clinical trials to epidemiologic analyses of alcohol policies and homicides rates.[58-60] The success of this program relies on what we recognize as the "P" values of successful international collaborations. These are strong **p**artnerships that must be based on mutual collaboration. It requires in-depth knowledge of the **p**eople, local cultural characteristics, and cultural idiosyncrasies. It requires **p**atience and di**p**lomacy to build **p**roductive and successful long-lasting research programs. These collaborations must be multidisciplinary by nature among a variety of health professionals from both HICs and LMICs to result in significant and sustainable trauma research contributions relevant to LMICs and beyond.

Policy Partnerships

Advancing surgery among national political priorities will continue to be a key task for those interested in strengthening surgical systems. Funding, resources, and political prioritization required for true systems-level change cannot occur in isolation within clinical and academic partnerships; it requires true engagement of the health system and its decision makers.

Many of the recent examples of national surgical planning (Zambia, India) have been shepherded through academic partnerships in the aftermath of the Lancet Commission on Global Surgery, itself a collaboration of many societies across

the globe.[33] International partners can often provide much-needed research and organizational support to efforts driven by local partners and priorities.

International trauma societies in high- and low-resource settings have already taken up the mantle of global collaboration with the purpose of addressing needs in surgical workforce, research development, and emergency surgical care. The West African College of Surgeons has been in existence since the 1960s, and COSECSA, described previously, provides a standard training pathway and internationally recognized surgical qualification for many countries across Africa. Both societies have collaborated extensively with organizations in the United States and Europe to provide faculty development, and particularly to provide training in clinical research knowledge and skills.[61] Encompassing many of the tenets of acute care and trauma surgery, the Association of Rural Surgeons of India has been an advocate for the rural poor since 1992 and in 2005 formed the International Federation of Rural Surgery in partnership with the Association of Rural Surgeons of Tanzania, the Association of Rural Surgical Practitioners of Nigeria, and the German Society for Tropical Surgery.[62,63] This organizational collaboration not only provides critical professional connectivity to rural acute care, but also has shaped policy in areas such as legislation for blood banking in India and pioneered low-cost surgical innovations such as the use of mosquito nets for use in hernia repair.[64]

The last few years have seen new partnerships between the American Association for the Surgery of Trauma and the European Society for Trauma and Emergency Surgery and other international organizations such as the International Association for Trauma and Intensive Care and the Panamerican Trauma Society. Operation Giving Back was initiated by the ACS in 2004 as an effort to coordinate surgical volunteerism. It now has evolved into an organization supporting broader outreach and working closely with WHO and surgical professional societies in Africa and Asia. Specific to trauma, the ACS's Committee on Trauma has created the International Injury Care Committee (I2C2), uniquely positioned to leverage historically successful endeavors in trauma systems, team training (Advance Trauma Life Support [ATLS]), rural trauma, and quality improvement in the United States with worldwide dissemination. I2C2 should now focus on developing an ATLS-like program to offer basic educational material for the creation of low-cost, effective trauma systems adapted for low-resource settings.

The private and nongovernmental sectors have been key in this process. The Bloomberg Group Philanthropies, for example, have partnered with WHO and other groups to create a Global Health Advocacy Incubator.[65] These initiatives have resulted in 11 countries passing new or improved road safety laws, thus protecting over 3.36 billion people. From 2007 to 2009, Bloomberg Philanthropies funded a pilot program in Cambodia, Mexico, and Vietnam to see if proven road safety interventions could be adapted and used on a global scale. This effort was expanded in 2010 to support the implementation of these interventions and successfully reduce road traffic fatalities and injuries in 10 LMICs that account for half of the global road crash fatalities (Brazil, Cambodia, China, Egypt, India, Kenya, Mexico, Russia, Turkey, and Vietnam). In 2015, Bloomberg Philanthropies launched phase 2 of the Initiative for Global Road Safety, which will address road traffic safety in 10 cities (Accra, Ghana; Addis Ababa, Ethiopia; Bandung, Indonesia; Bangkok, Thailand; Bogota, Colombia; Fortaleza and Sao Paolo, Brazil; Ho Chi Minh City, Vietnam; Mumbai, India; and Shanghai, China), five countries (China, India, Philippines, Tanzania, and Thailand), and four vehicle market regions (Africa, Latin America, India, and Southeast Asia) with the primary goal of reducing road traffic fatalities and injuries.

CONCLUSION

There has never been a better time to be a surgeon interested in global surgery. Acute care surgeons can make meaningful strides extending surgical access for the world's poor through innovative clinical, policy, and academic partnerships. It is imperative that surgical department chairs and professional society leadership embrace and encourage participation in these efforts.

VI

ATLAS OF TRAUMA

Introduction to the Atlas

Each preceding chapter has figures, tables, and drawings that aid the author and the editors in imparting and clarifying the messages of the chapter. In this edition of *Trauma,* the editors have devoted a special section to an atlas. It is not intended to include an exhaustive artistic rendering of every operation, but, rather, to focus on procedures that are commonly used in major trauma operations, along with related anatomical drawings. Some procedures that may have been commonly practiced in the past but are rarely currently done are not included. However, a few relatively infrequently used concepts and procedures have been included in this section because of sufficient need to clarify the opinions of the editors. The art has been kept in as simple a form as possible, so it is expeditiously available when needed for a quick refresher in anatomy, anatomical relationships, and/or surgical approach in the "heat of battle."

HEAD AND NECK

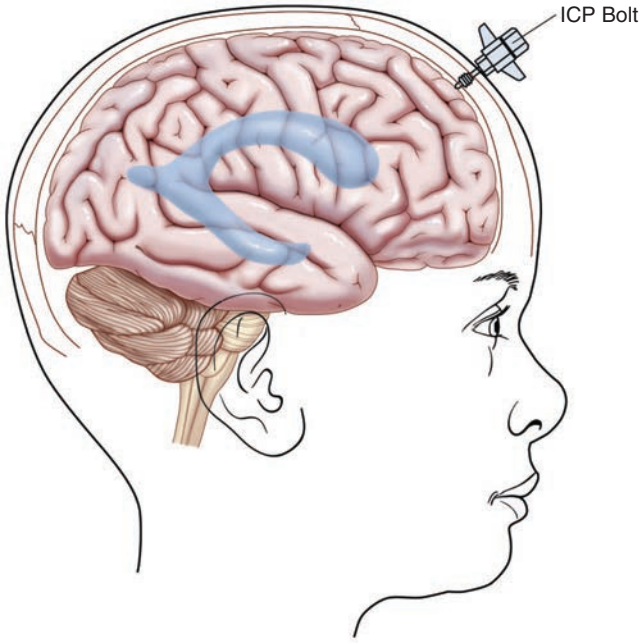

FIGURE 1 ICP Lateral
From a lateral perspective, this shows an ICP bolt inserted into the space around the brain via the skull bone to facilitate continuous ICP monitoring.

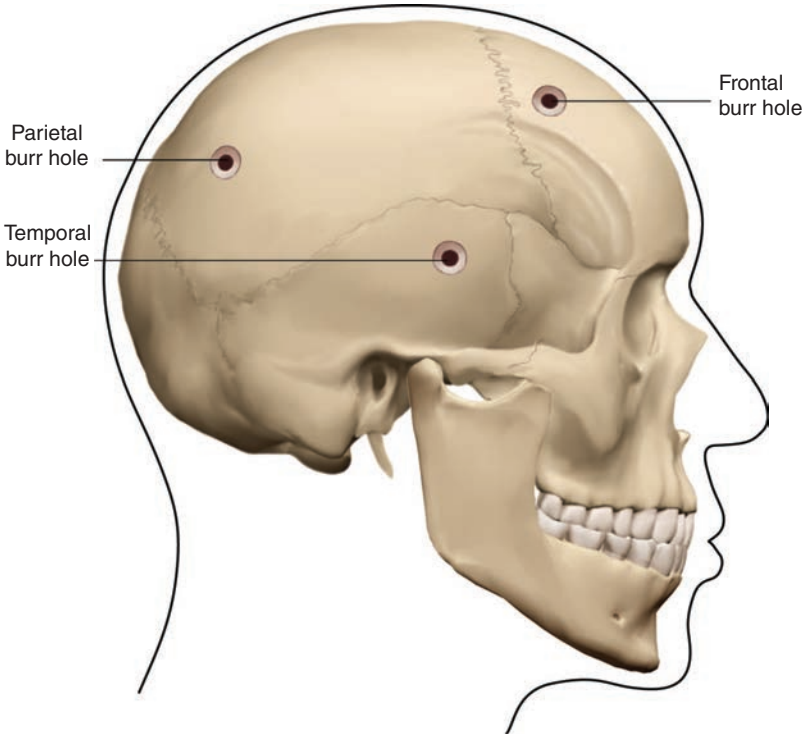

FIGURE 2 Burr Hole
The ideal location of a cranial burr hole depends on the anticipated injury in the three skull bones.

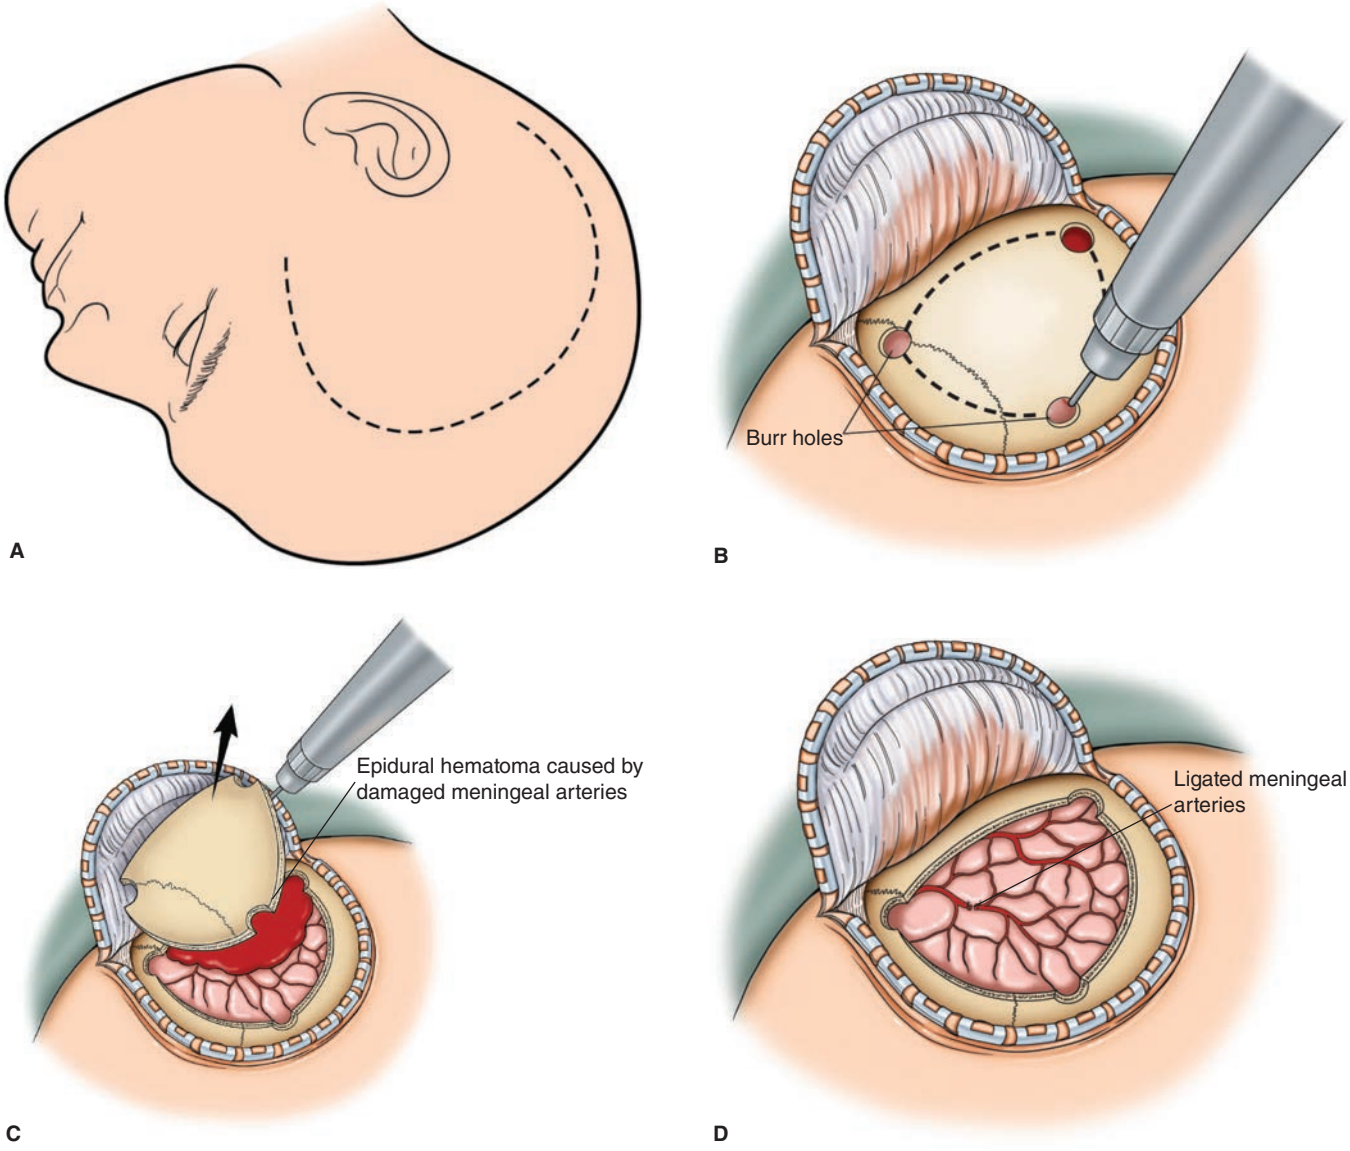

FIGURE 3 Steps in Performing a Lateral Parietal Craniotomy

A. The exact location and size of the skin flap vary, depending on extent of the wound, but must not extend to the midline at the top of the skull.

B. Skin clips are placed for hemostasis, and burr holes elevate the skull bone flap.

C–D. The bone flap is removed, the dura mater is opened to expose and release an epidural hematoma, and bleeding vessels are ligated. In the absence of significant brain swelling, the skull plate is reattached once hemorrhage is controlled and other necessary procedures have been accomplished. With significant brain swelling, the dura is closed, sometimes using dural substitutes, and the bone flap is not replaced at initial operation (decompressive craniotomy).

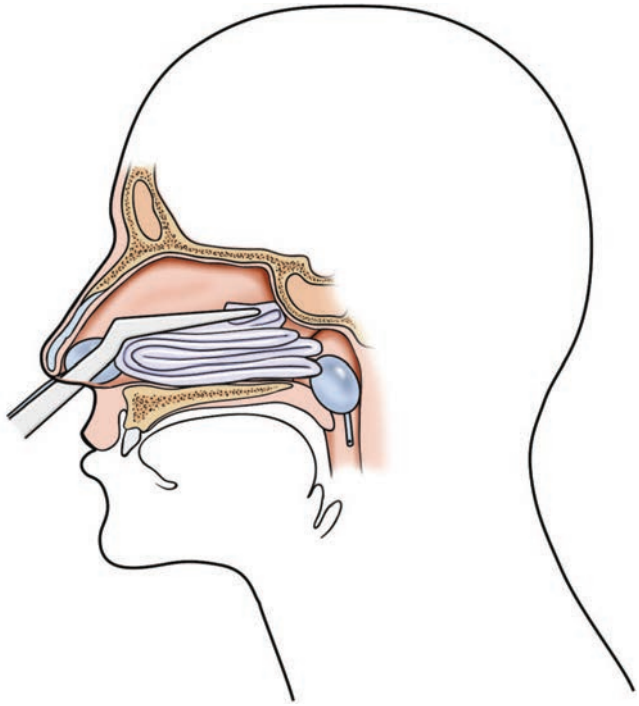

FIGURE 4 Nasal Packing for Hemorrhage Control
Under general or topical anesthesia, gauze impregnated with Vaseline to facilitate insertion is layered into a bleeding nasal passage to achieve hemostasis. Balloon devices are commercially available to provide posterior and anterior nasal packing.

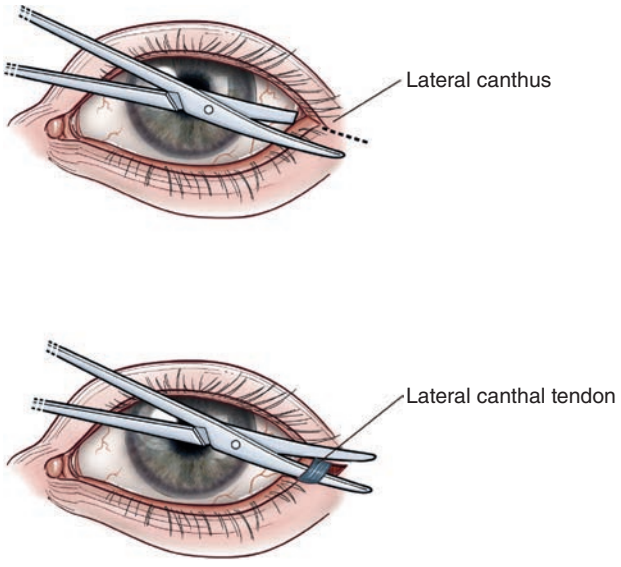

FIGURE 5 Lateral Canthotomy
This drawing of the eye demonstrates the location for creation of a lateral canthotomy in the eye covering. Note the lateral ligament, which may be cut with ocular scissors.

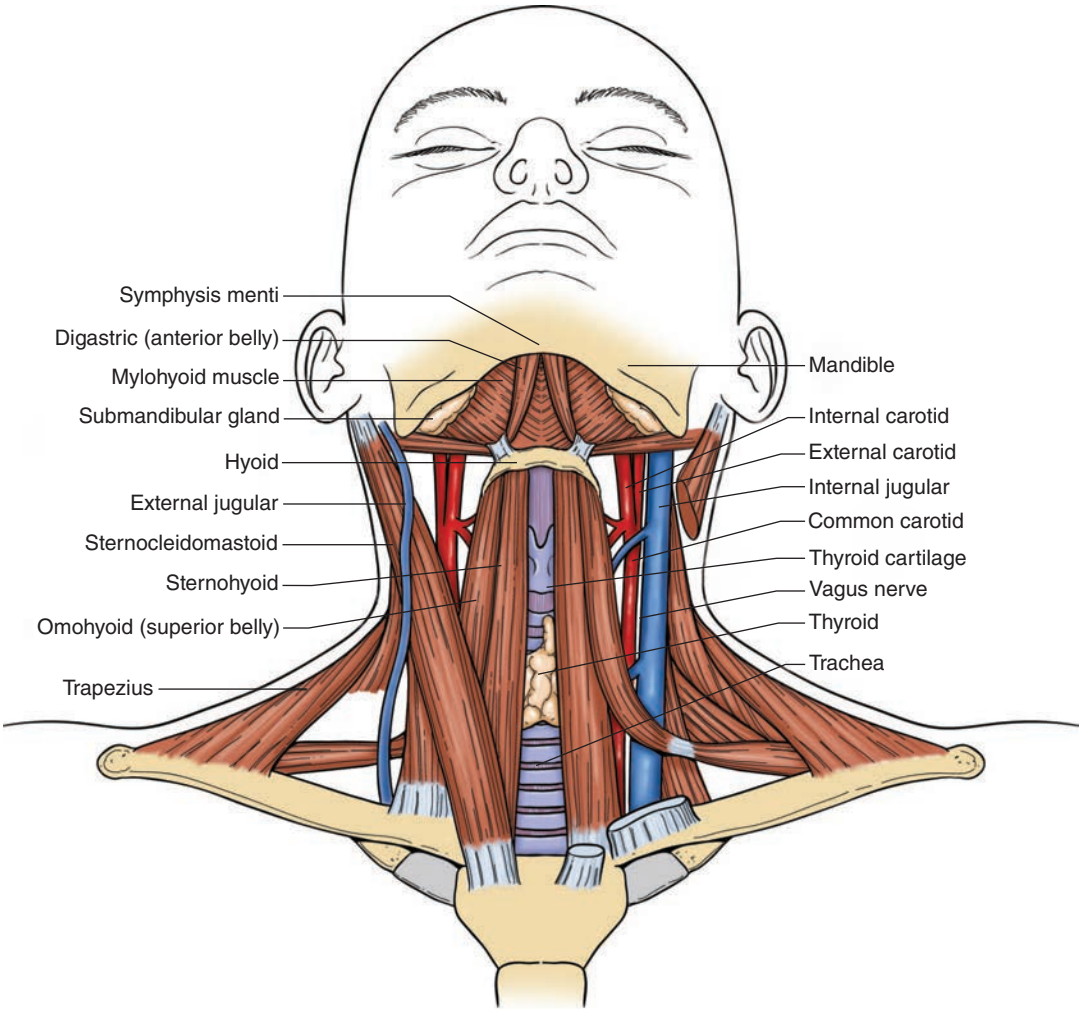

FIGURE 6 Anatomy of the Neck
Anterior perspective—Although usually approached from incisions just anterior to the sternocleidomastoid muscle, the surgeon must always review the cervical anatomy and its structural relationships prior to incision. The external jugular vein is a subcutaneous structure, and the internal jugular vein and carotid arteries are deep and medial in the neck.

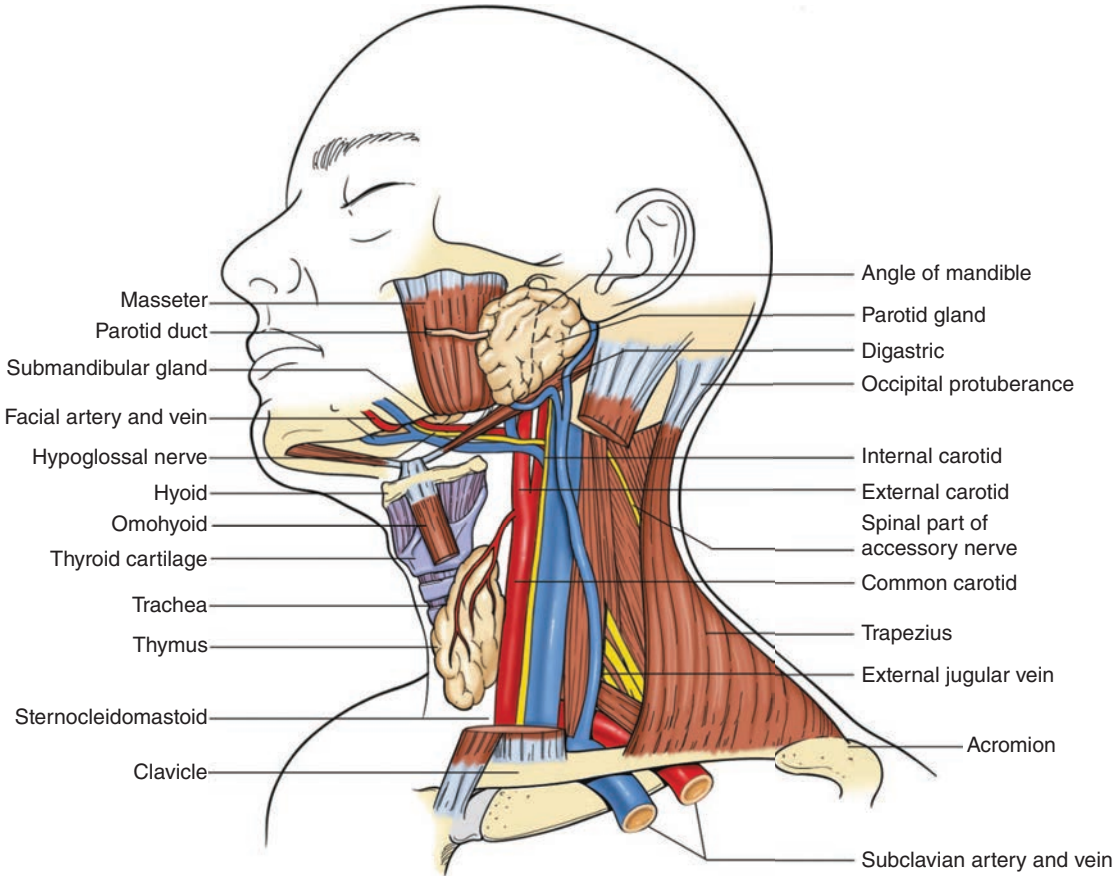

FIGURE 7 Lateral Anatomy of the Neck
This is the anatomy of the neck as seen from a left lateral view. Note the location and course of the facial vein, the division of which is the key to exposing the mid to upper structures in the deep neck.

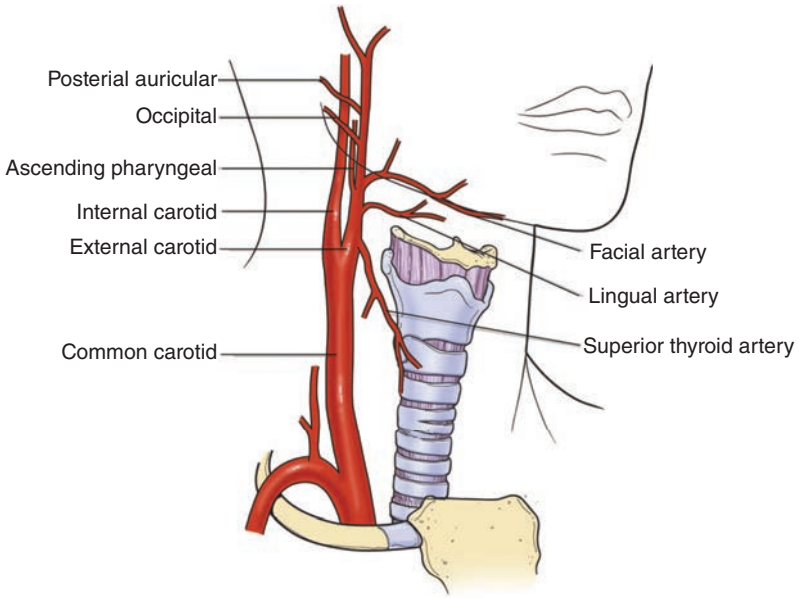

FIGURE 8 Carotid Artery
There are six branches of the external carotid artery. The right carotid artery is the mirror image of the left. Note that the internal carotid artery has no extracranial branches and is always lateral to the external carotid artery. The height of the bifurcation of the common carotid artery in the neck is variable. The facial vein, which can be divided between clamps with impunity, is not shown in this drawing. This division of the facial vein opens the deep anatomy of the mid lateral neck in the area of the bifurcation of the common carotid artery.

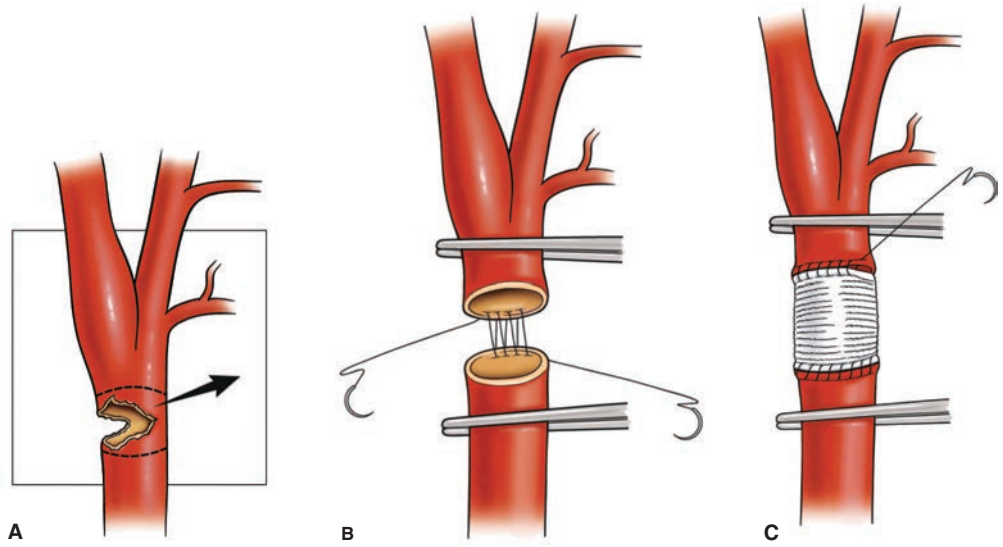

FIGURE 9 Repair Techniques for Injury to the Common Carotid Artery Proximal to the Bifurcation

A. The injured vessel is debrided after proximal and distal control is obtained. Local heparinized saline is injected distally.

B. If the injury is not extensive, end-to-end anastomosis with 5(0) polypropylene running suture using a "parachuting" technique is possible. Note, with adequate arterial collateral circulation, a temporary carotid artery shunt is not required.

C. If the artery is going to be under tension or stretched, an interposition graft of Dacron (shown), polytetrafluoroethylene (PTFE), or scavenged vein is inserted.

Prior to completely releasing the clamps and before prograde flow is reestablished to the brain, any microclots that might have formed during the procedure are adequately flushed out, both proximally and distally, then flow is directed into the external carotid artery, and, lastly, flow is directed into the internal carotid artery.

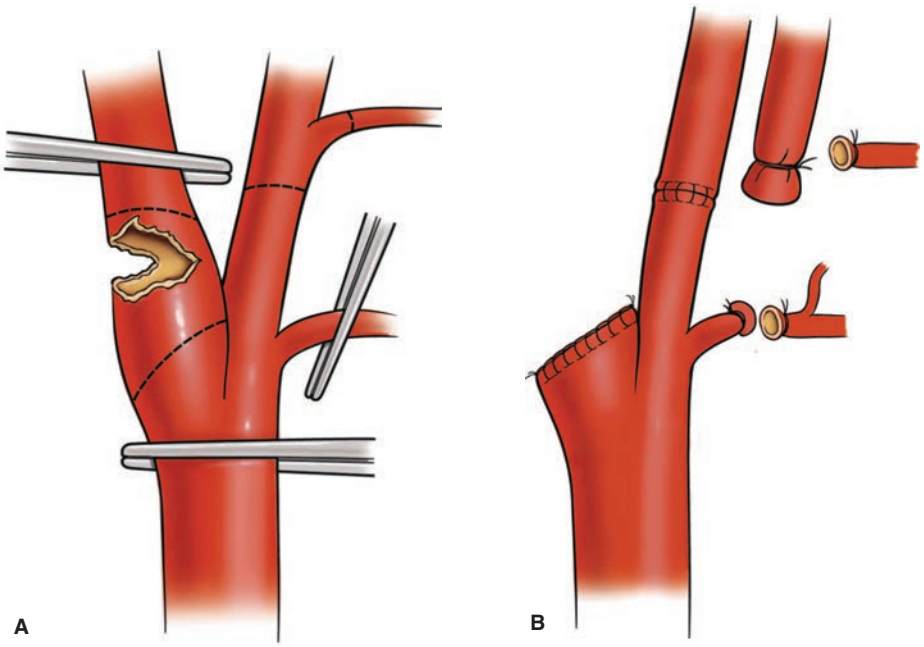

FIGURE 10 Transposition Technique for an Injury to the Proximal Internal Carotid Artery

A. Following proximal and distal control and instillation of local heparinized saline, the area of injury is resected, and the external carotid artery is mobilized for a distance sufficient to bridge the gap for the injured internal carotid artery.

B. The origin of the proximal internal carotid artery is oversewn, and one anastomosis is accomplished using the mobilized external carotid artery. Ligation of one or two branches of the external carotid artery may be required to accomplish significant mobilization.

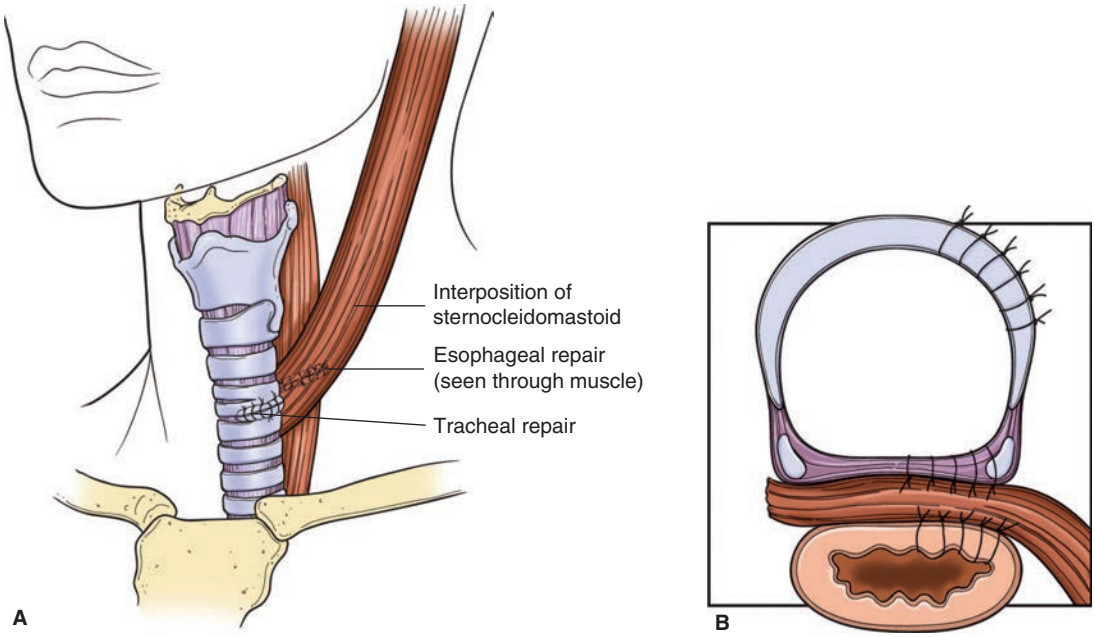

FIGURE 11 Repair of a Combined Injury to the Trachea and Esophagus

A. Following repair using interrupted absorbable sutures on the trachea and esophagus, a vascularized muscle pedicle (such as the sternal head of the sternocleidomastoid muscle) is interposed between these two tubular structures to reduce the postrepair complication of fistula formation.

B. The procedure demonstrated in cross section.

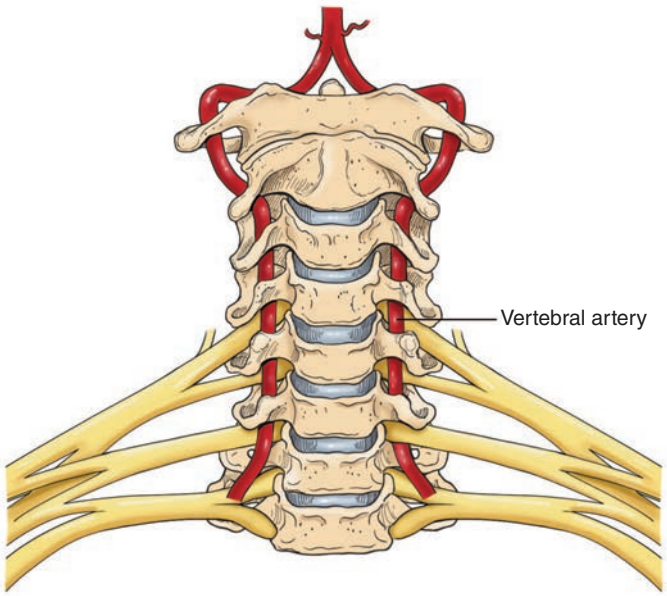

FIGURE 12 Vertebral Artery

This demonstrates the bilateral vertebral arteries arising as the first branch off the corresponding subclavian artery in the neck, entering the transverse foramina of the sixth cervical vertebra, and exiting the transverse foramina of the second cervical vertebra, to join the opposite vertebral artery to form the basilar artery. Note that all portions of the vertebral arteries are anterior to the cervical nerves.

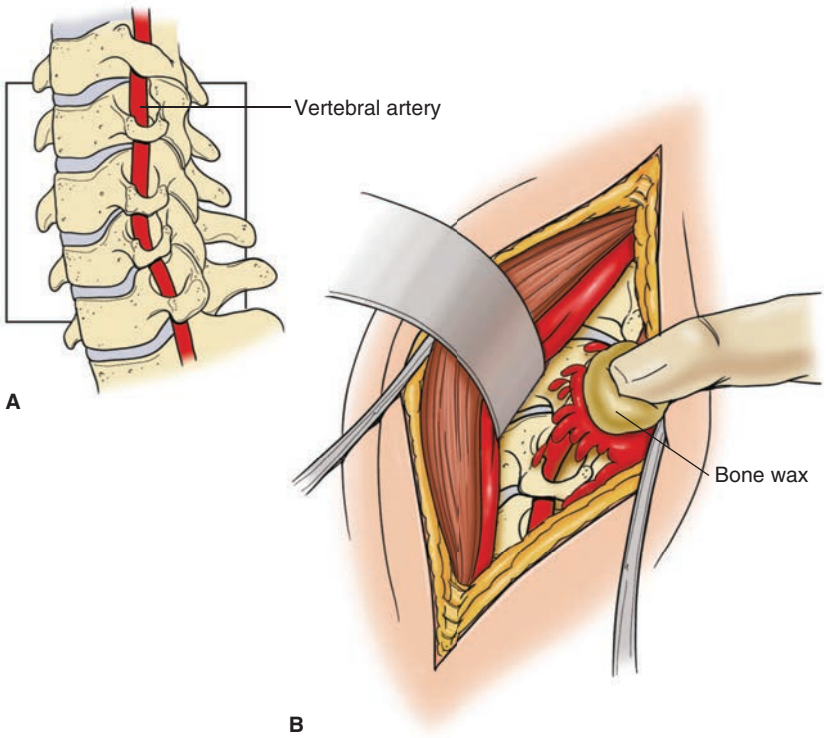

FIGURE 13 Control of Injured Vertebral Artery

A. The vertebral artery lies deep in the neck inside the transverse foramina of the cervical vertebrae. For uncontrolled bleeding from an injured vertebral artery within the transverse foramina of the neck, dissection and unroofing of this bony covering can be difficult and even produce additional injury and complications.

B. Bone wax pressed into the area of injury can rapidly control persistent bleeding.

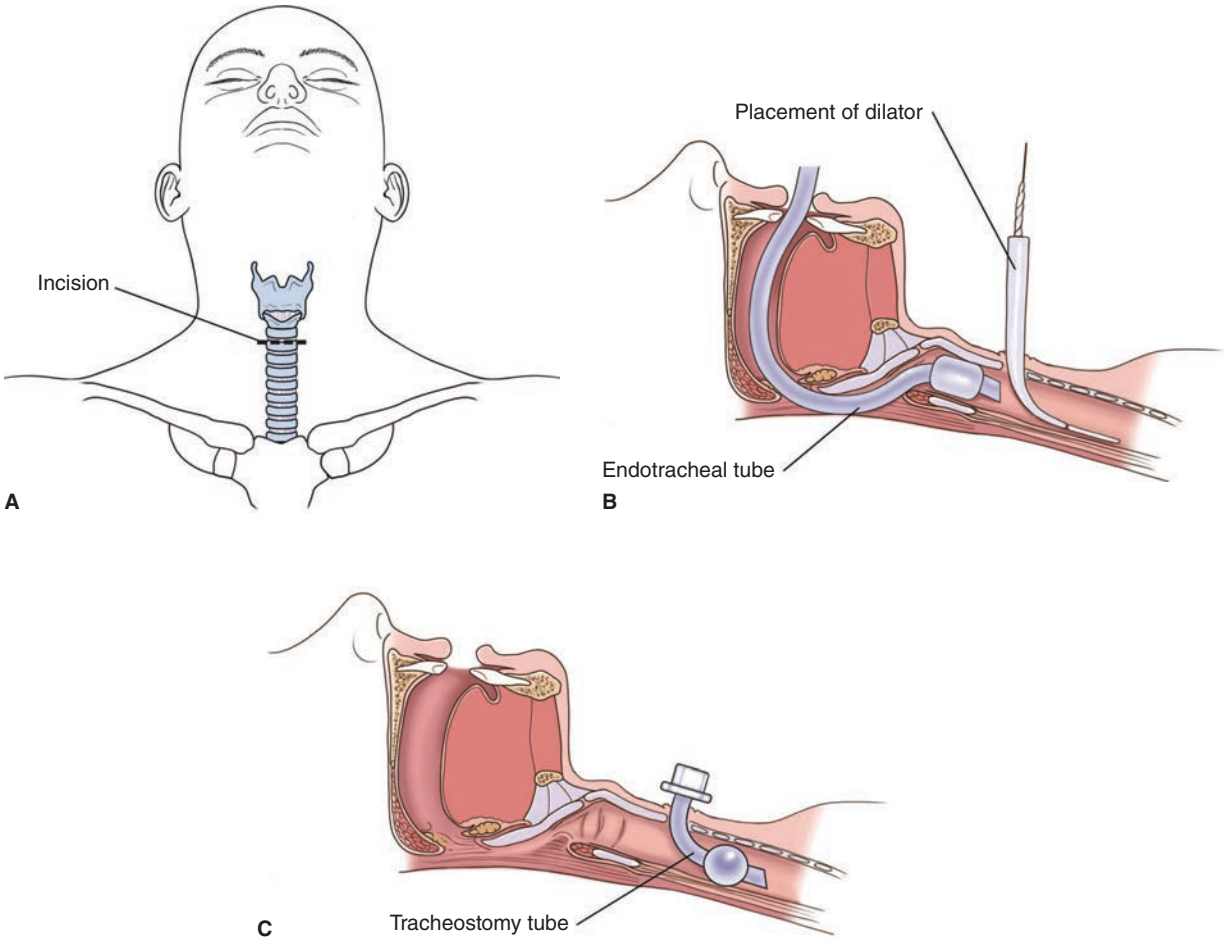

FIGURE 14 Percutaneous Tracheostomy

A. This drawing depicts the initial approach to a percutaneous tracheostomy. The trachea, location of the larynx, and the first few tracheal rings are palpated. The initial needle insertion site is between the first and second tracheal rings.

B. This is a lateral view of the dilation maneuver of the trachea as part of a percutaneous tracheostomy. A needle has been inserted between the first and the second tracheal rings, with a wire inserted through the needle. A dilating device is inserted over this wire into the trachea, and a tracheostomy tube is inserted into this stoma. During the insertion of the initial needle, care is taken to avoid perforation of the occluding balloon on the endotracheal tube.

C. This is a lateral view of a completed percutaneous tracheostomy. Note that a tracheostomy tube has been inserted through the orifice created by the dilator inserted between the first and second tracheal rings. The endotracheal tube inserted via the mouth has been removed.

CHEST AND THORACIC OUTLET

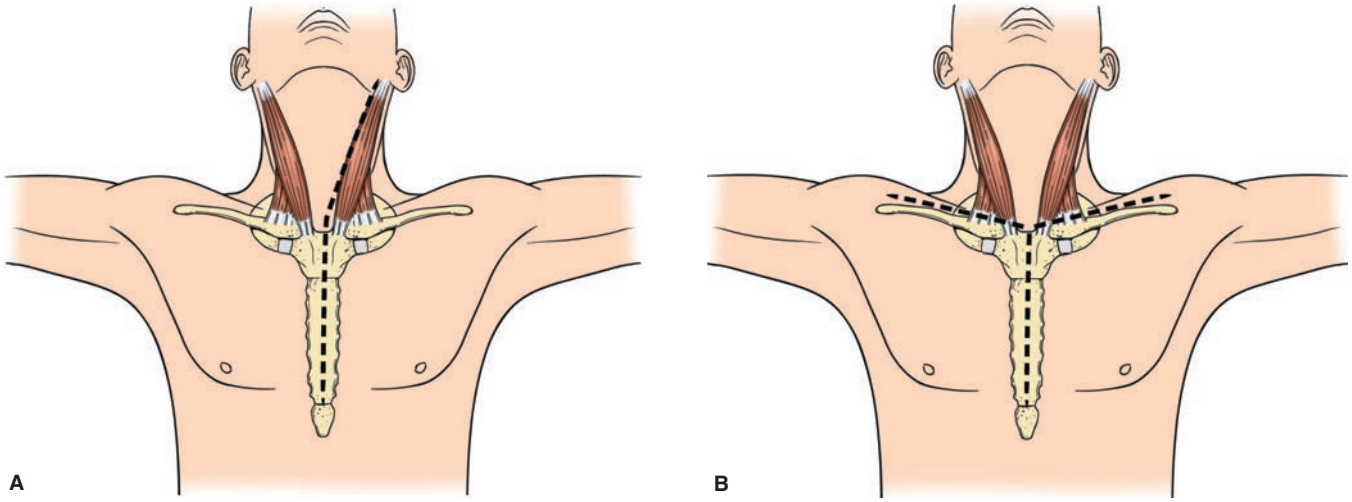

FIGURE 15 Cervicothoracic Incisions

A. For thoracic outlet injuries (zone 1 cervical injuries), median sternotomy may be combined with either a right or left classic anterior neck incision, which allows for proximal vascular control.

B. For injury to the proximal extrathoracic subclavian artery, supraclavicular extension of a median sternotomy allows for proximal control as well as exposure should division or removal of the clavicle be required for exposure and repair of the injury.

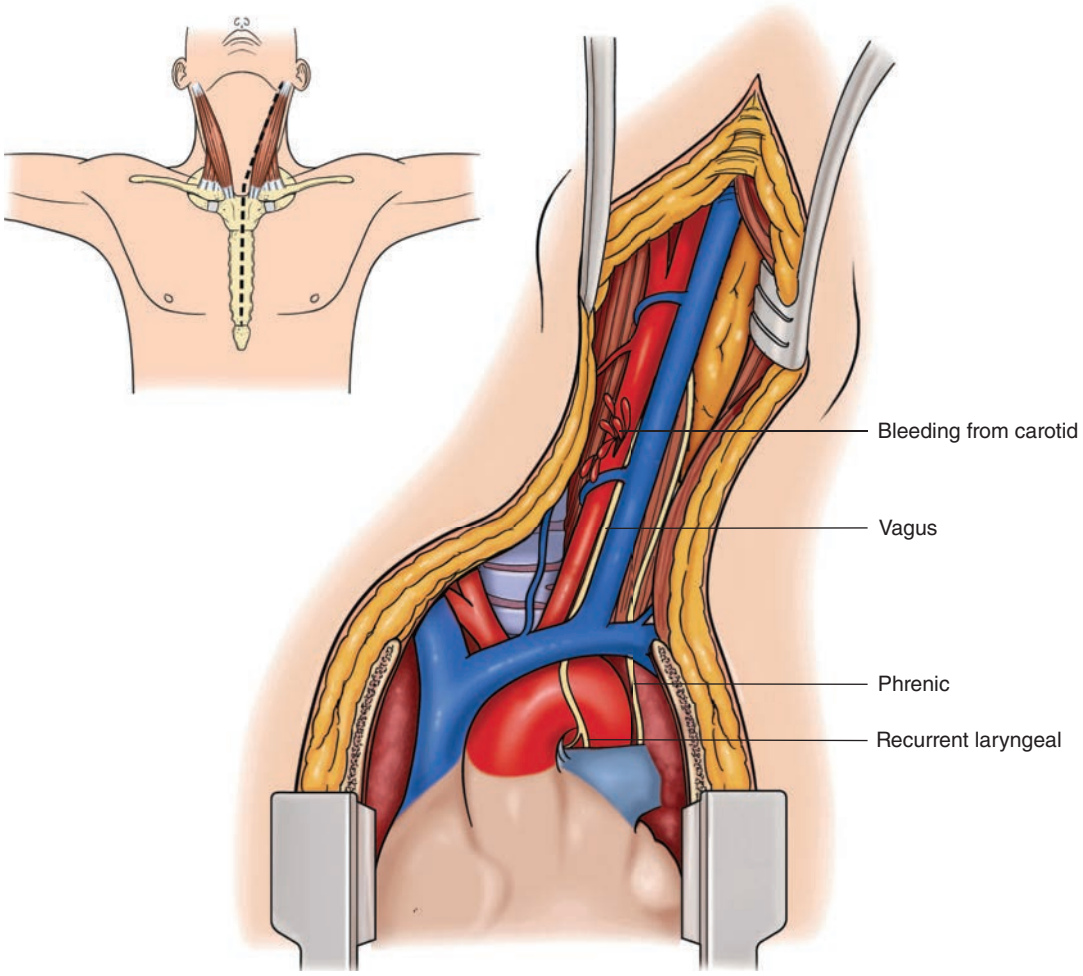

FIGURE 16 Median Sternotomy with a Cervical Extension for Access to an Injury to the Left Proximal Common Carotid Artery
A neck incision or a median sternotomy, alone, is insufficient for control and reconstruction of injury to the left proximal common carotid artery; however, a combined incision, aided by two retractors, affords excellent exposure. Note the location of the left vagus nerve with its recurrent laryngeal nerve around the aortic arch. Also, note the lateral location of the left phrenic nerve.

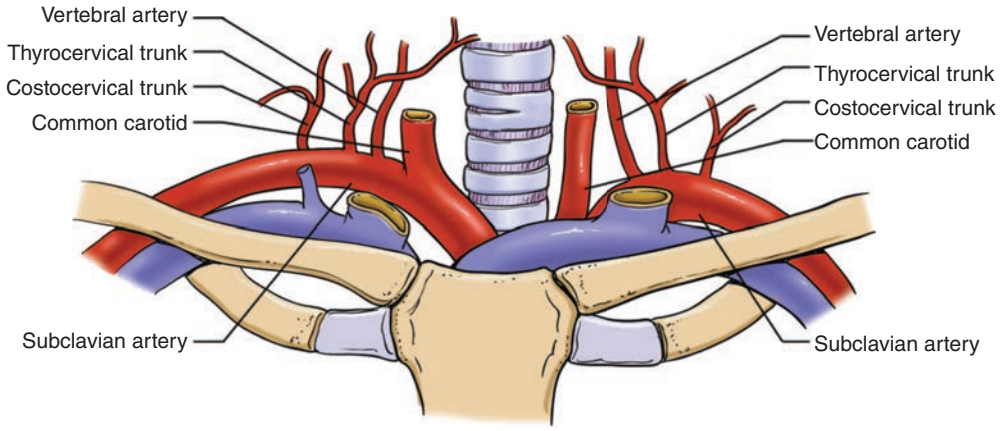

FIGURE 17 Subclavian Artery Anatomy
This illustrates the cervical anatomy of the subclavian arteries, with arms at the patient's sides, which places the clavicles at their lowest positions. The arms in the outward, extended positions result in clavicles covering the subclavian arteries. Note that both the right and left subclavian arteries have four branches (internal mammary arteries coming off the undersides of the subclavian arteries are not shown).

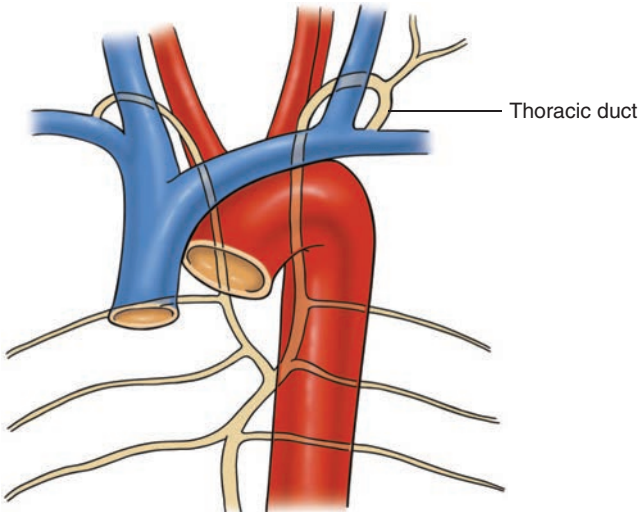

FIGURE 18 Anatomy of the Thoracic Duct
At the base of the mesentery, anterior to the abdominal aorta and very near the left renal vein, the cisterna chyli collects lymph from the mesenteric lymphatic channels and carries lymph upward, continuing anterior to the thoracic aorta on to the thoracic outlet, via the thoracic duct. Other numerous lymphatic collateral channels join this thoracic lymphatic duct, where it bifurcates in the upper posterior chest. Although the left thoracic duct is the larger, a thoracic duct empties into the right superior subclavian vein just as it receives the corresponding internal jugular vein. Note that the thoracic duct is anterior to the subclavian artery and posterior to the subclavian vein.

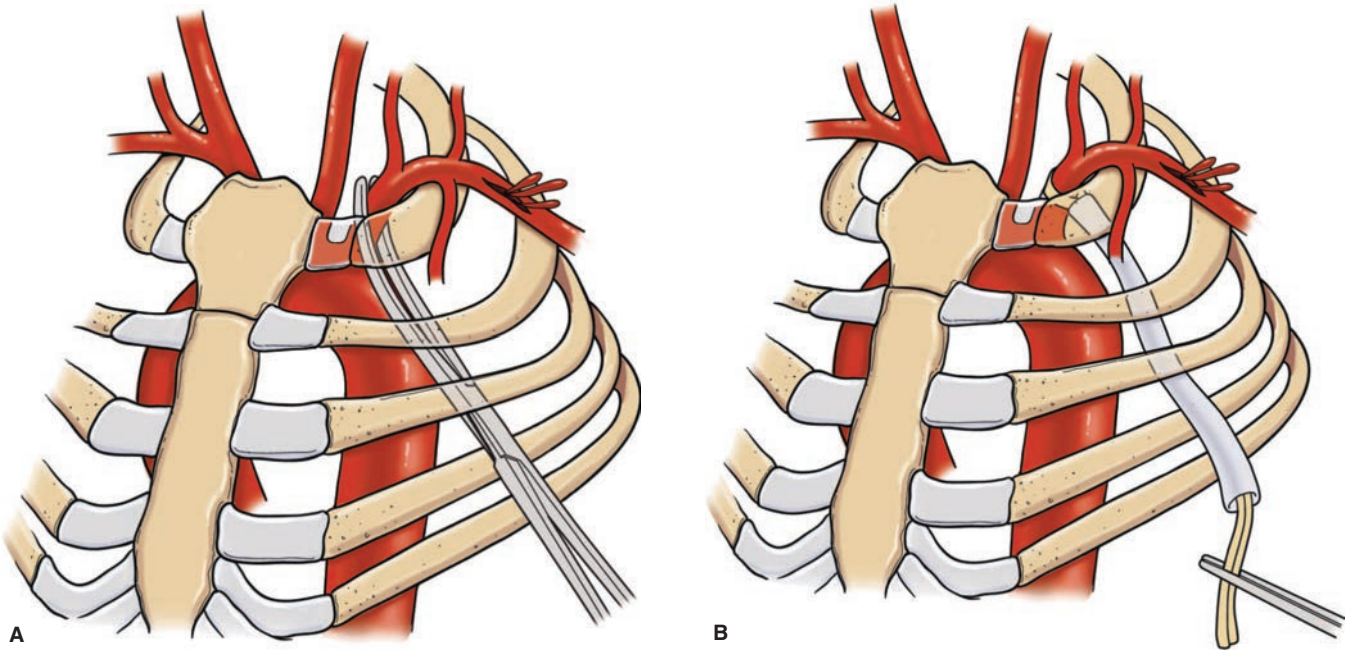

FIGURE 19 Controlling Hemorrhage from the Left Subclavian Artery
A. Temporary vascular control is achieved via short anterior third interspace incision with a vascular clamp applied to the intrathoracic left subclavian artery.
B. Alternately, control can be achieved using a Rumel tourniquet.
Note: In the emergency room, this injury can be immediately temporarily controlled with the tamponading finger or an inflated 30-mL Foley balloon.

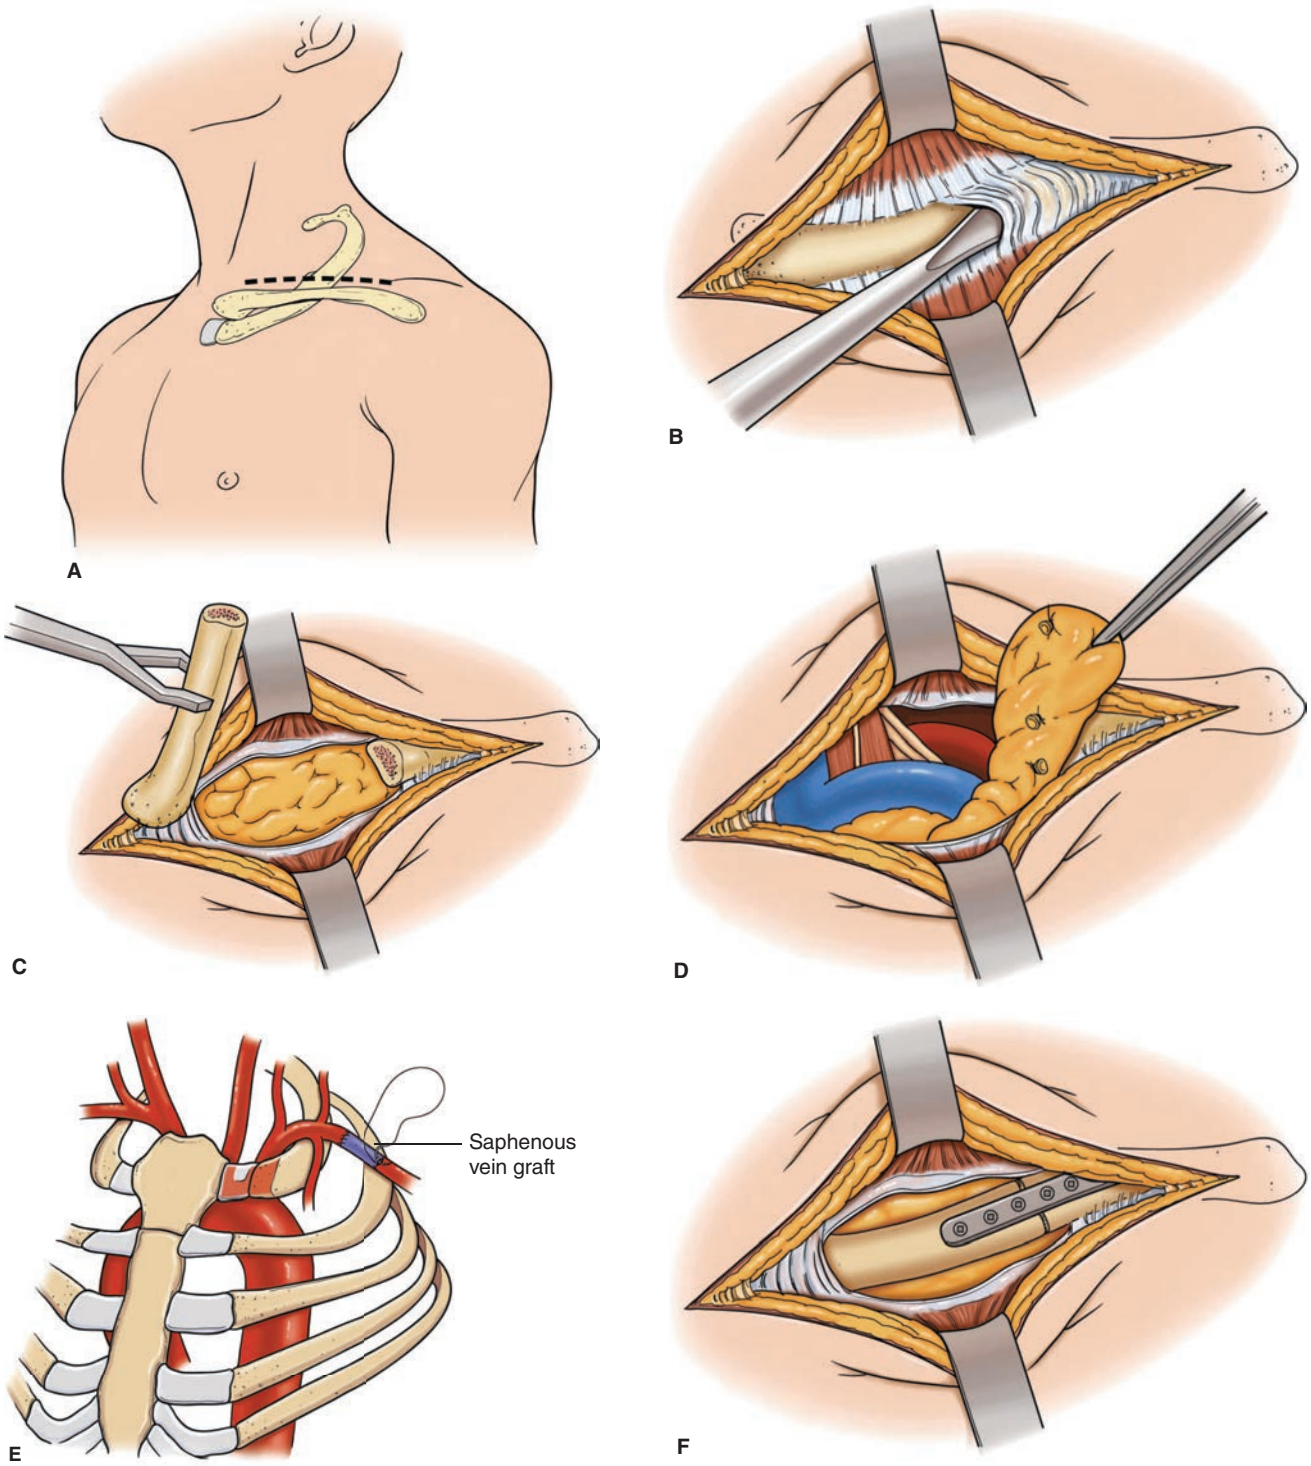

FIGURE 20 Exposure and Repair of an Injury to the Subclavian Artery

A. Although endovascular stent graft options are increasingly being used for injury to the subclavian artery, they are not always available, so direct exposure may be required. With the arm prepped free but positioned at the patient's side, clavicular division or resection might aid in exposure. A liberal supraclavicular incision is made over the clavicle.

B. The bone is exposed using a periosteal elevator.

C. The clavicle is divided in its middle portion, and the proximal end may be retracted medially.

D. The key to the fossa containing the subclavian artery is to remove the scalene fat pad. The phrenic nerve lays on the middle one-third of the scalene anticus muscle, the lateral half body of which is divided to aid exposure.

E. The subclavian artery is extremely fragile, and a saphenous vein is the preferred conduit to use in an open reconstruction.

F. Following vascular reconstruction, the clavicle can be reconstructed with an orthopedic plate or a sternal wire with the twisted knot placed anteriorly.

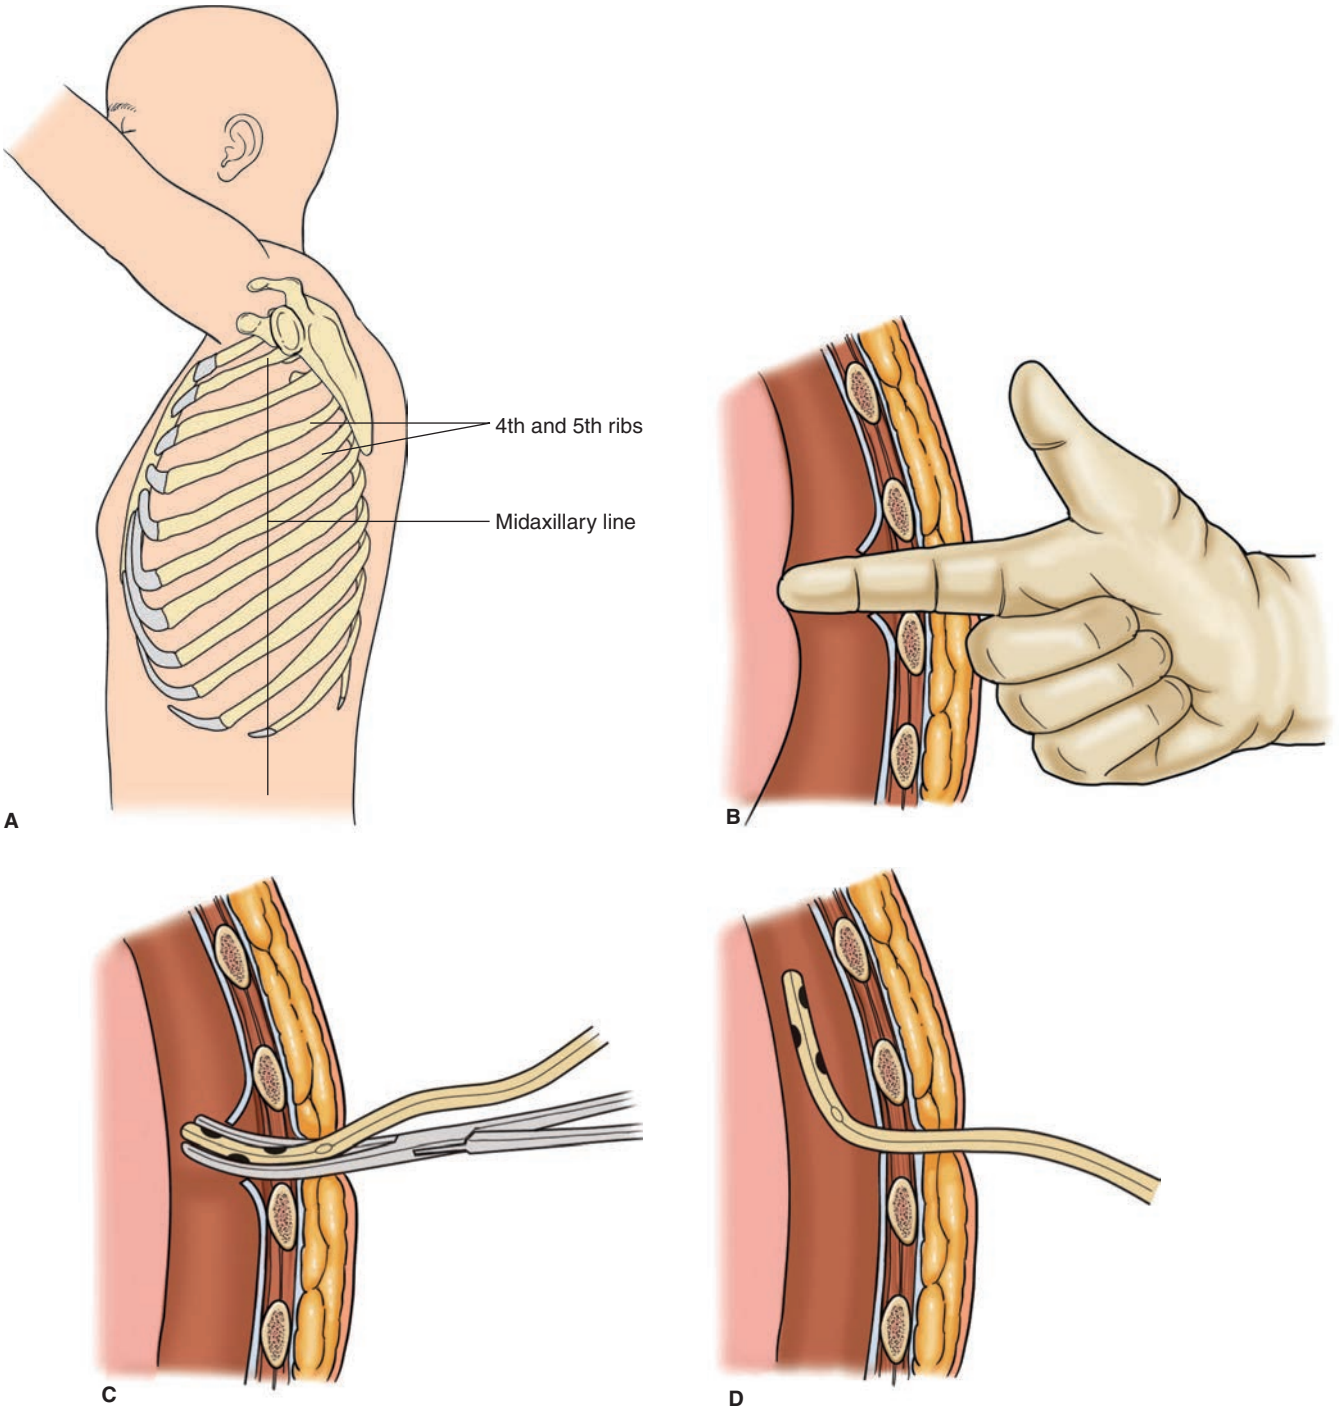

FIGURE 21 Tube Thoracostomy, the Most Commonly Performed Thoracic Operative Procedure

A. The lateral anatomy in the auscultatory triangle at the fourth intercostal space in the midclavicular line is the point for chest tube insertion.

B. Following adequate local anesthesia, a transverse incision through the skin and subcutaneous tissue is made. A large Kelly clamp is then used to spread the intercostal muscles and make a hole in the pleura. Up to 25% of patients have some element of pleural symphysis, and entering the pleura with a trocar or other similar instrument risks producing an iatrogenic lung injury. A finger digital exploration to localize the pericardium or a diaphragmatic injury and/or release pleural adhesions is performed before the thoracostomy tube is inserted.

C. After an appropriately sized hole is created, a chest tube is introduced with the aid of a large curved clamp attached to the tip and directing the tube to the posterior apex location of the pleural space. The tube is attached to an appropriate collection, water seal, and negative pressure device.

D. The chest tube is aimed toward the apex of the pleura, with the last hole in the tube inside the chest wall.

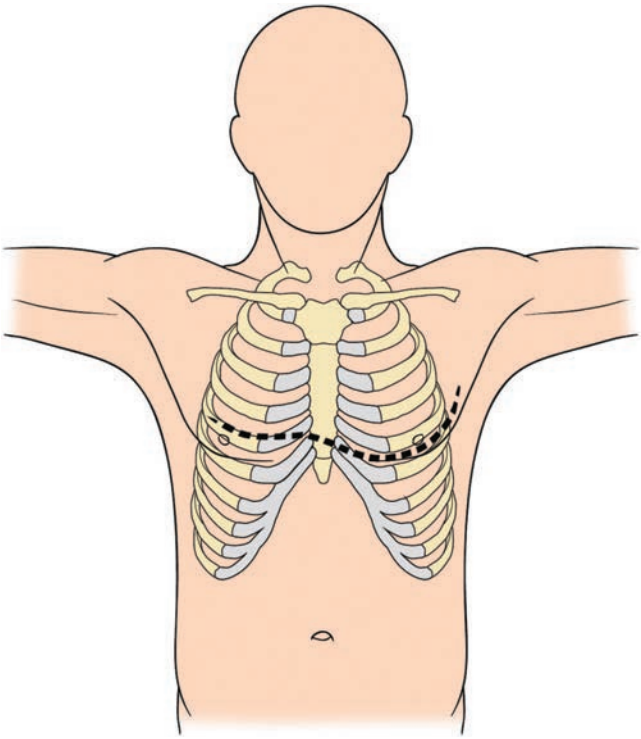

FIGURE 22 Resuscitative Thoracotomy 1
This depicts the standard left anterolateral thoracotomy. The dotted line depicts the incision for a left anterolateral thoracotomy into a bilateral anterolateral (clamshell) thoracotomy. Note that the left incision is in the area of the fourth or fifth interspace, and below the mammary crease.

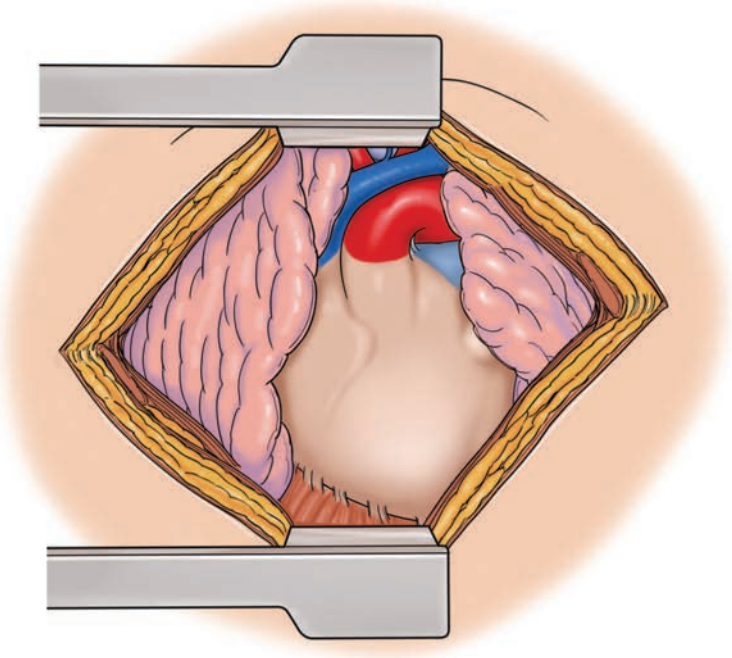

FIGURE 23 Resuscitative Thoracotomy 2
This is the anterior mediastinum and both anterior thoraces following bilateral anterolateral or clamshell thoracotomy. Note that one can visualize both lungs, the pericardium, the heart and all of its chambers, the superior and inferior vena cava, the ascending aorta, the pulmonary artery, the innominate vein, the innominate artery, and the left common carotid artery. This drawing does not show, but assumes the ligation of both divided ends of the right and left internal thoracic (mammary) arteries.

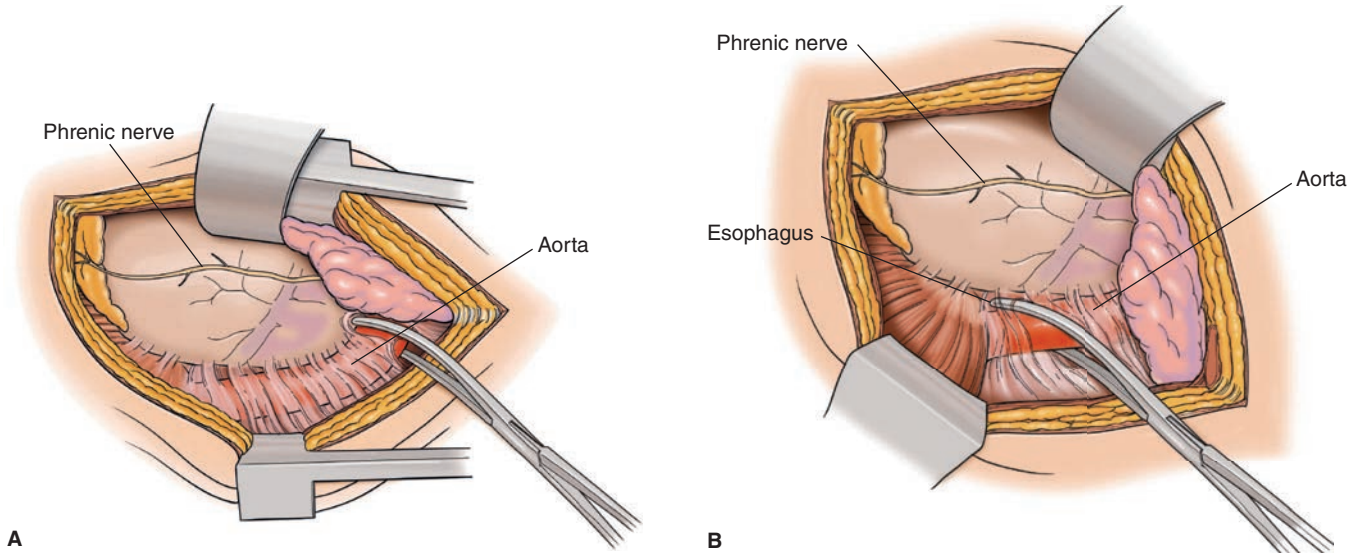

FIGURE 24 Cross-clamping of the Descending Thoracic Aorta

A. With the patient in the supine position, a left fourth or fifth interspace curvilinear incision is made beneath the nipple and breast fold aiming to the axilla. The aorta is clamped higher in the chest, at the proximal descending thoracic aorta, using a vascular clamp.

B. Alternately, the aorta may be cross-clamped low in the chest. The lung is pushed upward, showing the heart within the pericardium, the phrenic nerve, the diaphragm, and the aorta. The esophagus is seen anterior to the aorta and the spine, with the segmental arteries coming off at each interspace. The aorta is cross-clamped low in the thorax using a vascular clamp.

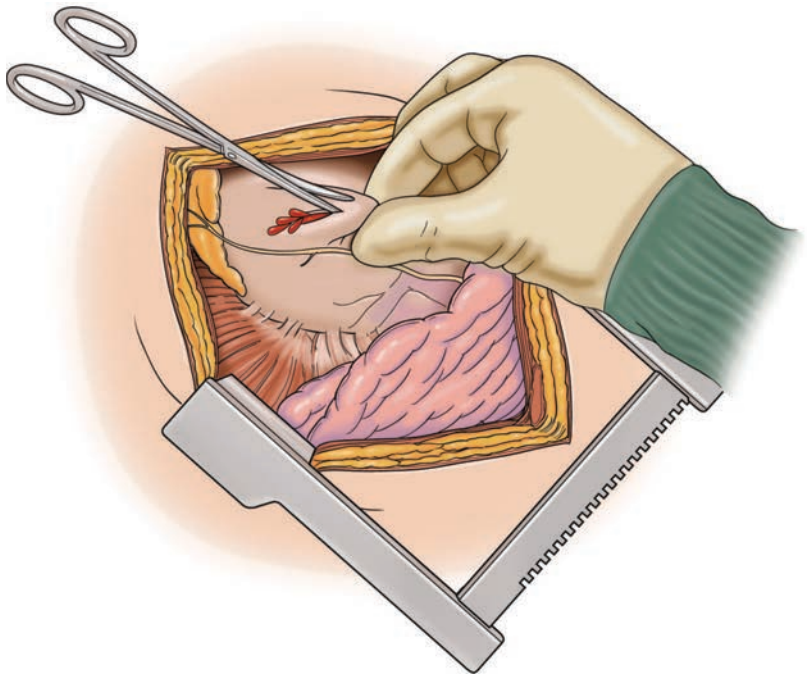

FIGURE 25 Opening the Pericardium to Explore the Heart

Using scissors or a scalpel, the left pericardium is incised, with the lung positioned posteriorly. The incision is made anterior and parallel to the phrenic nerve. With a tense hemopericardium, purchase of the pericardium is difficult, making this maneuver challenging. The ratchet mechanism of the chest wall retractor is positioned posteriorly.

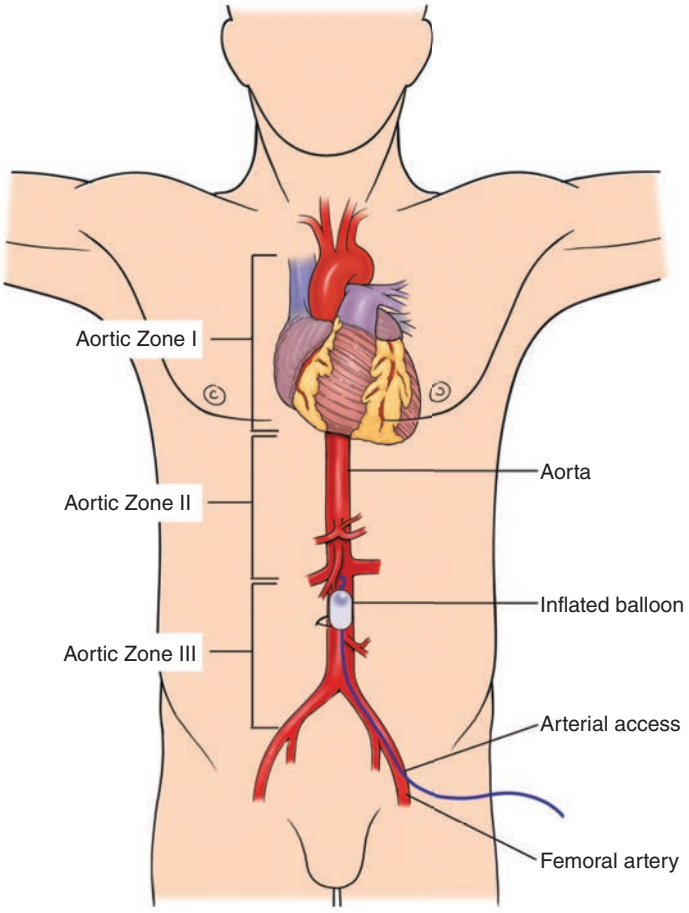

FIGURE 26 REBOA (Resuscitative Endovascular Balloon Occlusion of the Aorta)
REBOA is an occluding aortic balloon introduced via the common femoral artery either percutaneously or by direct cutdown. In this instance, the balloon has been inflated distal to the renal arteries (zone III).

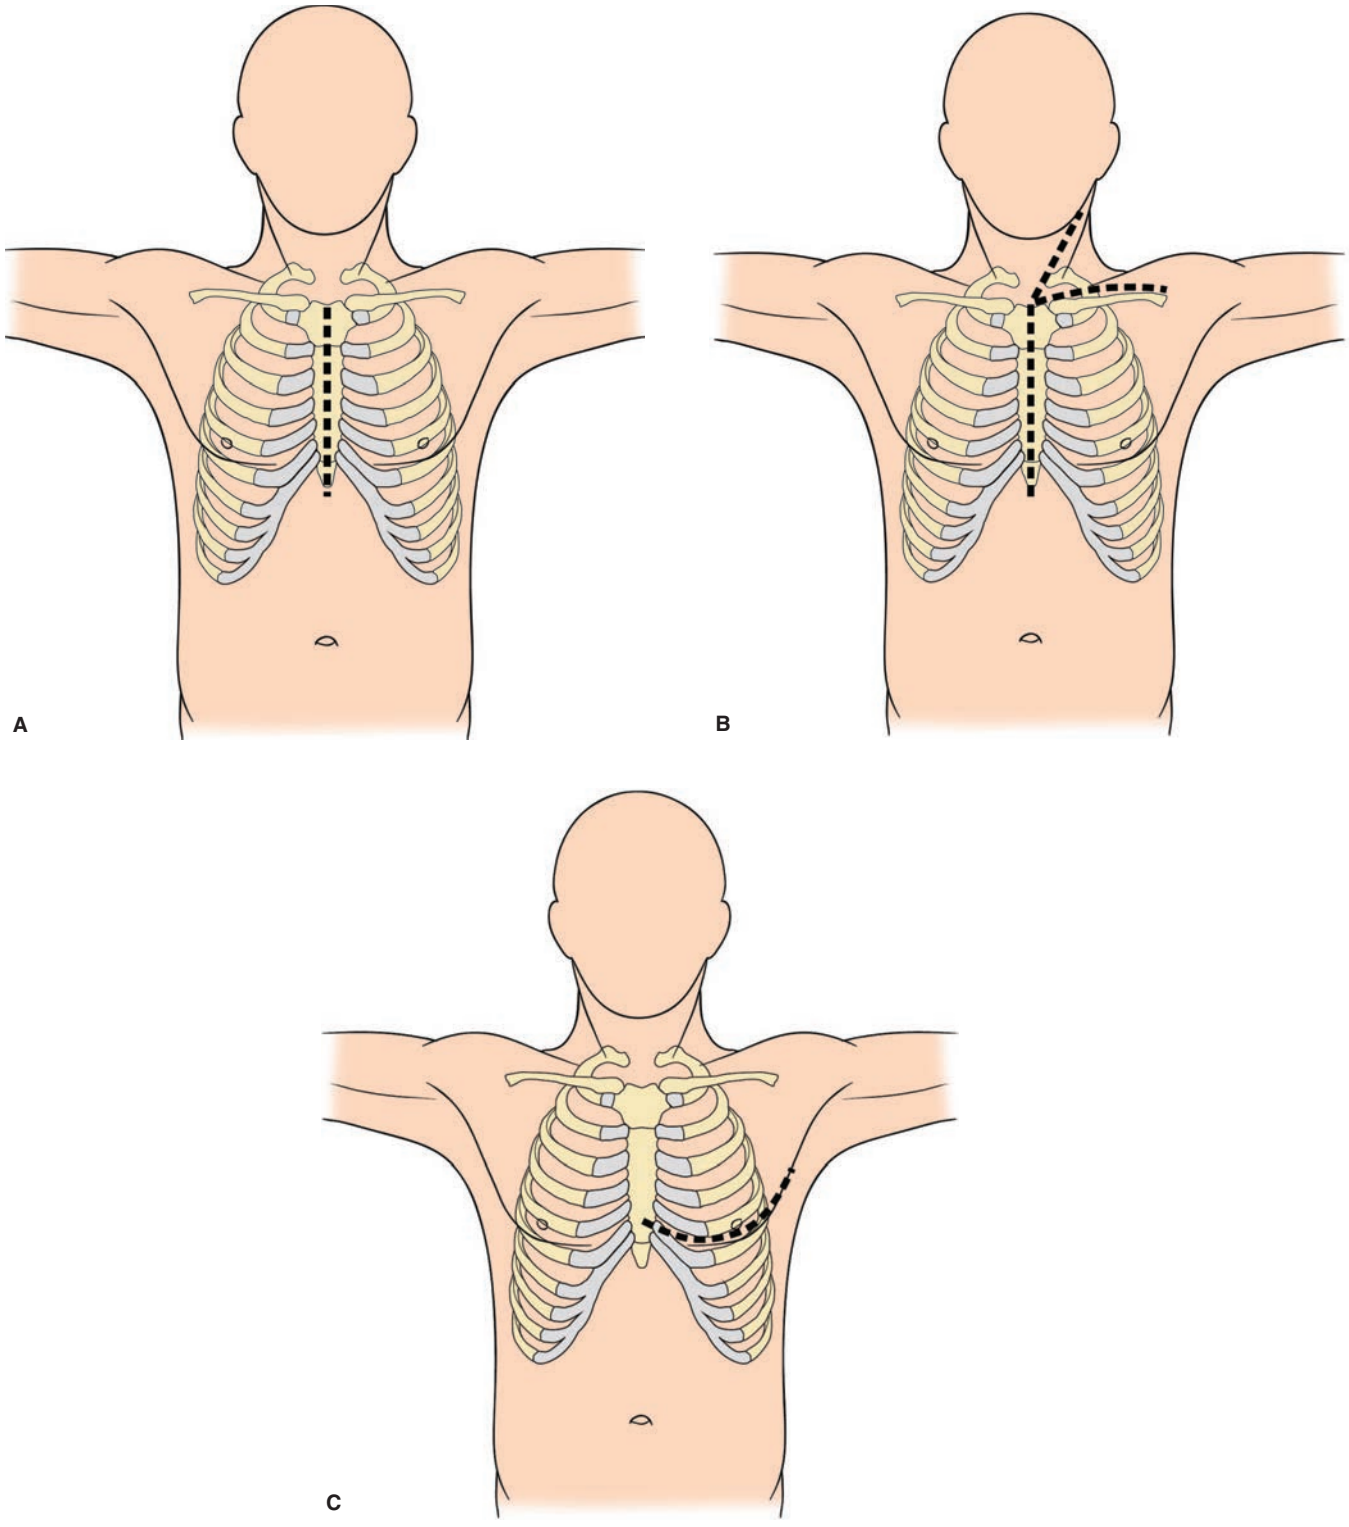

FIGURE 27 Options for Thoracic Incisions

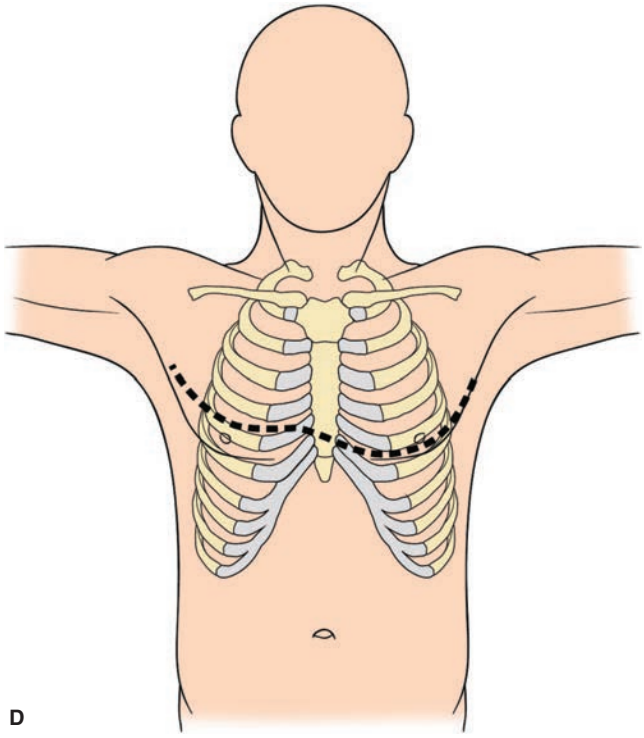
A. The median sternotomy is the standard incision for anterior cardiac and thoracic outlet vascular injury, but is not an appropriate incision for approach to posterior mediastinal structures or the pulmonary hilum.

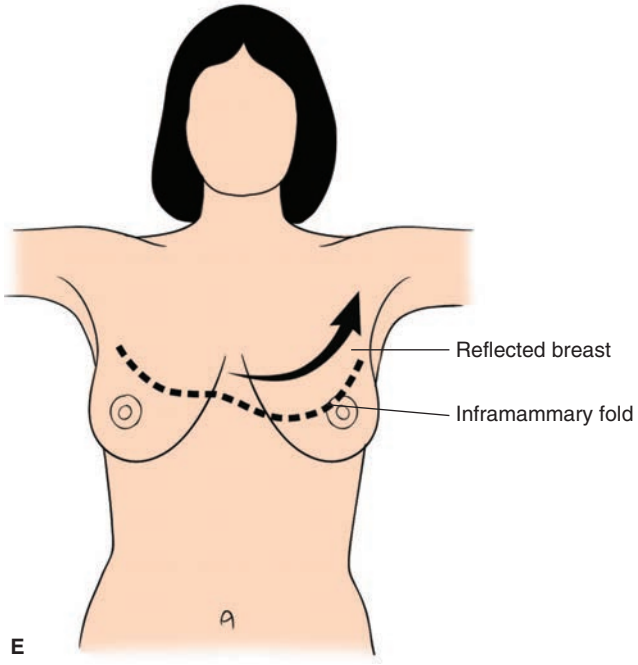
B. A median sternotomy with an anterior neck or supraclavicular extension is used for thoracic outlet great vessel injuries to zone I of the neck.

C. The anterolateral incision, particularly on the left, is the utility emergency thoracotomy for trauma and resuscitation. It is made from the sternal edge, under the mammary fold, and in a curvilinear fashion toward the axilla, staying in close proximity to the fourth or fifth intercostal space. This incision should not be a straight line incision nor be carried through the female breast.

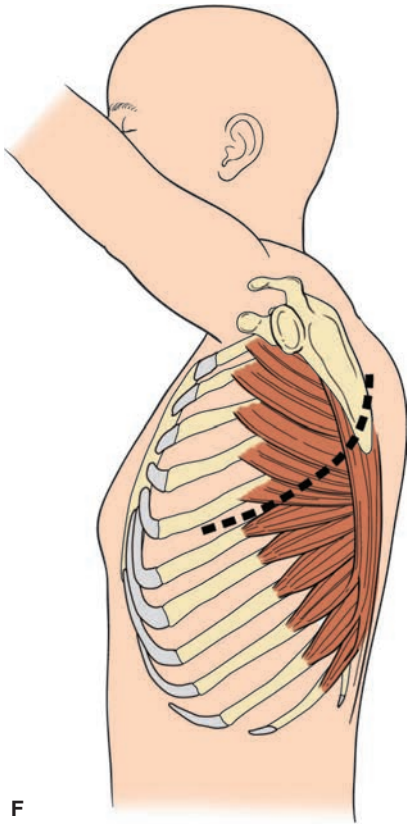
(continues on next page)



D



E



F

FIGURE 27 Options for Thoracic Incisions (*continued*)

D. Bilateral anterolateral incisions may be either separate or combined and transternal. When transternal, the sternum is traversed with a Gigli saw or other cutting device, and the internal thoracic arteries are ligated on both sides on the upper and lower incision sites (four ligatures). Both incisions should be curvilinear, with the transternal cut high enough on the sternum to expose the mid-portion of the heart and also with sufficient sternum to accomplish a solid bony closure. On occasion, when a right-sided injury is suspected high in the pleural cavity, the incision might even be above the right nipple.

E. In the female, the anterolateral incision is at the inframammary fold and is accomplished by moving the breast tissue cranially.

F. With the patient in a lateral decubitus position, a posterolateral fourth or fifth interspace incision can be made from near the area of the nipple, laterally around to near the spinal canal. This incision for trauma traverses the latissimus dorsi muscle and portions of other chest muscles. The scapula must be retracted superiorly to achieve fourth or fifth interspace incisions. This incision provides exposure of posterior mediastinal structures, such as the aorta, lung hilum, esophagus, trachea, and azygos vein.

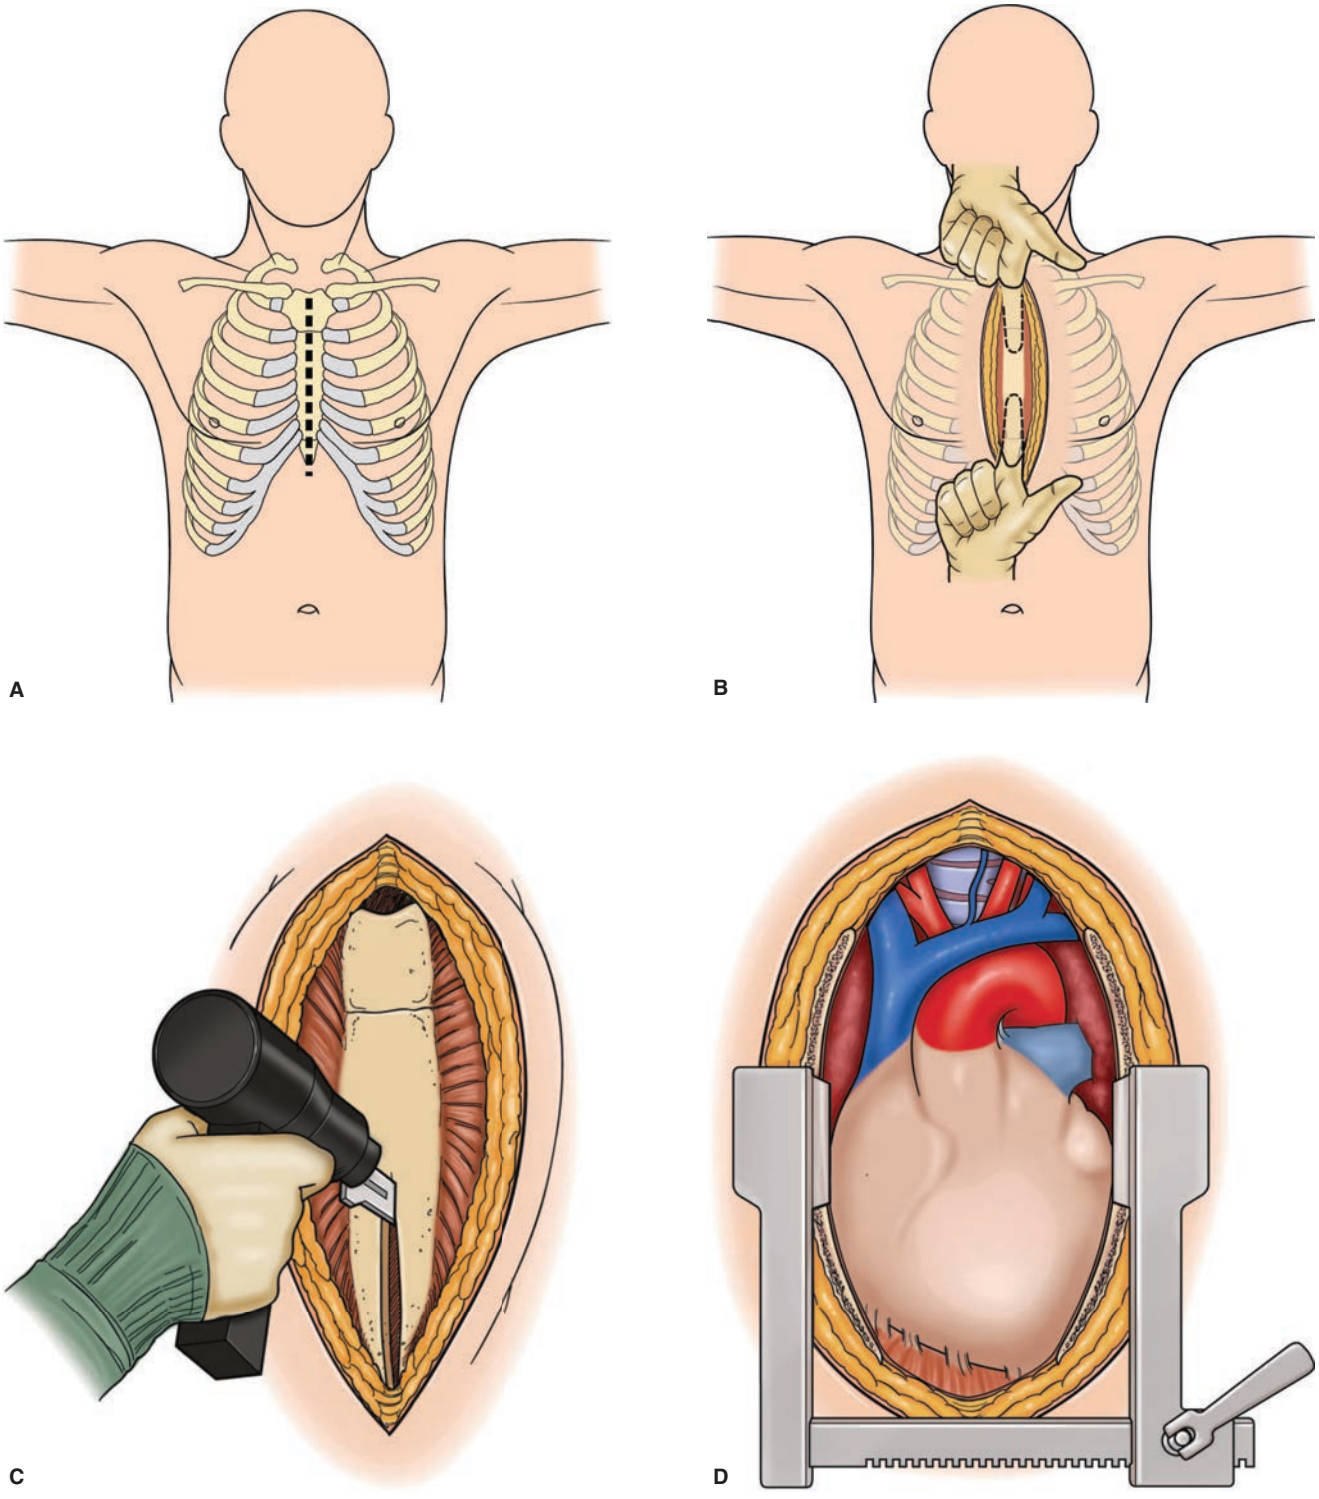


FIGURE 28 Technique for Performing Median Sternotomy

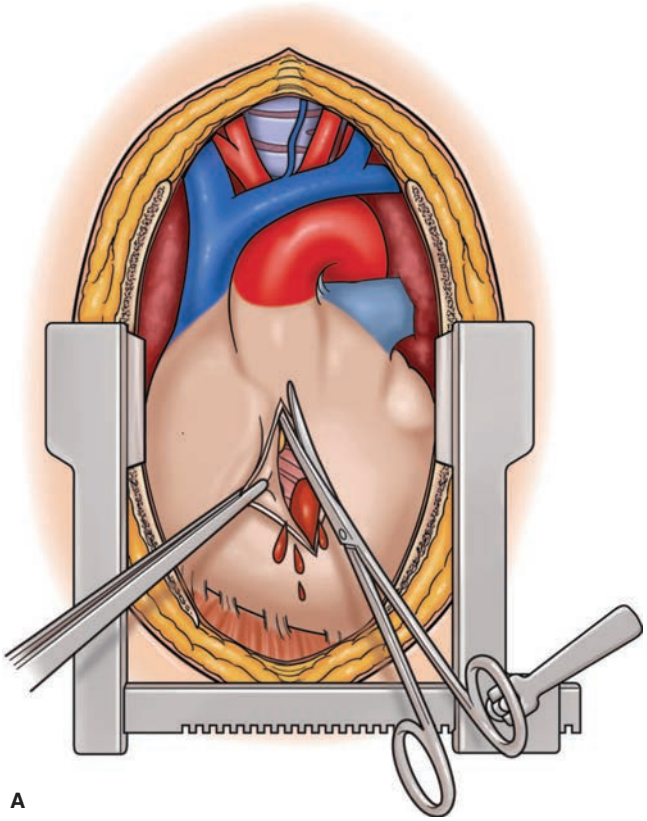
A. With the patient appropriately prepped and draped, a skin incision is made from the manubrial notch to below the xiphisternum.

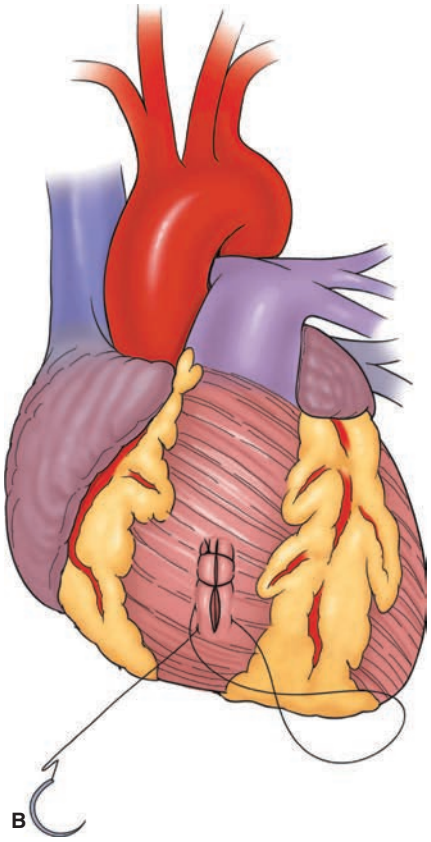
B. Using blunt dissection, the fingers are inserted just beneath the sternum from below and above, carefully dissecting the pericardium and loose fatty tissue away from the back of the sternum.

C. Using a sternal saw, keeping in the midline of the sternum, and exerting upward pressure on the saw, the total length of the sternum is cut. Care is taken not to divert into the right or left chest cavity.

D. A sternal retractor is placed into the incision, first with the two blades touching each other, and then slowly opening the sternum to avoid fracture of the sternum or any ribs. The pericardium, the thoracic vena cava, ascending aorta, pulmonary artery, and lower neck structures are now exposed. The left innominate vein, in the upper extent of the incision, is enclosed in fatty and thymic tissue, and care must be taken not to injure this vein.



A

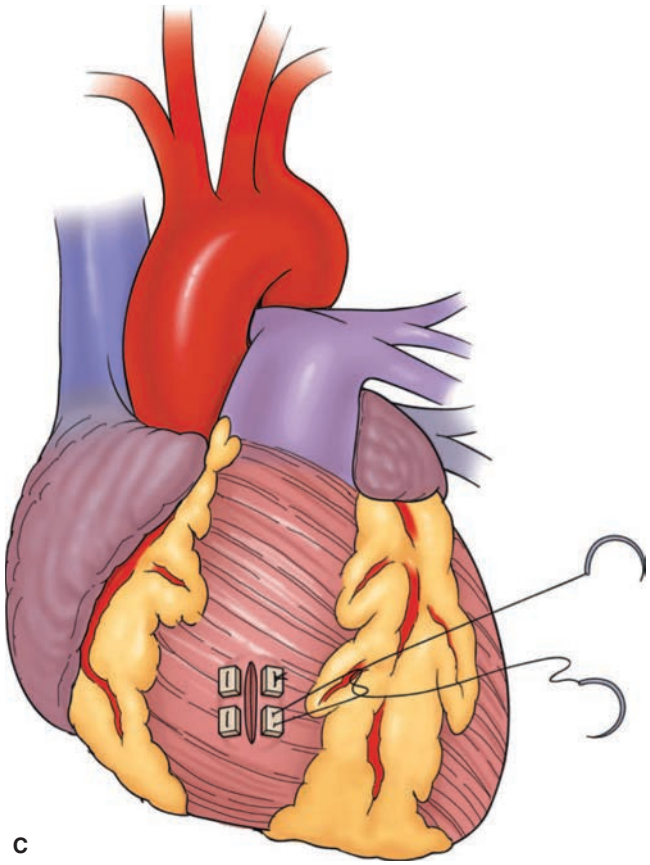


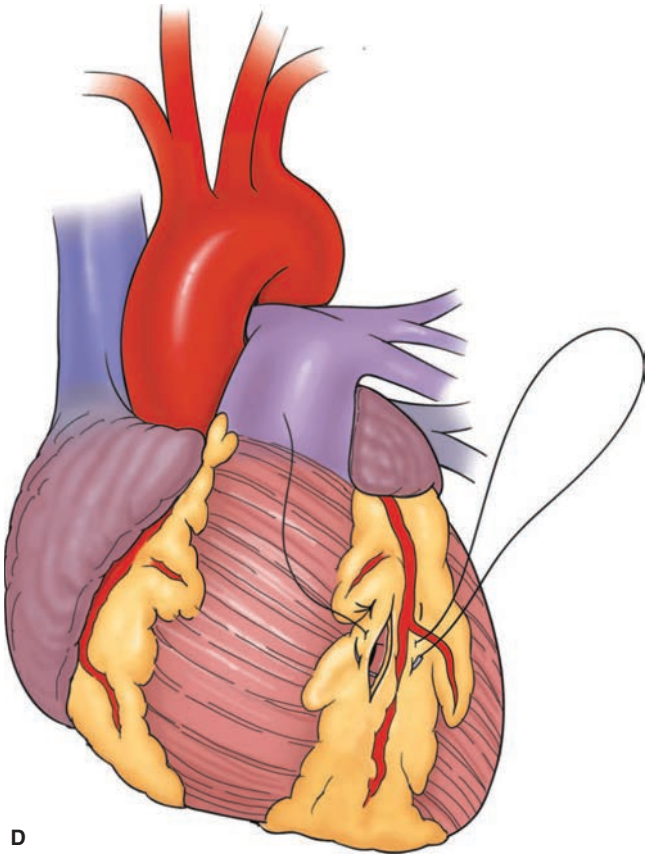
B

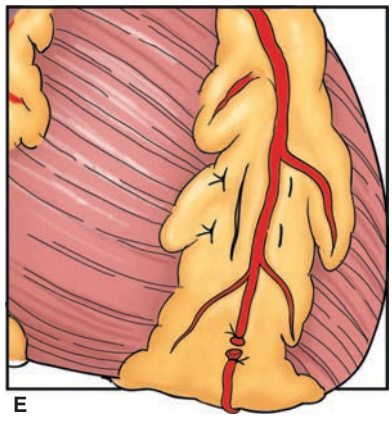
FIGURE 29 Cardiorrhaphy

A. Through a median sternotomy, the tense pericardium is incised in the midline and the clot extracted as digital hemorrhage control is accomplished.

B. Cardiorrhaphy is accomplished by simple direct closure of the penetrating wound using 4(0) polypropylene suture. Repair is accomplished prior to cardiac defibrillation. Often, traction on a figure-of-eight suture will cause all bleeding to stop, and the suture is simply tied.







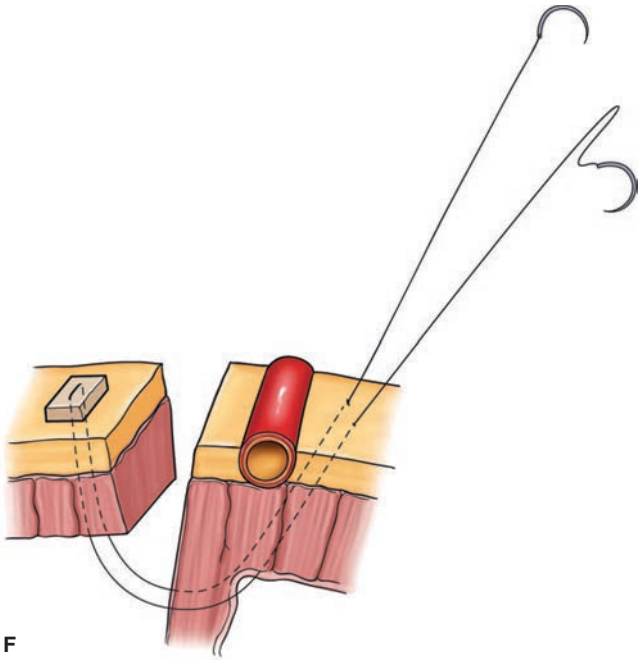


FIGURE 29 **Cardiorrhaphy (*Continued*)**

C. Some surgeons prefer to accomplish cardiorrhaphy with pledgets, an adjunct most useful on the left ventricular wall exposed to high pressures.

D. For injury to the heart, very near a coronary artery, it is possible to use the double needle armed suture to go under the artery with both needles and tie the suture (with or without pledgets) lateral to the injury. For a distal coronary artery injury, simple ligation is sufficient.

E. Completed closure and ligated distal coronary artery injury.

F. Cross section demonstrating the coronary artery undercircling technique.

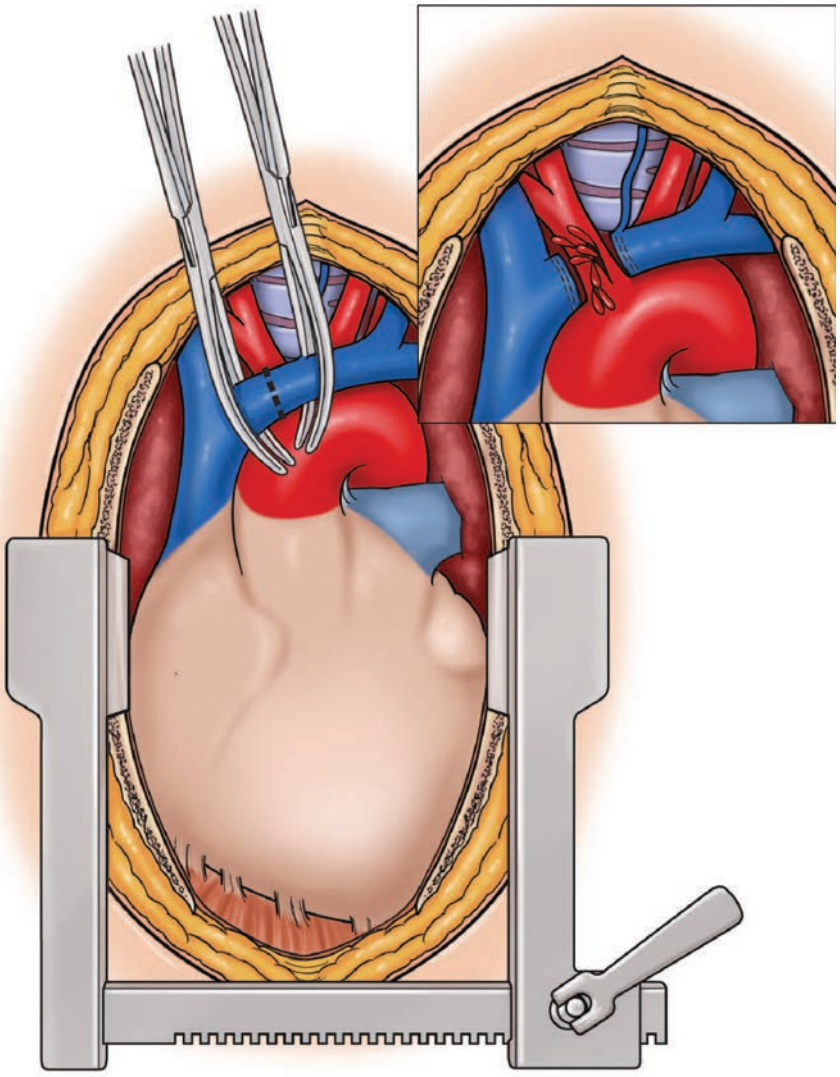

FIGURE 30 Penetrating Injury to the Innominate Artery
When a bullet or knife traverses the left innominate vein and injures the underlying artery, the vein can be divided for access. Optimally, the vein should be reconstructed, but this is not essential if the right innominate vein is normal.

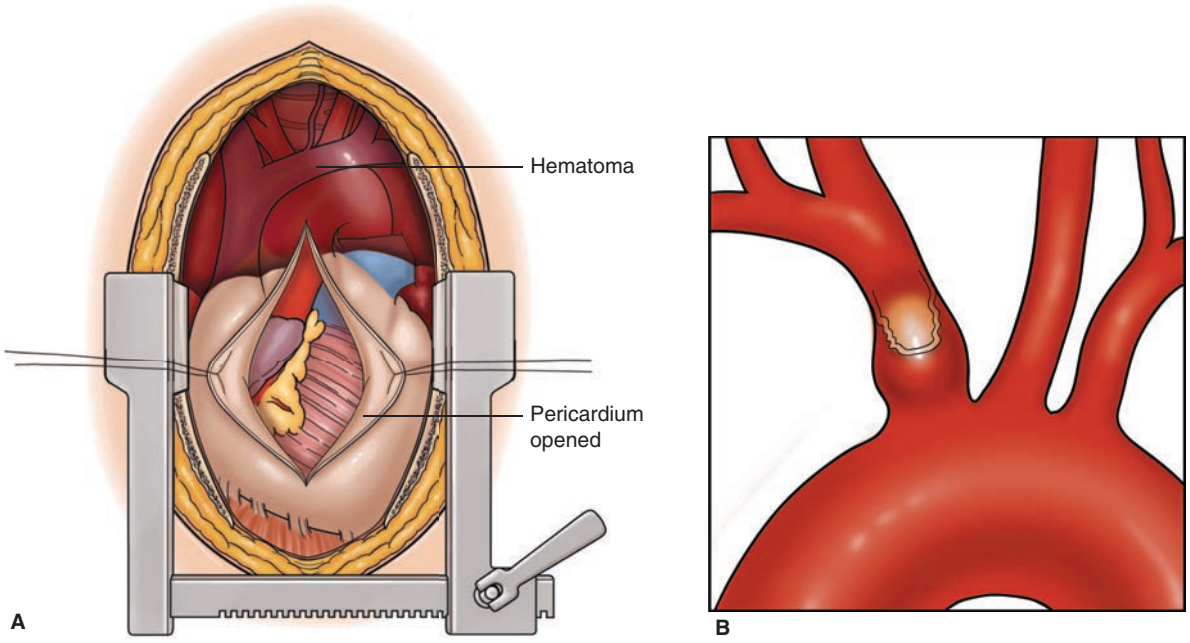

FIGURE 31 Exposure and Management of Injury to the Innominate Artery

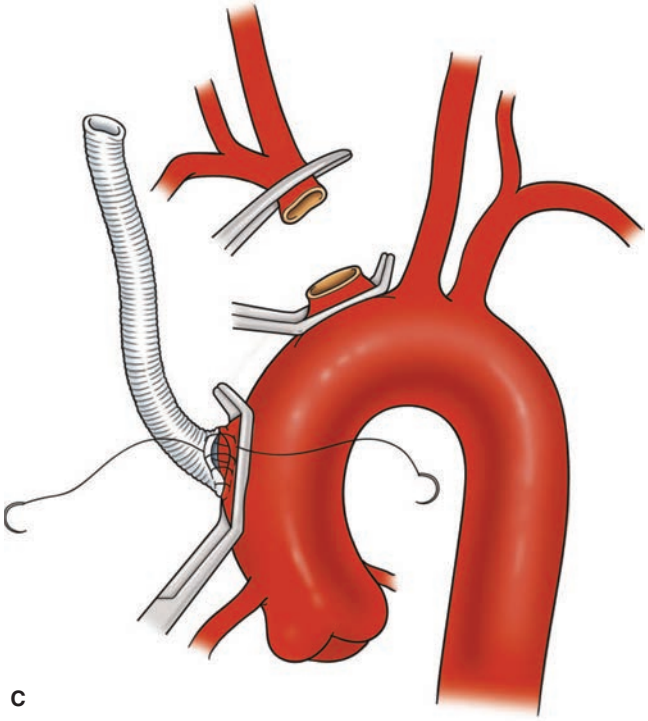
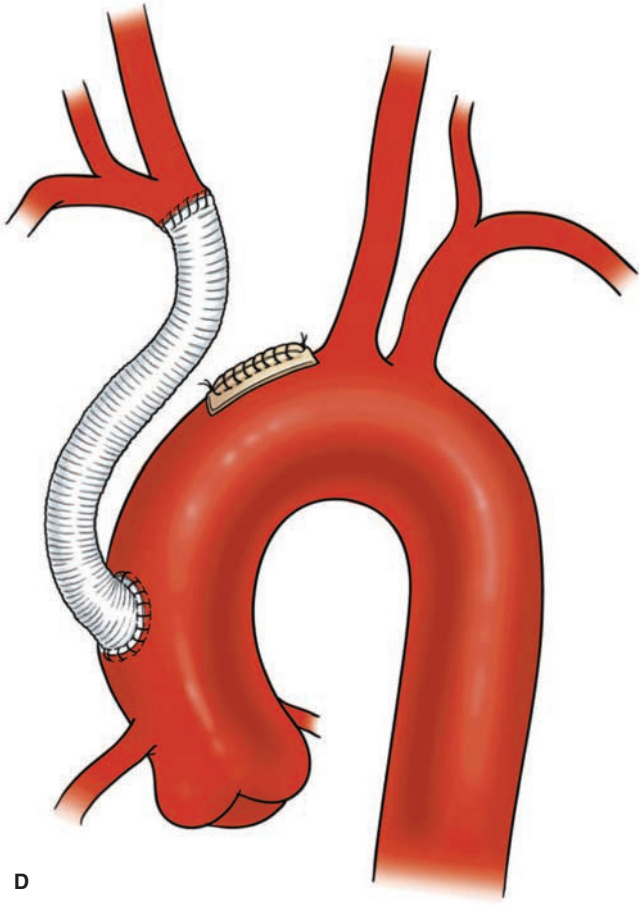
A. The pericardium is opened vertically via a median sternotomy with the sternal retractor in place to expose the anterior heart and ascending aorta. The source of intrapericardial bleeding must be determined. The pericardial incision extends superior to the ascending aorta near the aortic arch. At the thoracic outlet, note the hematoma, which is encountered with an injury to the innominate artery or vein or proximal common carotid artery. In this drawing, the upper limits of the incision are extended into the neck (can be either to right or left of midline) so that the distal control of the thoracic outlet great vessels can be obtained. Note, also, that the innominate vein is in the center of the hematoma.

B. A blunt injury to the proximal innominate artery is actually a fracture of the aortic arch intima at the takeoff of the innominate artery. The intima of the innominate artery is rolled up with the presentation of the arterial discoloration, and injury appears to be in the innominate artery. Through a median sternotomy with a right neck extension, the ascending aorta, aortic arch, innominate vein, innominate artery, subclavian artery, and right and left carotid arteries are exposed.

(continues on next page)



C



D

FIGURE 31 Exposure and Management of Injury to the Innominate Artery (*Continued*)

C. Without systemic heparinization or hypothermia, a Dacron graft is sutured end to side to the ascending aorta. In some instances the innominate vein might be divided to expose the area of injury. A partially occluding clamp is placed on the aortic arch proximal to the takeoff of the innominate artery and another vascular clamp is placed just proximal to the bifurcation of the innominate artery.

D. The graft is sutured to the distal innominate artery, taking care to back-flush and clear the graft of any clot prior to the completion of the suture line. The aortic plate proximal to the injury is oversewn using two pledget strips.

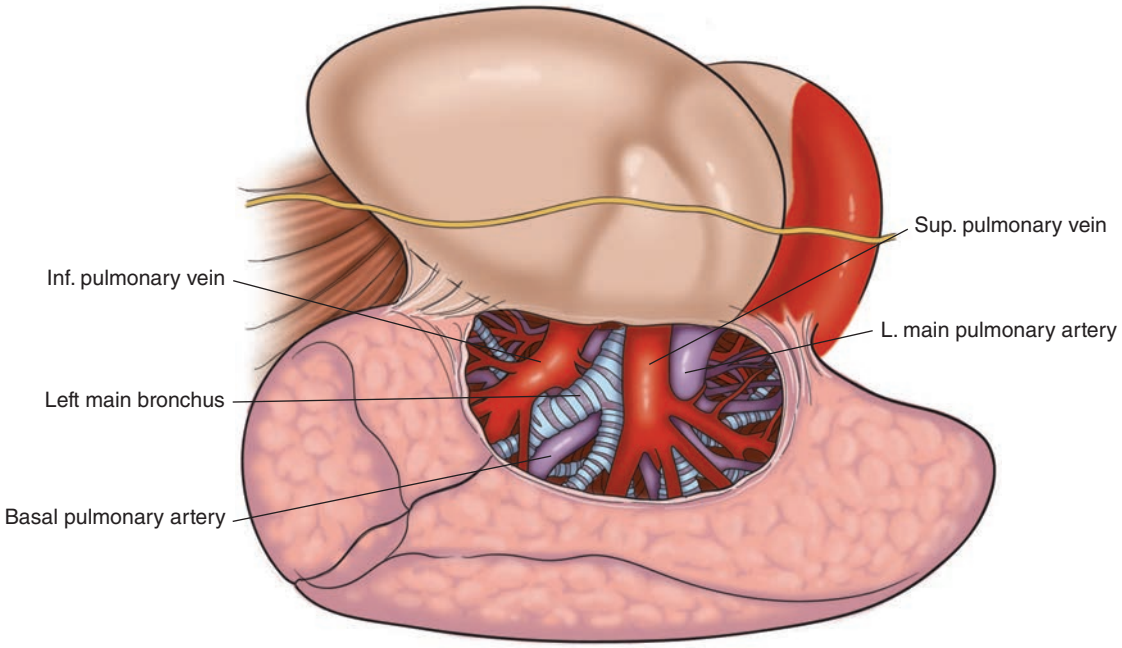


FIGURE 32 Anatomy of Left Pulmonary Hilum
The anatomy of the two pulmonary hila are slightly different. Before performing a trauma lobectomy or even pneumonectomy, a review of the related anatomy can reduce catastrophic iatrogenic bleeding and prevent bronchial injury. With the lung displaced posteriorly and inferiorly, the highest structure in the left pulmonary hilum, the main left pulmonary artery, is exposed and then sharply separated from the aortic arch. This artery goes behind the left superior pulmonary vein (draining the left upper lobe), and the artery continues downward, giving off branches to the left upper lobe and then to its terminal branches to the left lower lobe. The left mainstem bronchus is behind the superior pulmonary artery. Both the superior and inferior pulmonary veins drain into the left atrium.

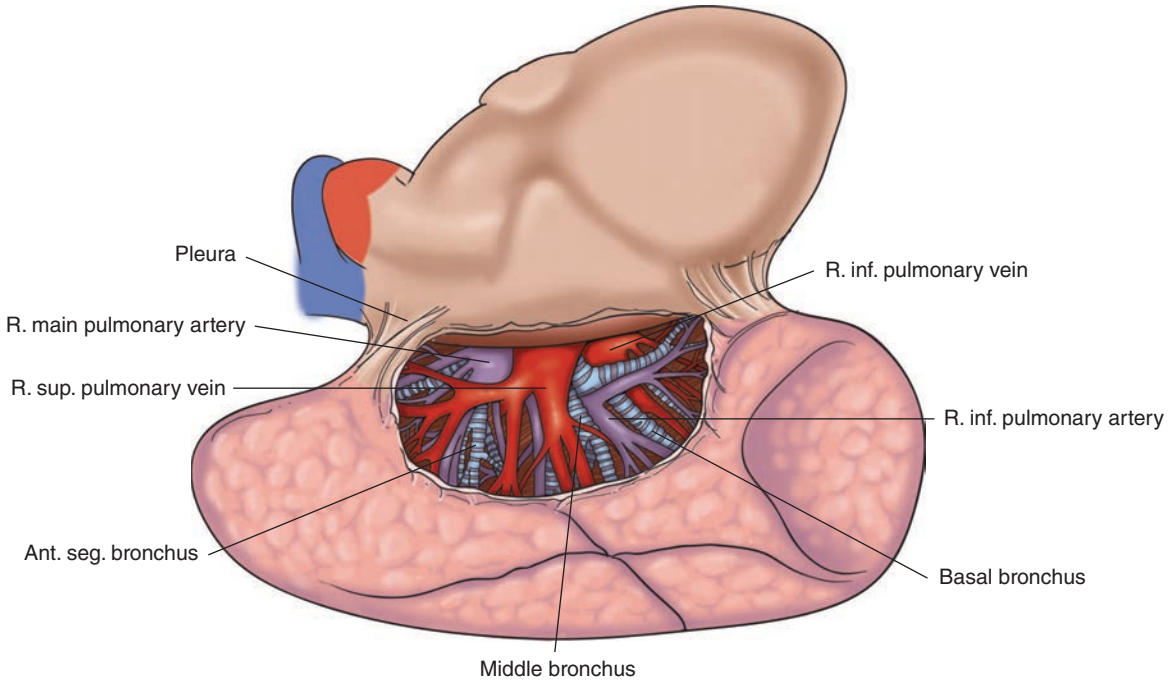

FIGURE 33 Anatomy of Right Pulmonary Hilum
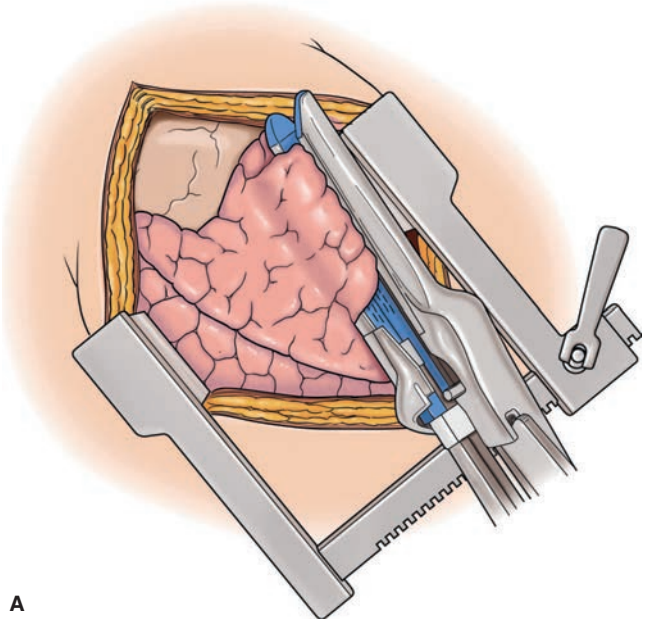
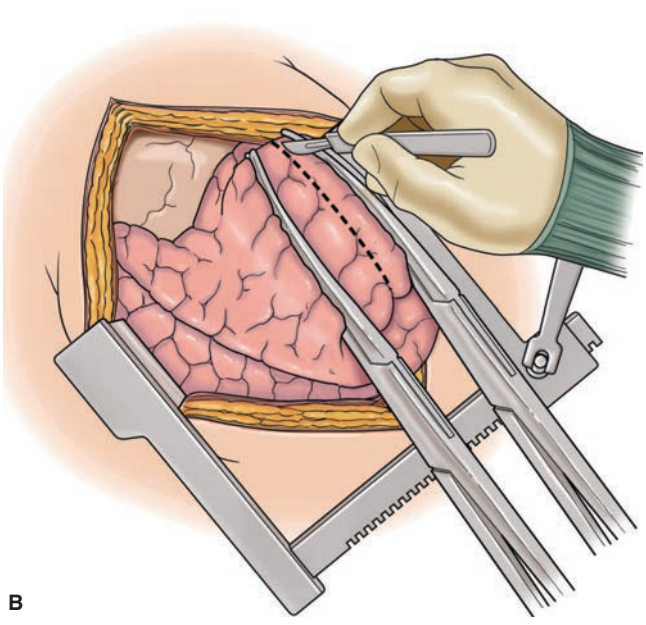
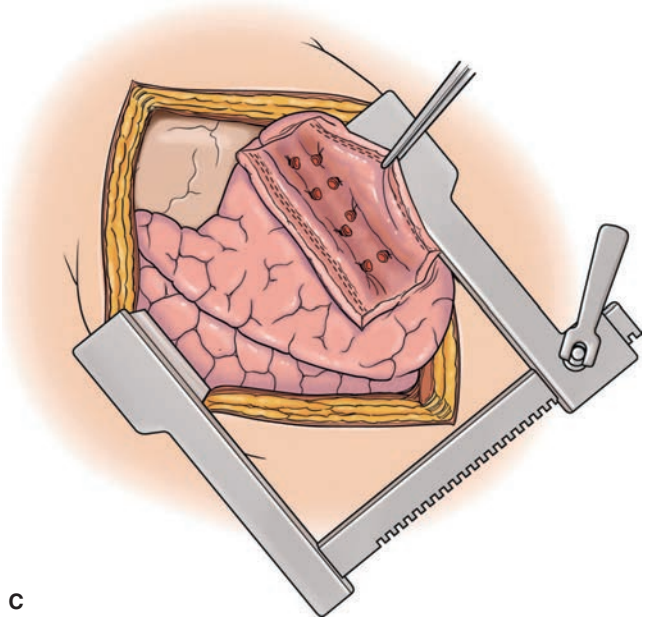
The right lung has three lobes, so the anatomy is different from that of the left lung. To expose either hilum, the pleura covering the vessels and bronchus is mobilized. The highest vessel in the hilum is the right pulmonary artery, giving off branches to the upper and middle lobes, and then continuing to the arborization into the lower lobe. The middle lobe bronchus and artery come off the bronchus intermedius and right intermedius pulmonary artery in an anterior fashion. The inferior pulmonary vein is in a similar position to that on the left.



A



B



C

FIGURE 34 Pulmonotomy

A. A through-and-through hole to the lung or even a large tangential laceration might be controlled with clamps or a linear stapler. The linear stapler is inserted into the tract, thereby joining the two holes. The stapler is fired and the lung cut, exposing the base of the tract.

B. A pulmonotomy can also be accomplished by placing two large vascular clamps through the tract and cutting the lung between clamps. A polypropylene suture is run back and forth under the clamps, and other sutures control the base of the tract in a manner similar to when the stapler is used.

C. Persistent bleeding points and air leaks are closed with 4(0) polypropylene suture. This nonanatomic procedure is extremely well tolerated.

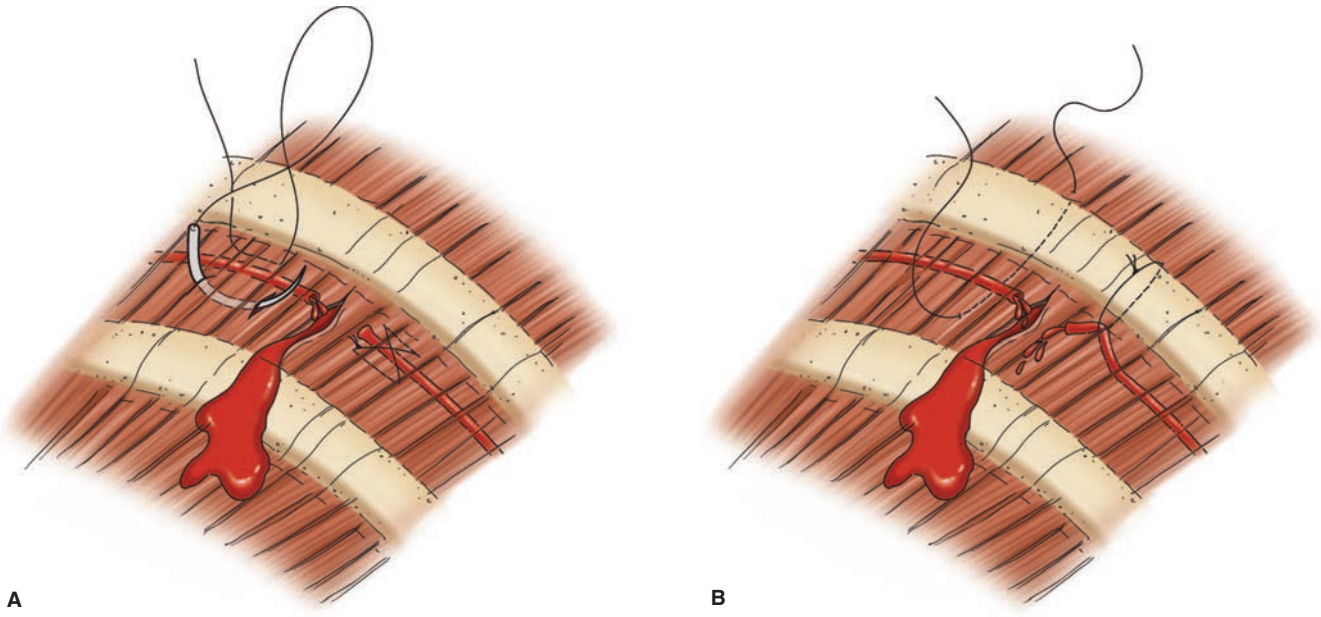


FIGURE 35 Controlling Bleeding from an Intercostal Artery

A. Bleeding from an intercostal artery, injured by a knife, missile, or fractured rib, can be extremely difficult to expose and control. One approach is a figure-of-eight suture ligation of the bleeding intercostal artery at the inferior border of the rib, where the injury occurred.

B. Alternatively, absorbable suture can be used to encircle a rib lateral to the bleeding points, pressing the vessel up against the inferior groove of the rib with the encircling suture.

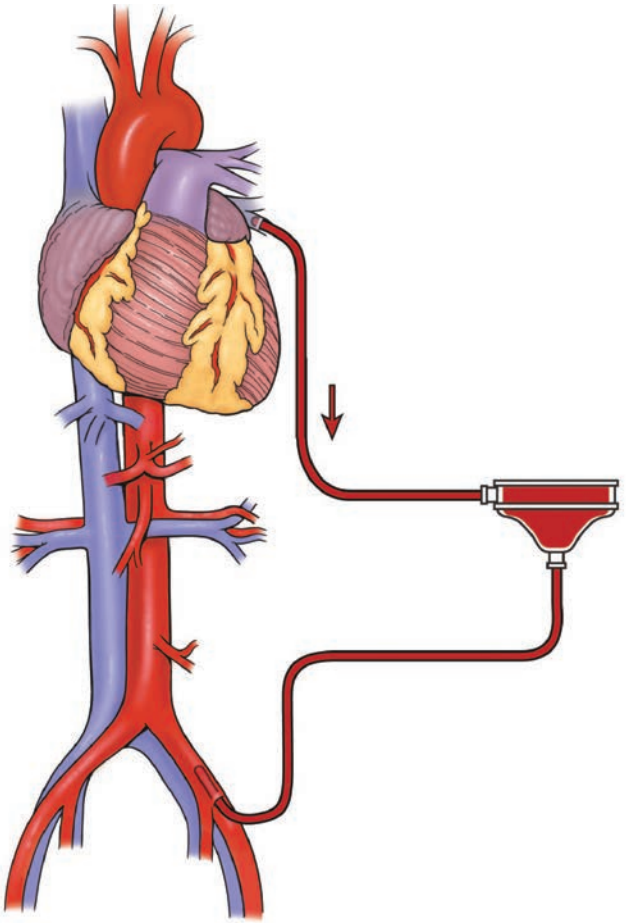

FIGURE 36 Partial Left Heart Bypass 1
Partial left heart bypass using a centrifugal pump is often accomplished without heparin or on low-dose heparin. The outflow is from a cannula inserted into the left atrial appendage via the superior pulmonary vein, and the inflow is via a cannula in the left common femoral artery. This bypass is most often used in cases requiring open repair of a blunt injury of the descending thoracic aorta.

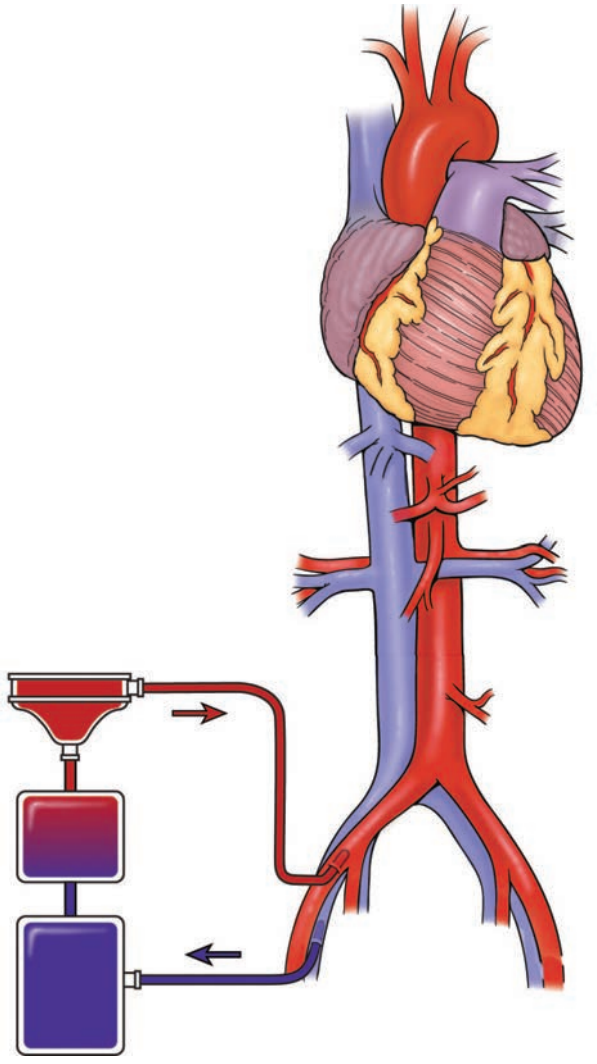

FIGURE 37 Partial Left Heart Bypass 2
One of the options for partial left heart bypass, used for reconstruction of the aorta, is the femoral vein to femoral artery circuit with a centrifugal pump often with an inline oxygenator.

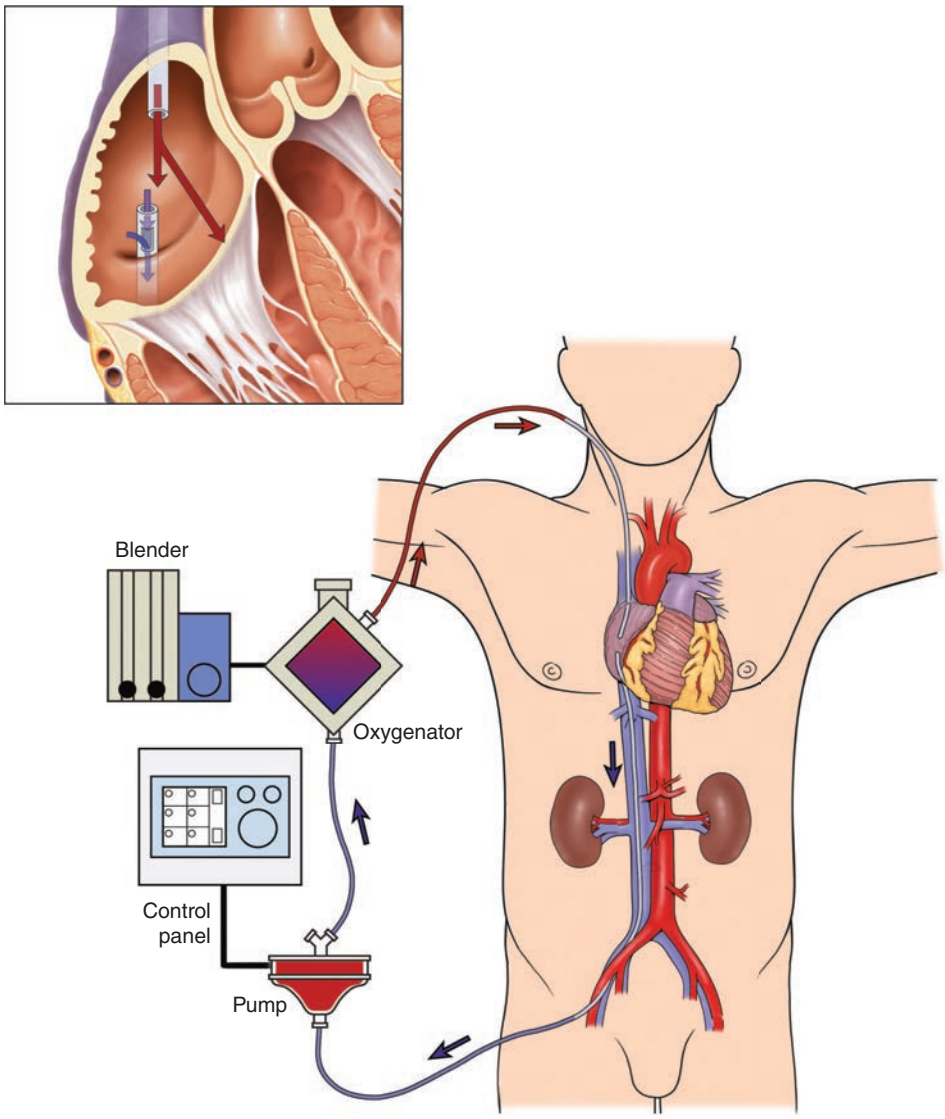

FIGURE 38 ECMO (Extracorporeal Membrane Oxygenation) 1
This drawing demonstrates the two-catheter technique of inserting catheters into the right atrium. The lower catheter is inserted into the femoral vein and threaded into the right atrium for the purpose of draining venous blood to the oxygenation and mixer device. The upper catheter is inserted via the subclavian vein or internal jugular vein into the right atrium, near the tricuspid valve, for the purpose of delivering oxygenated blood into the right-sided circulation of the heart.

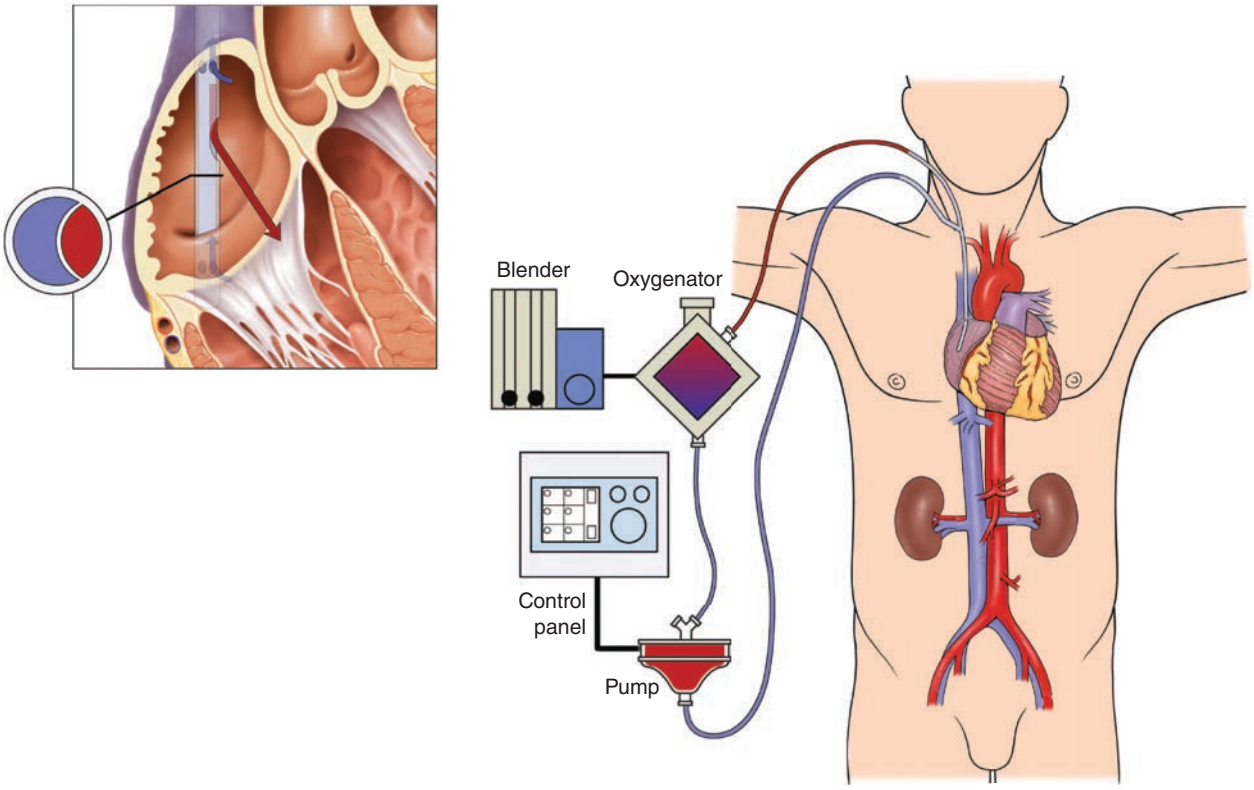

FIGURE 39 ECMO (Extracorporeal Membrane Oxygenation) 2
This drawing demonstrates the single-catheter technique in performing ECMO. Note that a special double lumen catheter is inserted into the right atrium via the internal jugular vein or the subclavian vein, and extended into the intrathoracic inferior vena cava. This single catheter allows for the withdrawal of nonoxygenated blood and the delivery of oxygenated blood after it has been processed via the oxygenator/mixer.

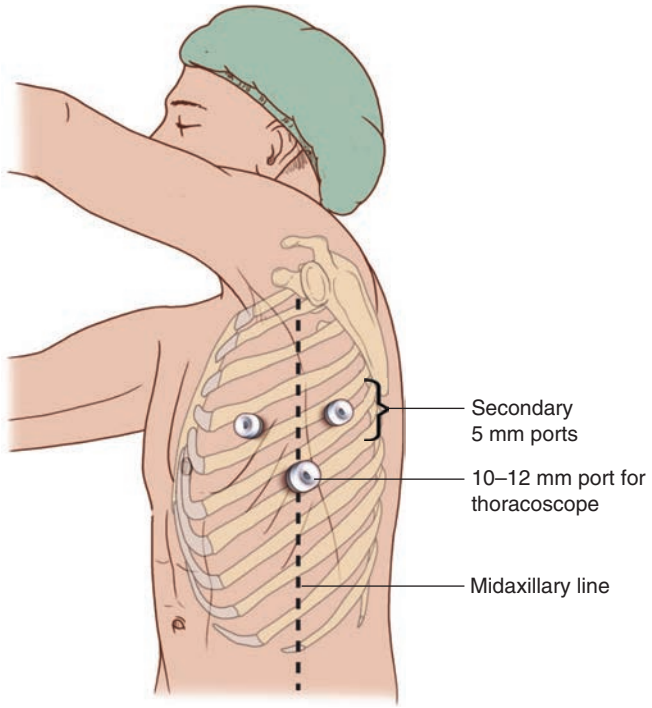

FIGURE 40 VATS (Video-Assisted Thoracoscopic Surgery)
The drawing of a patient in the right lateral decubitus position demonstrates the insertion of ports for performing a VATS.

ABDOMEN AND PELVIS

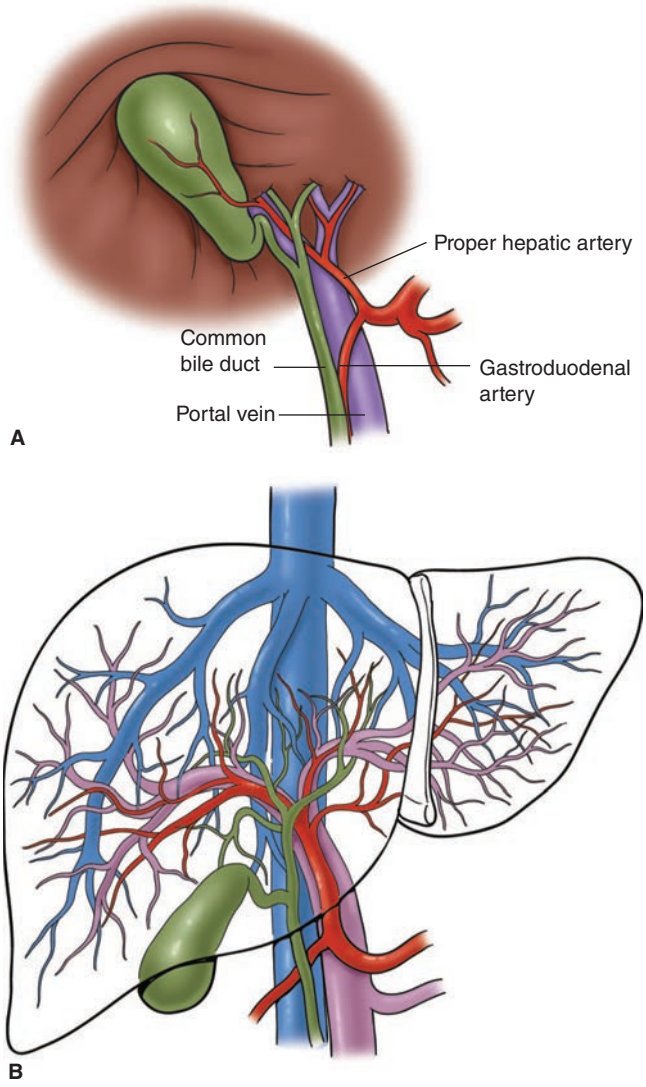

FIGURE 41 Biliary and Vascular Anatomy of the Liver

A. This drawing depicts the anatomy of the gallbladder and porta hepatis. Although many variations may exist, review of this area can be helpful prior to operating on an injury in this location.

B. This drawing illustrates the vascular anatomy of the liver.

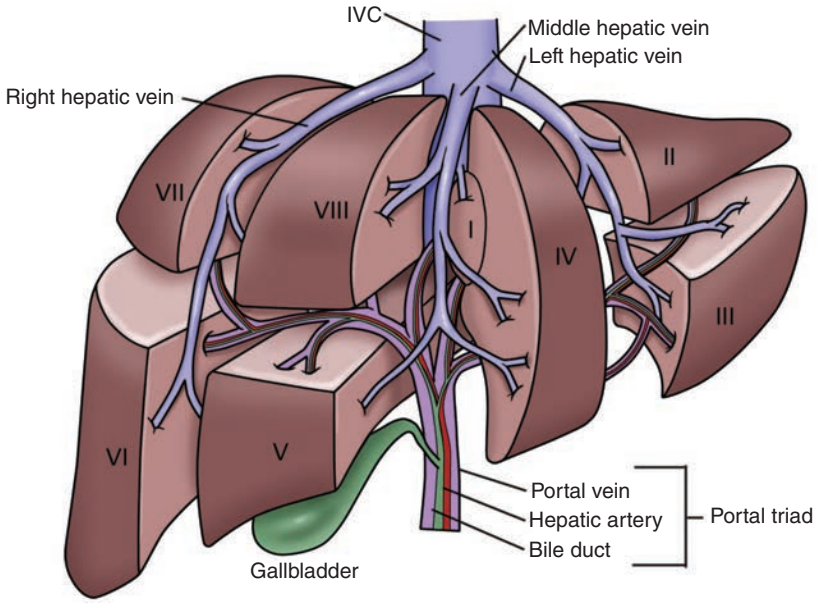

FIGURE 42 Hepatic Segments
These are the eight segments of the liver, defined by their portal circulation. Note that there are at least three major venous outflows from the liver. Not shown here are several direct venous outflows directly from the liver to the retrohepatic IVC.

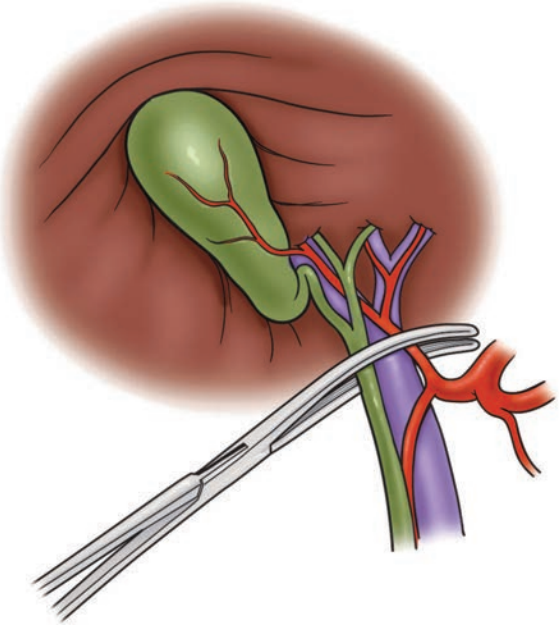

FIGURE 43 The Pringle Maneuver
Using a noncrushing (vascular) clamp, the entire porta hepatis can be occluded to decrease bleeding from an injured liver. This is a temporary occlusion of the portal vein, hepatic artery, and common bile duct. It is accomplished by palpating the foramen of Winslow and precisely placing the clamp on only the desired structures.

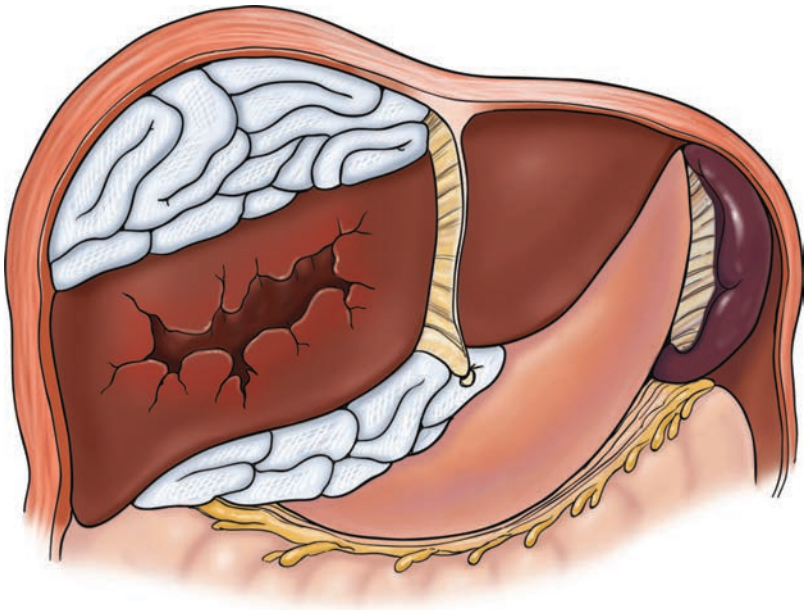

FIGURE 44 Perihepatic Packing
Temporary packing of a bleeding liver is the prime example of damage control. Laparotomy packs are placed above and below a bleeding area in the liver, making a "liver sandwich." Care is taken not to obstruct the inferior vena cava or to produce too much constriction, leading to liver necrosis.

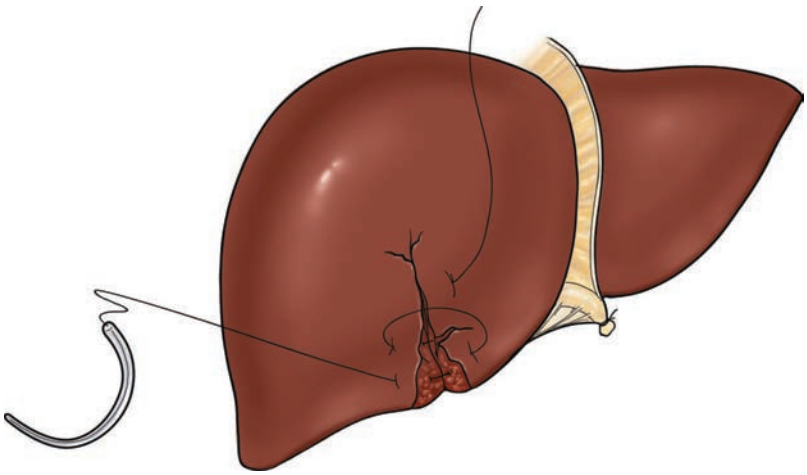

FIGURE 45 Hepatorrhaphy
Using a large, special blunt "liver" needle on an absorbable suture, a deep figure-of-eight suture can stop troublesome bleeding. Sutures should be tied loosely, rather than snug and tight, since the liver swells postoperatively, and tight sutures can cause hepatic necrosis.

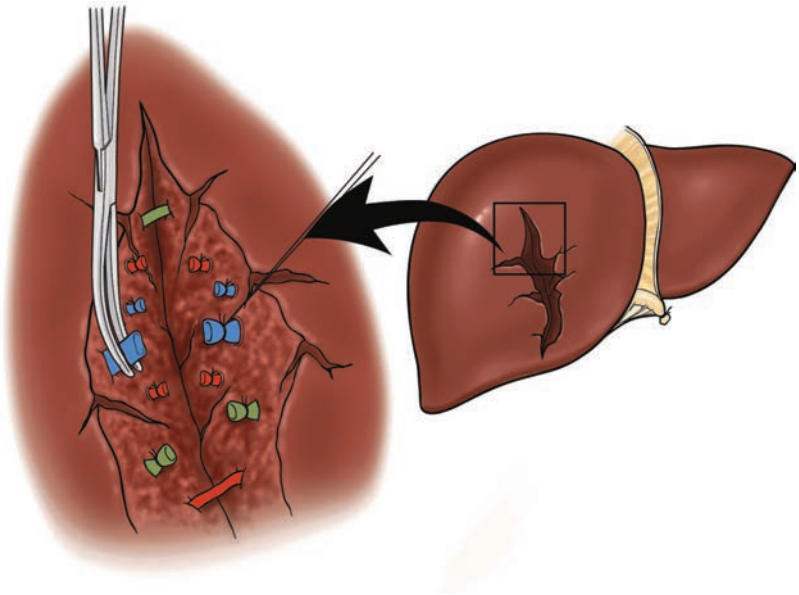

FIGURE 46 Hepatotomy
Gross, large ligatures to the liver may cause liver necrosis and postoperative fever. The injury is unroofed by performing a hepatotomy, with direct ligation of the biliary and vascular structures.

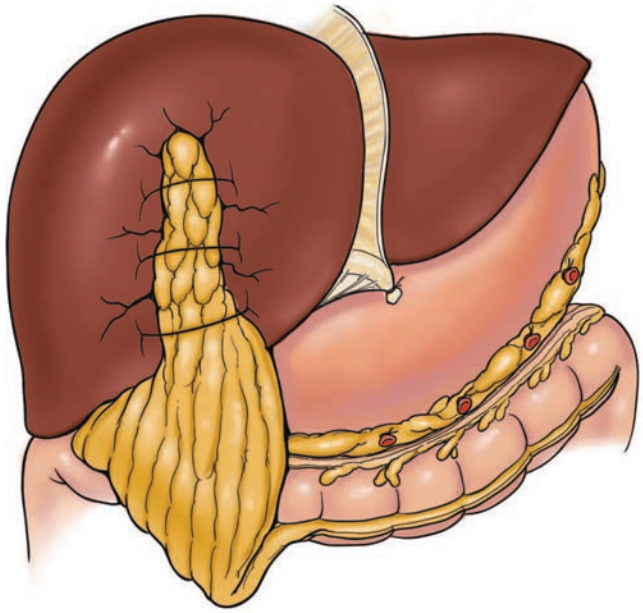

FIGURE 47 Omental Pedicle Packing of Hepatic Laceration or Hepatotomy Site
The left side of the omentum is mobilized off of the transverse colon, preserving a vascular pedicle from the right side of the omentum. The sutures attaching the omentum to the liver are loosely applied, so as not to strangulate the omentum.

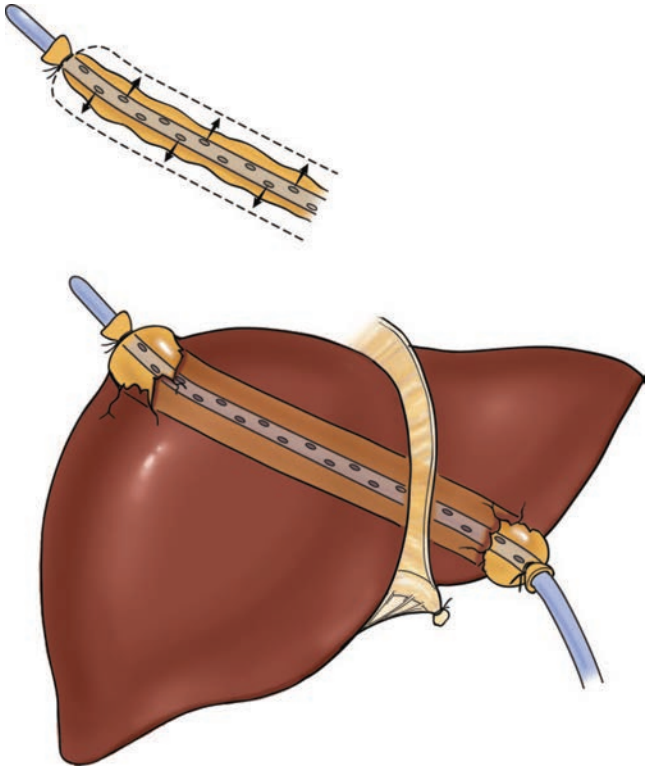

FIGURE 48 Hepatic Balloon Tamponade
A custom, temporary balloon is fashioned using a Penrose drain and a rubber catheter, sealing off the ends of the drain placed over the catheter. After insertion into the body of the liver, the catheter is then filled with saline.

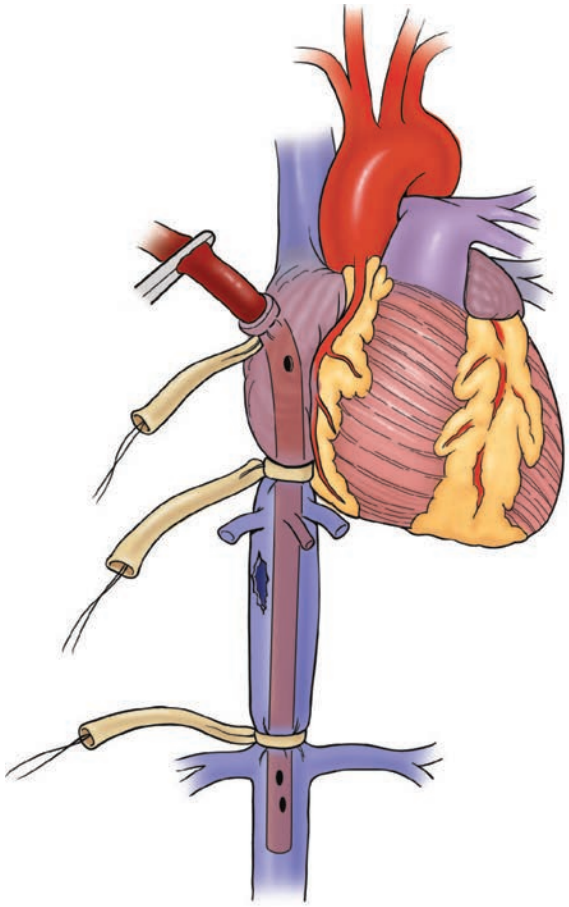

FIGURE 49 Atriocaval Shunt
Isolation of uncontrolled bleeding from the retrohepatic vena cava can be accomplished with an atriocaval shunt. The underlying principle is shunting lower body blood to the right atrium. A 38F chest tube with an extra hole cut near the base end and clamped at the base is inserted via a purse string suture into the right atrial appendage and advanced into the infrarenal inferior vena cava. Assure the last hole in the tube is below the area of the suprarenal inferior vena cava Rumel tourniquet. A second Rumel tourniquet is placed around the intrathoracic intrapericardial inferior vena cava. Finally, a Pringle maneuver accomplishes total hepatic and near-total retrohepatic vena cava vascular isolation to allow repair or reconstruction.

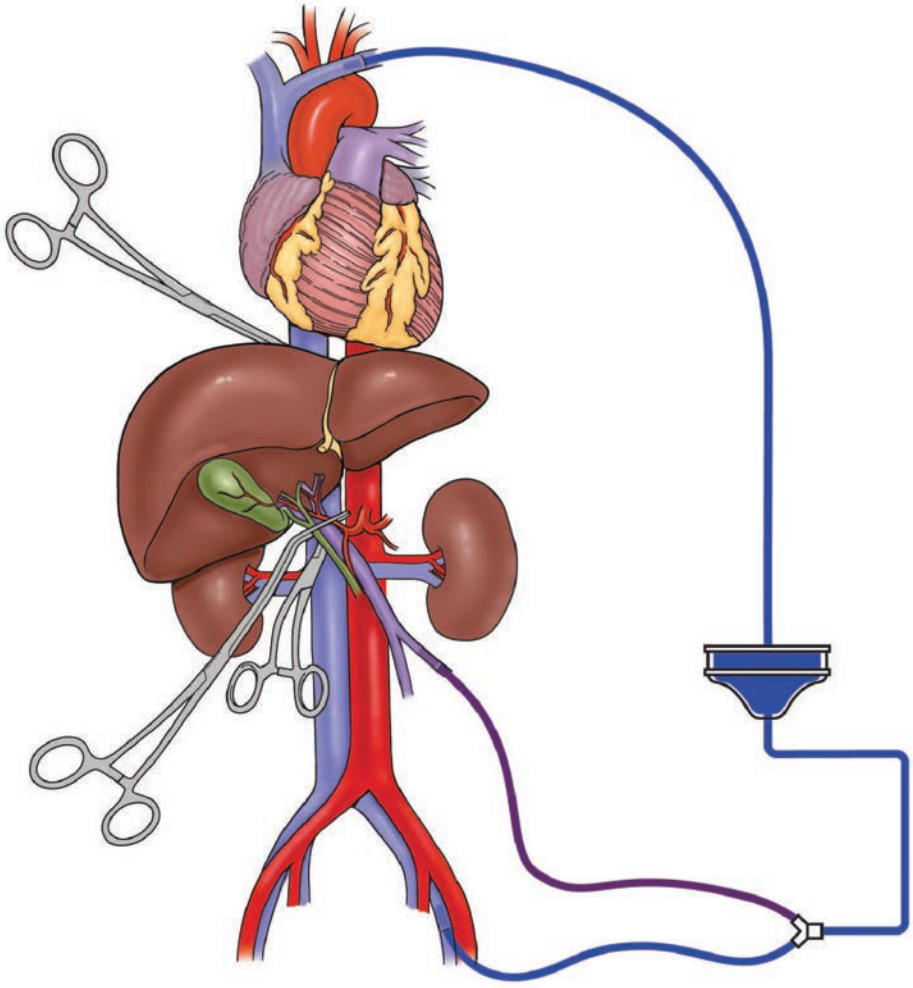

FIGURE 50 Venovenous Bypass
This illustrates a venous bypass circuit using a centrifugal pump for a patient with a complex injury to the retrohepatic vena cava. Cannulae are inserted into the inferior mesenteric, portal, and femoral veins, respectively. This venous blood is pumped, via a centrifugal pump, into the right heart using a cannula inserted into the subclavian vein, innominate vein, or the right atrial appendage.

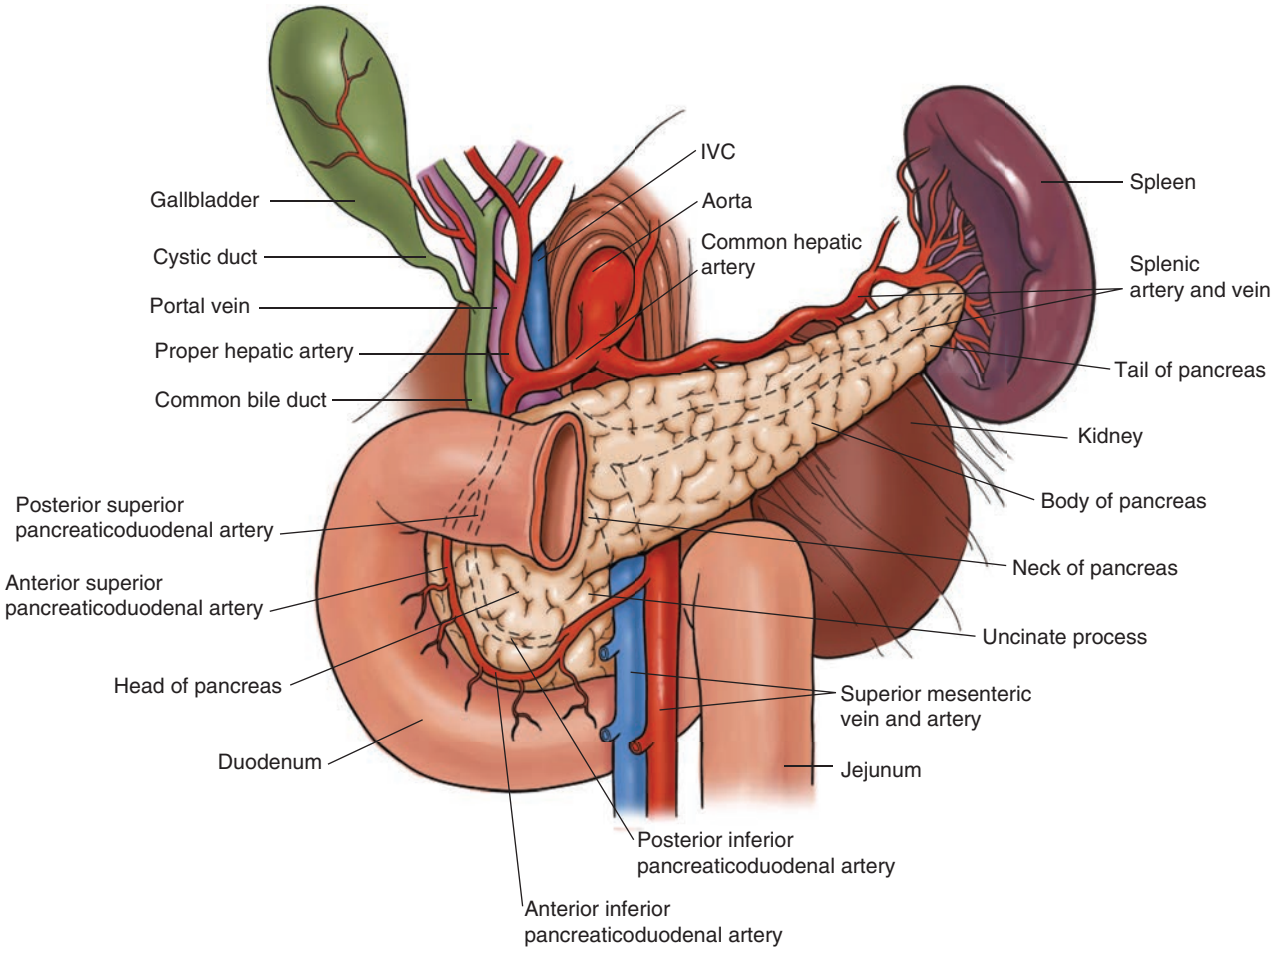

FIGURE 51 Anatomy and Vascular Supply of Duodenum, Pancreas, and Spleen
Complex anatomy of duodenum, pancreas, and spleen in upper abdomen makes management difficult when multiple injuries are present.

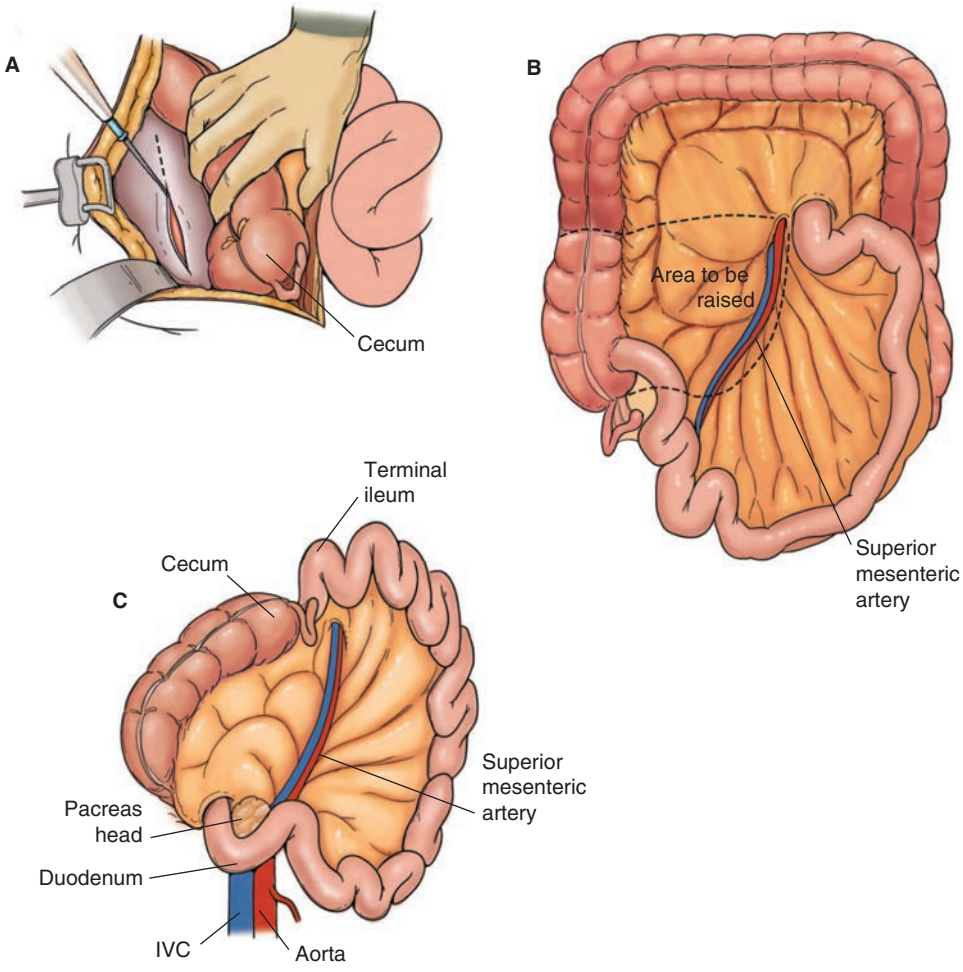

FIGURE 52 Right Medial Visceral Rotation Extended into Cattell-Braasch Maneuver

A. An extensive Kocher maneuver, division of the right line of Toldt, and sharp and blunt dissection toward the midline will expose the posterior head of the pancreas, anterior D_3, infrahepatic inferior vena cava, renal veins, right kidney, and right ureter.

B. Division of the retroperitoneal attachments of the small bowel mesentery from the right lower quadrant to the left upper quadrant completes the Cattell-Braasch maneuver.

C. Using this combination of maneuvers, the structures named above, posterior D_3, and the origin of the superior mesenteric artery can be visualized as well.

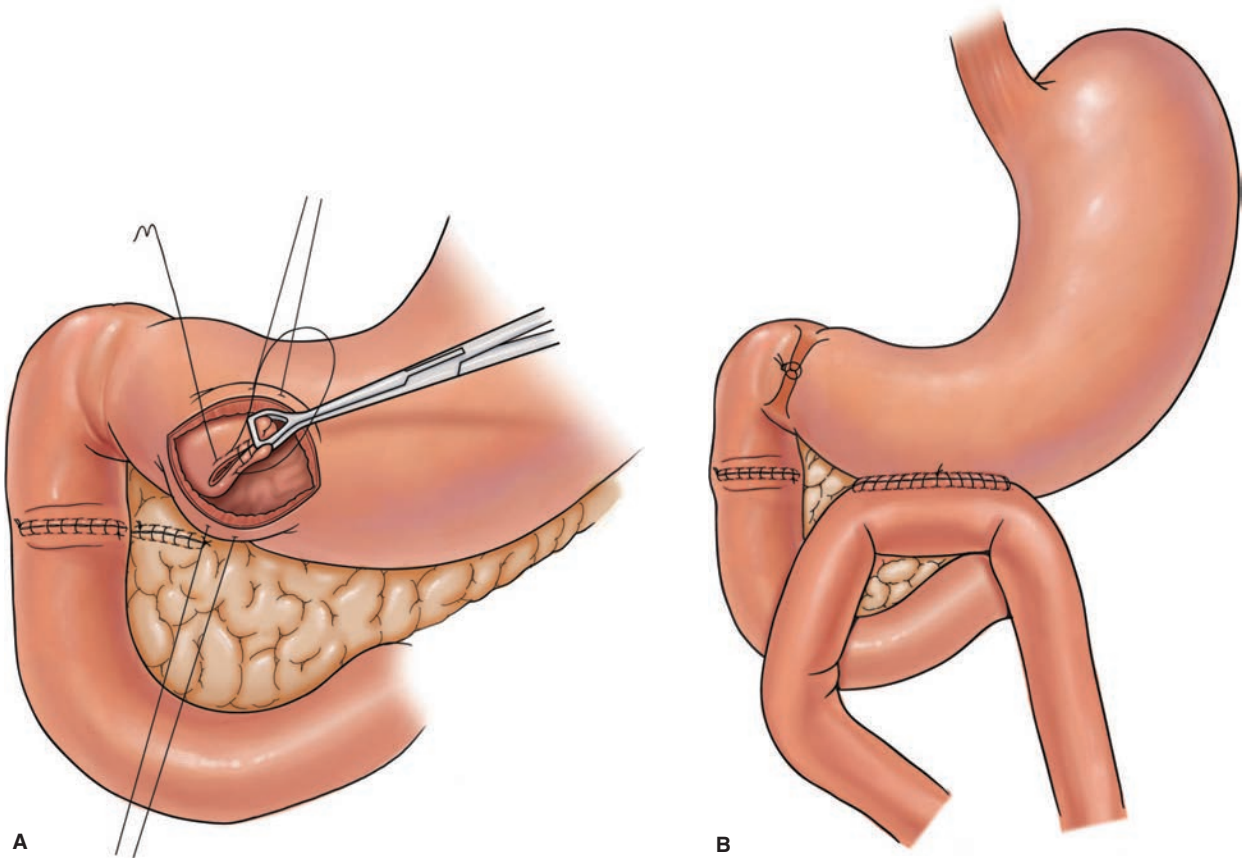

FIGURE 53 Pyloric Exclusion with Gastrojejunostomy

A. For a complex combined injury to the head of the pancreas and duodenum, pyloric exclusion is performed to decrease the risk of a postoperative lateral duodenal fistula. After control of the injury of the duodenum and pancreas has been accomplished, a dependent gastrotomy is made in the antrum of the stomach. The pylorus is palpated and grasped with Babcock clamps and closed with a #1 polypropylene suture. Almost every suture tends to cut through the pylorus, and the gastroduodenal outlet reopens in 2 to 3 weeks.

B. Following closure of the pylorus, a dependent antecolic gastrojejunostomy is created at the gastrotomy site. Patient should be screened for the presence of *Helicobacter pylori* postoperatively and treated if positive.

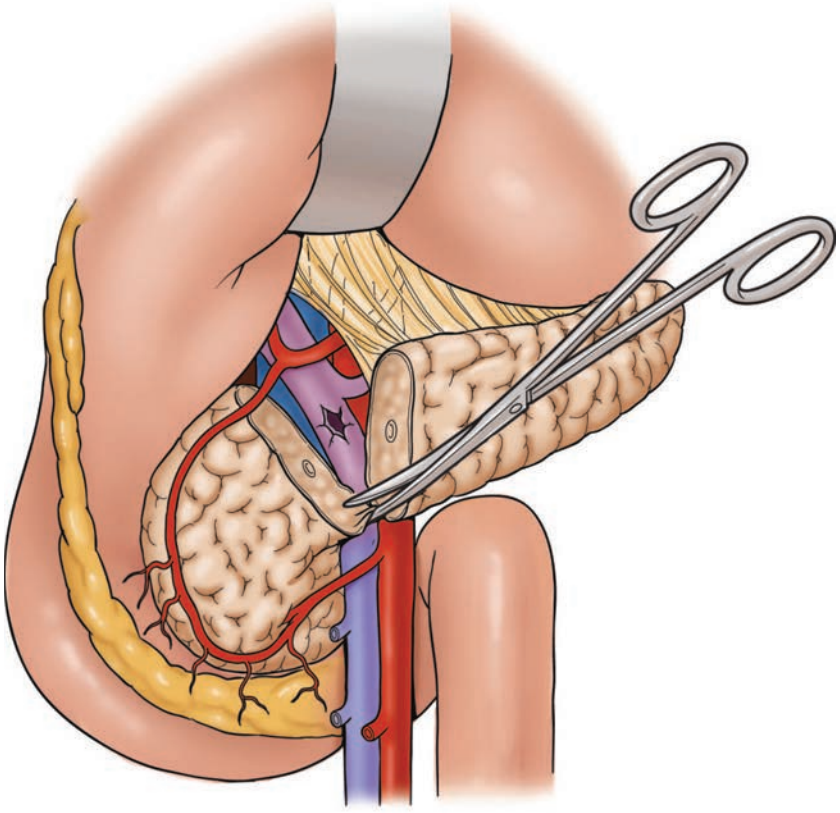

FIGURE 54 Division of Neck of Pancreas to Expose the Portal Vein
The portal vein is formed behind the neck of the pancreas as the superior mesenteric vein is joined by the splenic vein. Bleeding from this area following penetrating trauma presents an exposure problem, but there are very few sizable veins entering the portal vein from the posterior surface of the pancreas. After the superior mesenteric vein is exposed, a dissecting finger can be placed behind the pancreas, and anterior to the superior mesenteric/portal vein. Using scissors or a stapler, the neck of the pancreas is deliberately divided over the dissecting finger under direct vision. This exposes the extent to the proximal portal vein, and appropriate vascular control and repair can be accomplished. The distal end of the pancreas can then be resected with the spleen or reconstructed as a distal end-to-end pancreatojejunostomy.

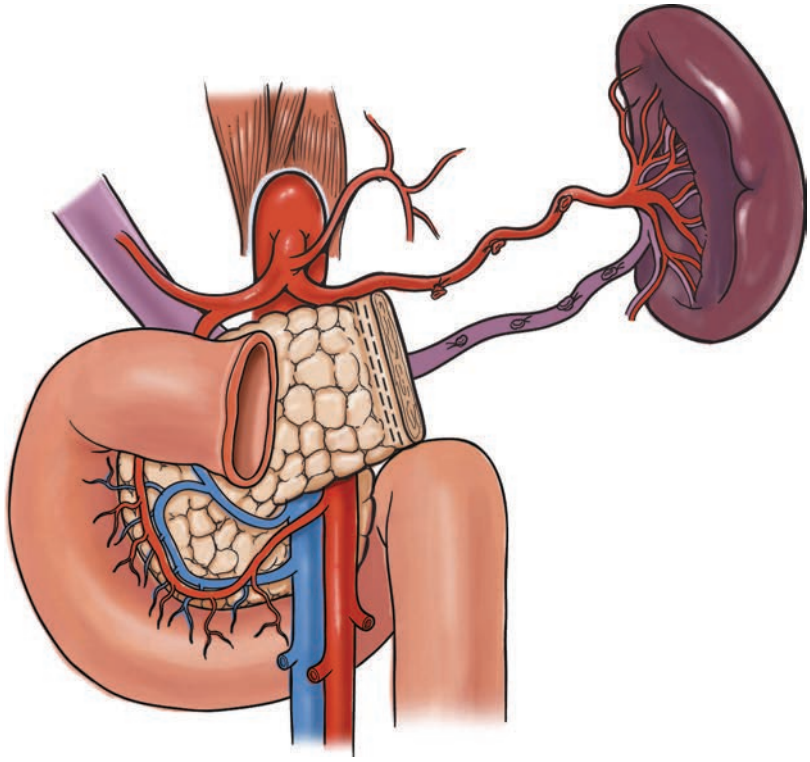

FIGURE 55 Distal Pancreatectomy without Splenectomy in a Child
Because of the immature immune status of children under the age of 2 and possibly up to the age of 10, OIS grade III pancreatic injuries (ductal injury) are treated with spleen-saving distal pancreatectomy.

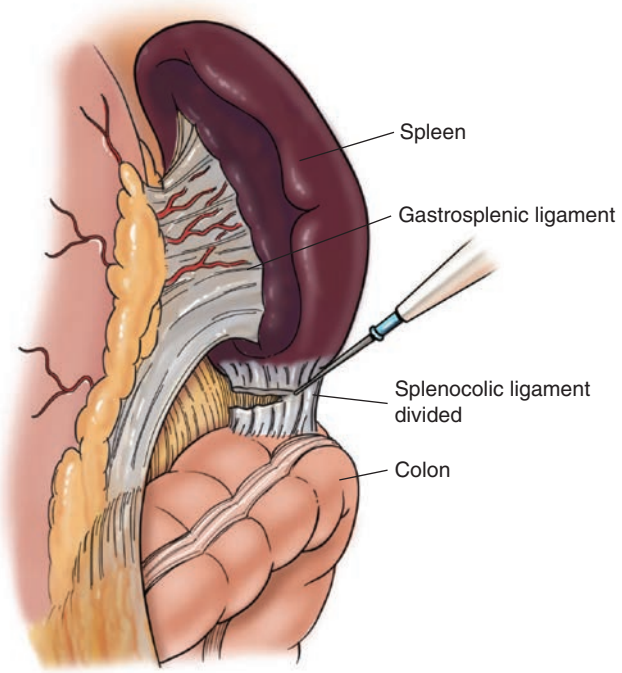

FIGURE 56 Spleen 1
This is the splenic regional anatomy, knowledge of which is necessary to accomplish mobilization of the spleen. The spleen can be mobilized by dividing the splenocolic ligament and ligating the vasa brevia arteries between the stomach and spleen. In this view, the tail of the pancreas and the splenic artery and vein are not demonstrated. Care must be taken to avoid damaging the colon, stomach, and pancreas.

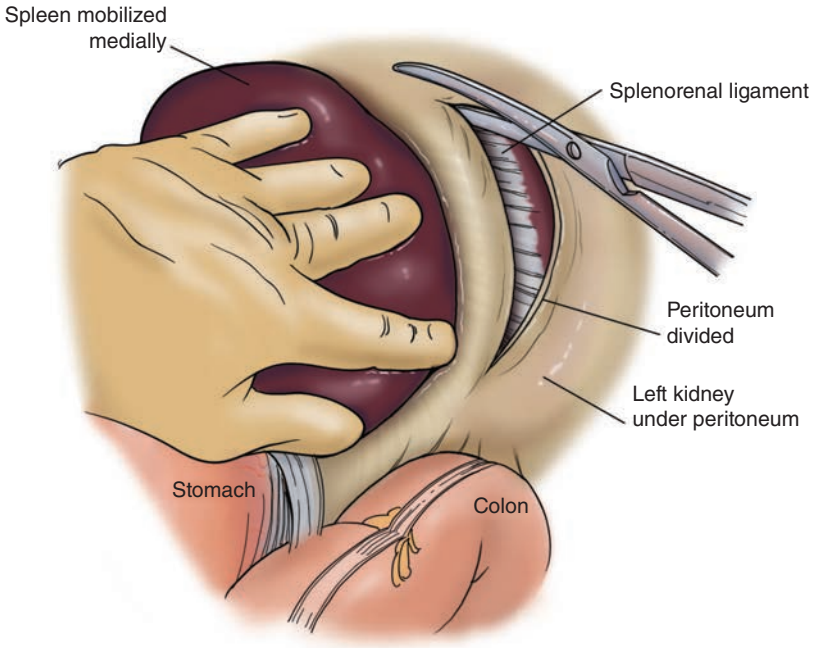

FIGURE 57 Spleen 2
These are additional maneuvers in mobilization of the spleen. Division of the splenorenal ligament and peritoneum overlying the left kidney is illustrated. Often, this maneuver can be accomplished bluntly.

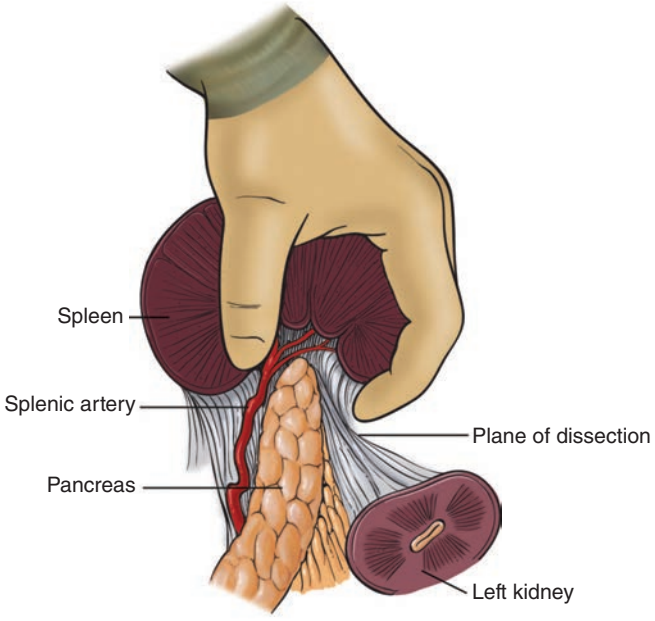

FIGURE 58 Spleen 3
The final movement of the mobilized spleen is by continuing blunt dissection with the tips of the fingers, separating the kidney from the spleen, bringing the tip of the tail of the pancreas and the splenic artery and vein branches in the hilum of the spleen to the midline of the anterior abdomen. In this location, these vessels can be divided, with care taken to avoid injury to the tail of the pancreas.

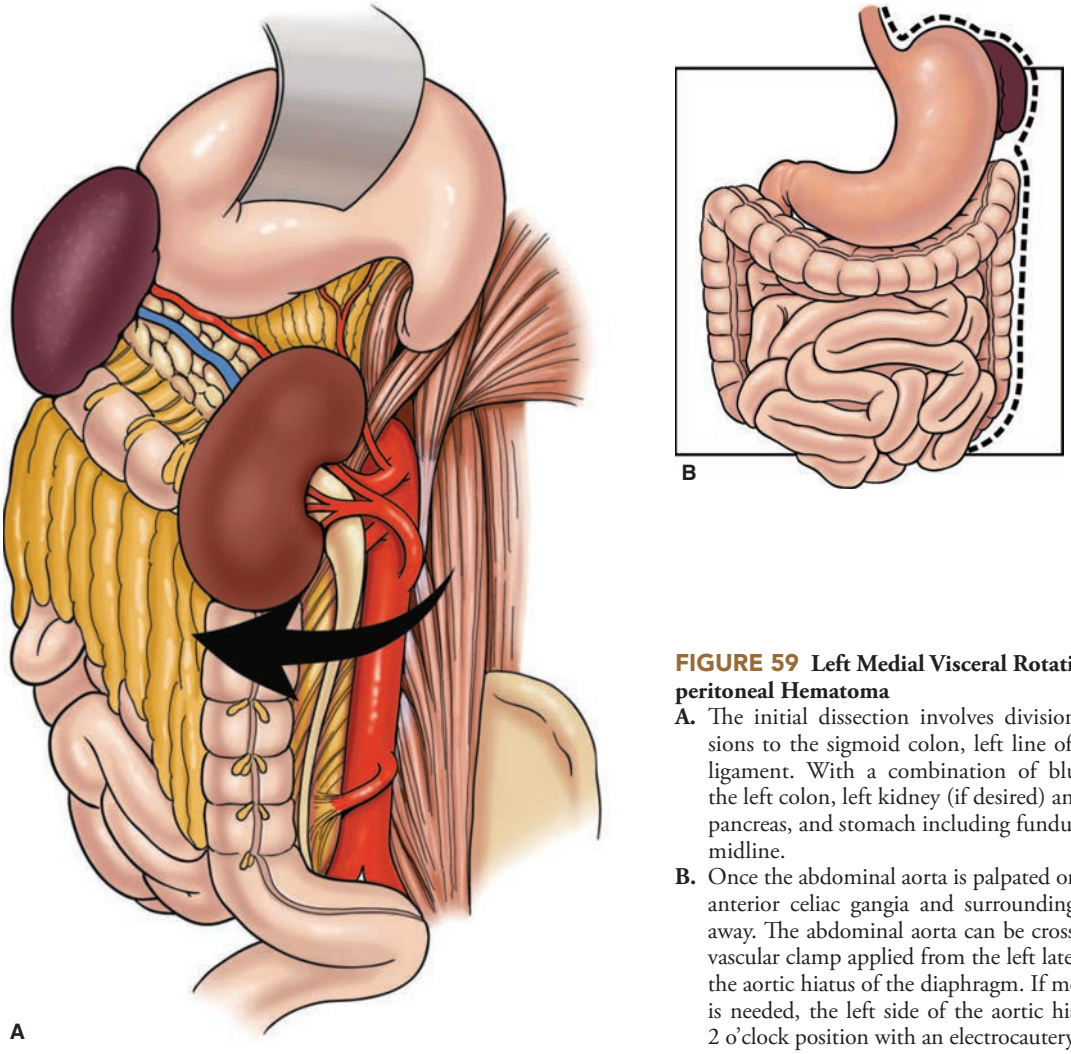

FIGURE 59 Left Medial Visceral Rotation for Suprarenal Retroperitoneal Hematoma
A. The initial dissection involves division of the congenital adhesions to the sigmoid colon, left line of Toldt, and the lienorenal ligament. With a combination of blunt and sharp dissection, the left colon, left kidney (if desired) and ureter, spleen, tail of the pancreas, and stomach including fundus are mobilized toward the midline.
B. Once the abdominal aorta is palpated on the lumbar vertebrae, the anterior celiac gangia and surrounding lymphatics are dissected away. The abdominal aorta can be cross-clamped with a DeBakey vascular clamp applied from the left lateral position just inferior to the aortic hiatus of the diaphragm. If more proximal aortic control is needed, the left side of the aortic hiatus can be divided at the 2 o'clock position with an electrocautery.

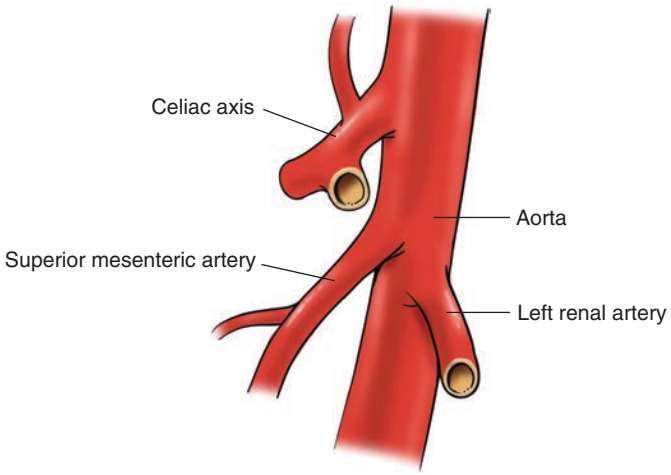

FIGURE 60 Superior Mesenteric Artery
This is the surgical anatomy of the celiac axis, superior mesenteric artery (SMA), and renal arteries. Note that the muscle decussations at the celiac axis are contiguous with the diaphragmatic crura and are located at the level of the diaphragm. Also note the very close proximity of these four arteries. The celiac ganglia around the celiac axis and SMA can be quite thickened and appear as fibrous tissue. They are composed of nerves coming from the greater, middle, and lesser splanchnic nerves that originate from thoracic vertebrae.

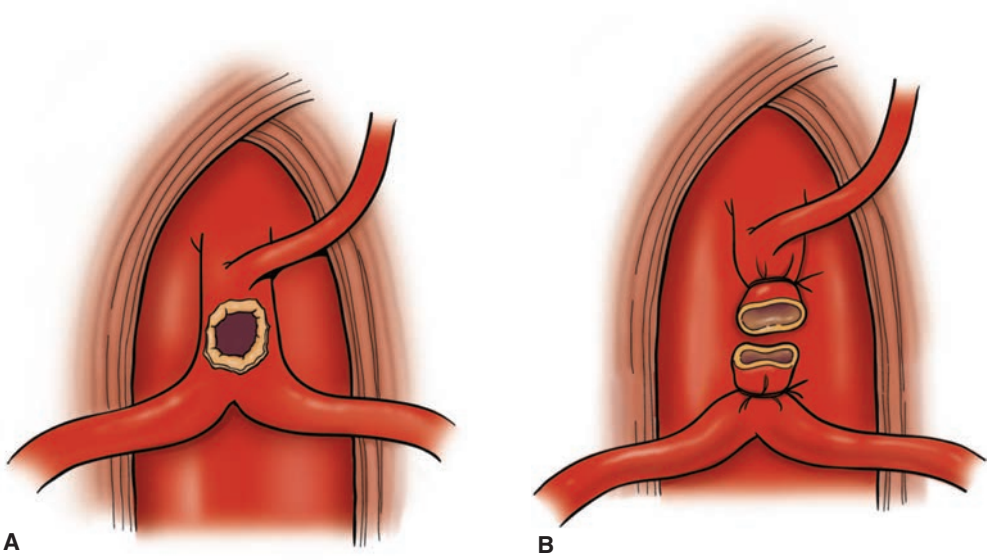

FIGURE 61 Bleeding from the Celiac Axis
A. Drawing illustrating injury to the celiac axis.
B. Ligation of celiac axis with preservation of left gastric artery.

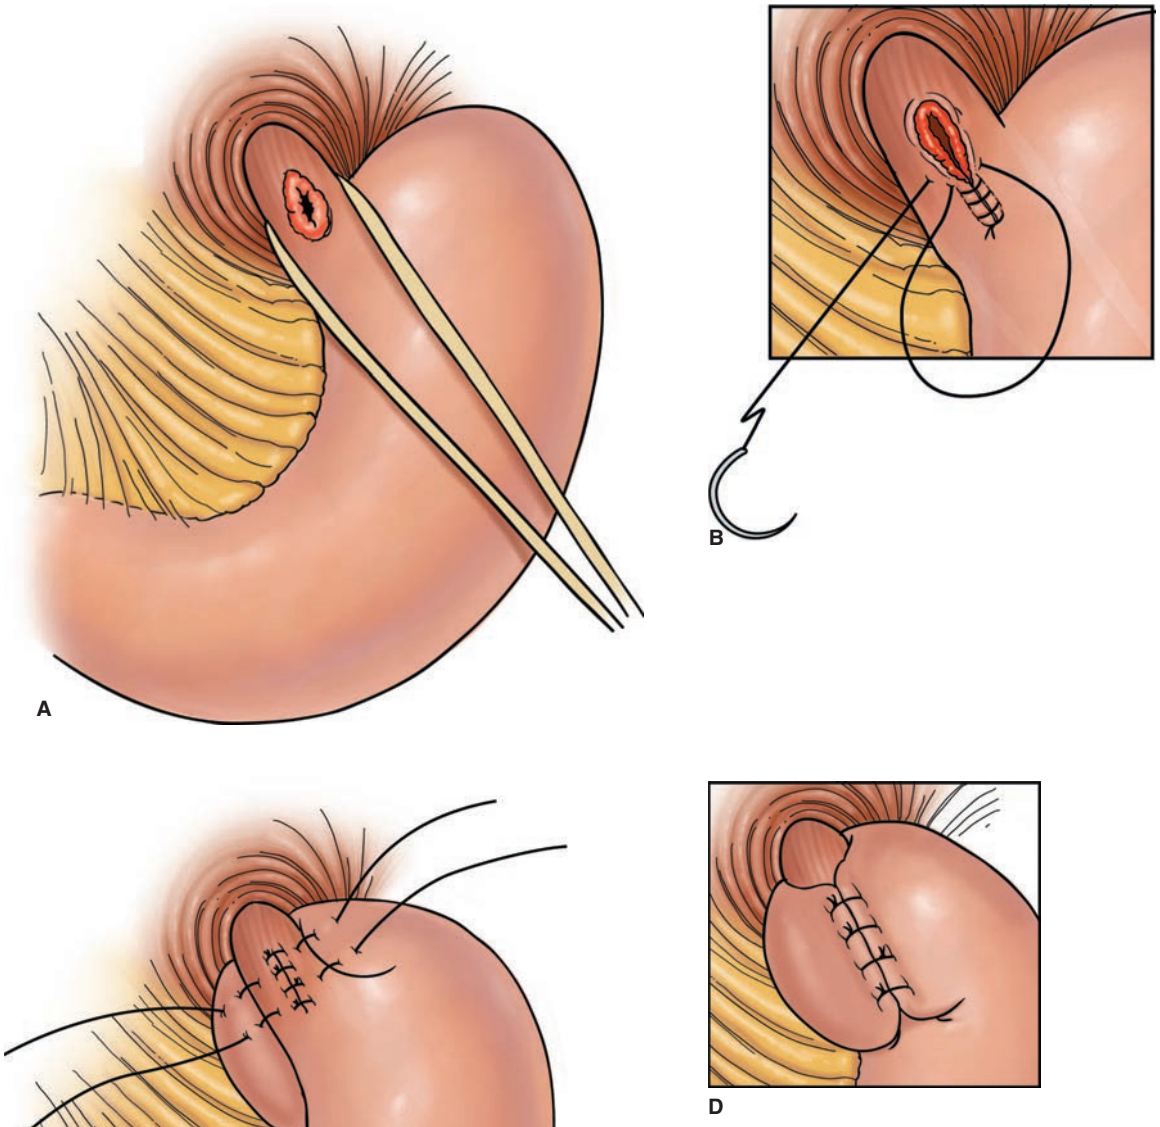

FIGURE 62 Exposure and Repair of an Injury at the Esophagogastric Junction

A. High gastric injuries can be difficult to expose and repair. Following mobilization of the left lobe of the liver by lysing the left triangular ligament, the liver is retracted and the esophagus encircled with a Penrose drain for downward traction.

B. Anterior holes can be suture repaired, taking care not to cause a stricture at this location.

C–D. For an extensive esophagogastric junction injury, the greater curvature of the stomach is mobilized, ligating the vasa brevia vessels, and a fundoplication might be added for a more secure closure.

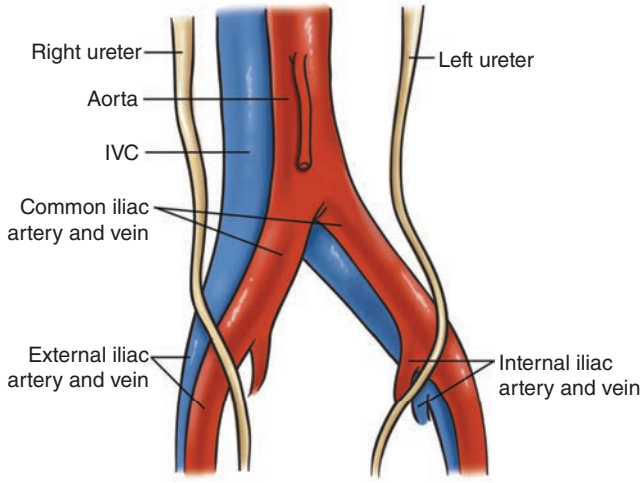

FIGURE 63 **Iliac Anatomy**
This illustrates the distal abdominal aorta, the proximal inferior vena cava, and the common and external iliac arteries, as well as the accompanying iliac veins. The orifices of the internal iliac arteries and veins can be seen as the ureters cross anterior to the iliac arteries at this location.

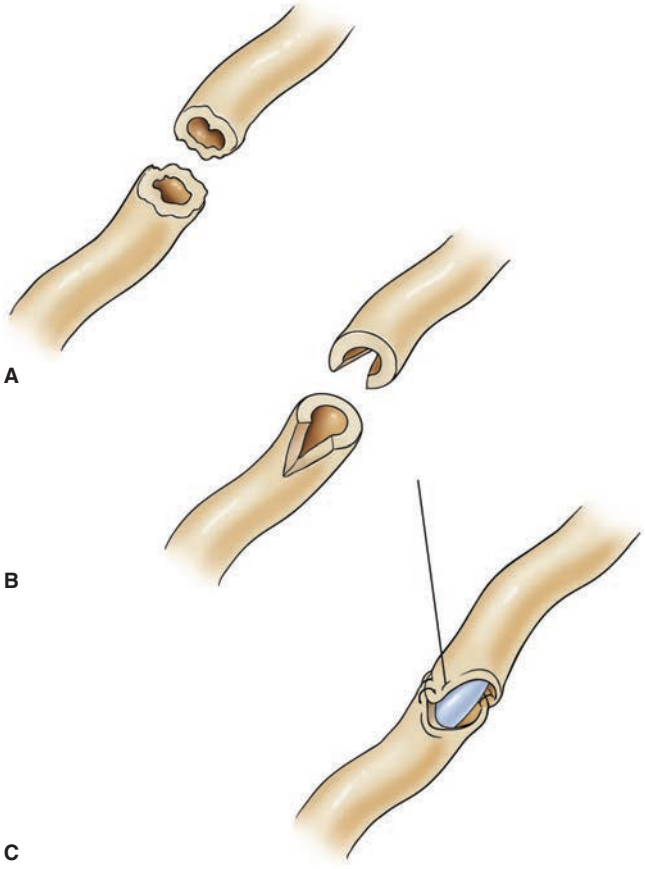

FIGURE 64 **Repair of the Transected Ureter**
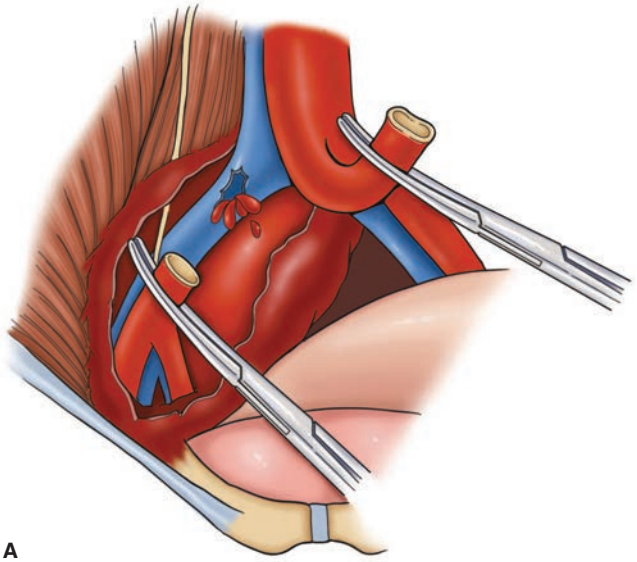
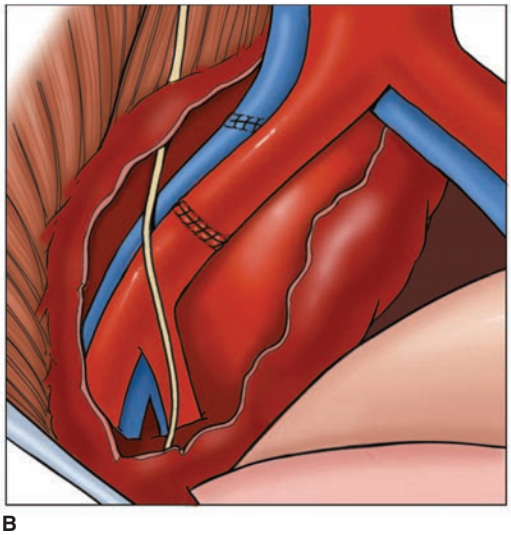
A. Drawing of a transected ureter.
B. Spatulated transected ureter.
C. Direct absorbable suture repair of transected ureter over stent.



A

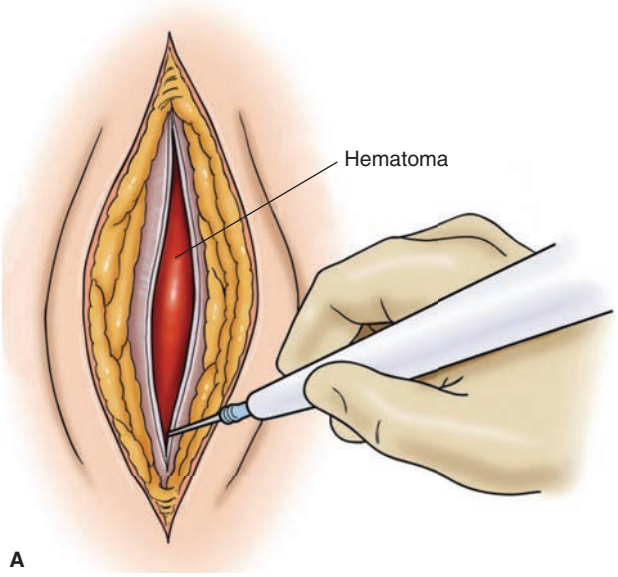


B

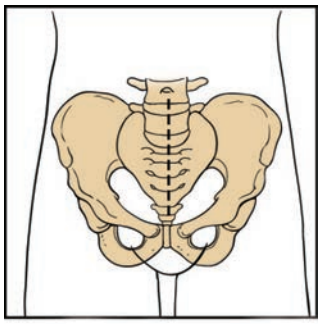
FIGURE 65 Deliberate Division of the Right Common Iliac Artery

A. Exposure of an injury to the right common iliac vein is very difficult. Deliberate division of right common iliac artery between vascular clamps facilitates exposure and repair of an underlying venous injury.

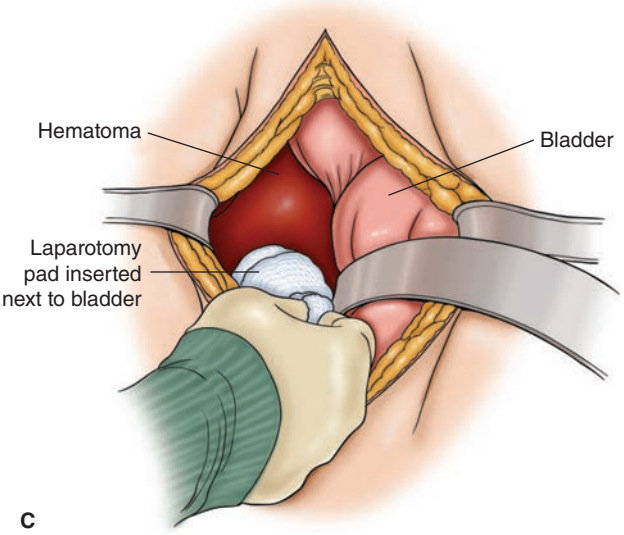
B. Following venous control, the right common iliac artery is reanastomosed.



A



B 6-8 cm midline incision



C

FIGURE 66 Pelvic Packing for Fracture with Retroperitoneal Bleeding

A–B. Through a low midline incision, the area of the extraperitoneal bladder is approached, taking care to stay outside the peritoneal cavity.

C. Any free blood is removed, and the sides of the bladder are retracted.

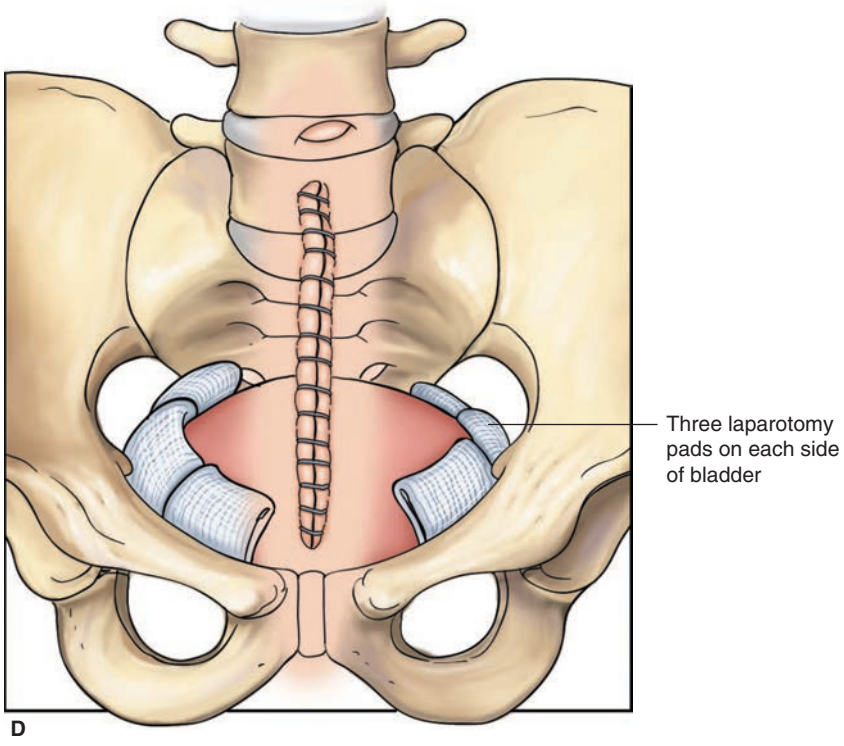


FIGURE 66 Pelvic Packing for Fracture with Retroperitoneal Bleeding (*Continued*)

D. Three laparotomy pads are placed on each side, lateral and posterior to the bladder. The laparotomy pads are left in place as a damage control tactic (to be removed later), and the lower midline incision is closed. Some surgeons also ligate the internal iliac arteries bilaterally. Others recommend leaving these vessels intact to provide a route for embolization should bleeding continue.

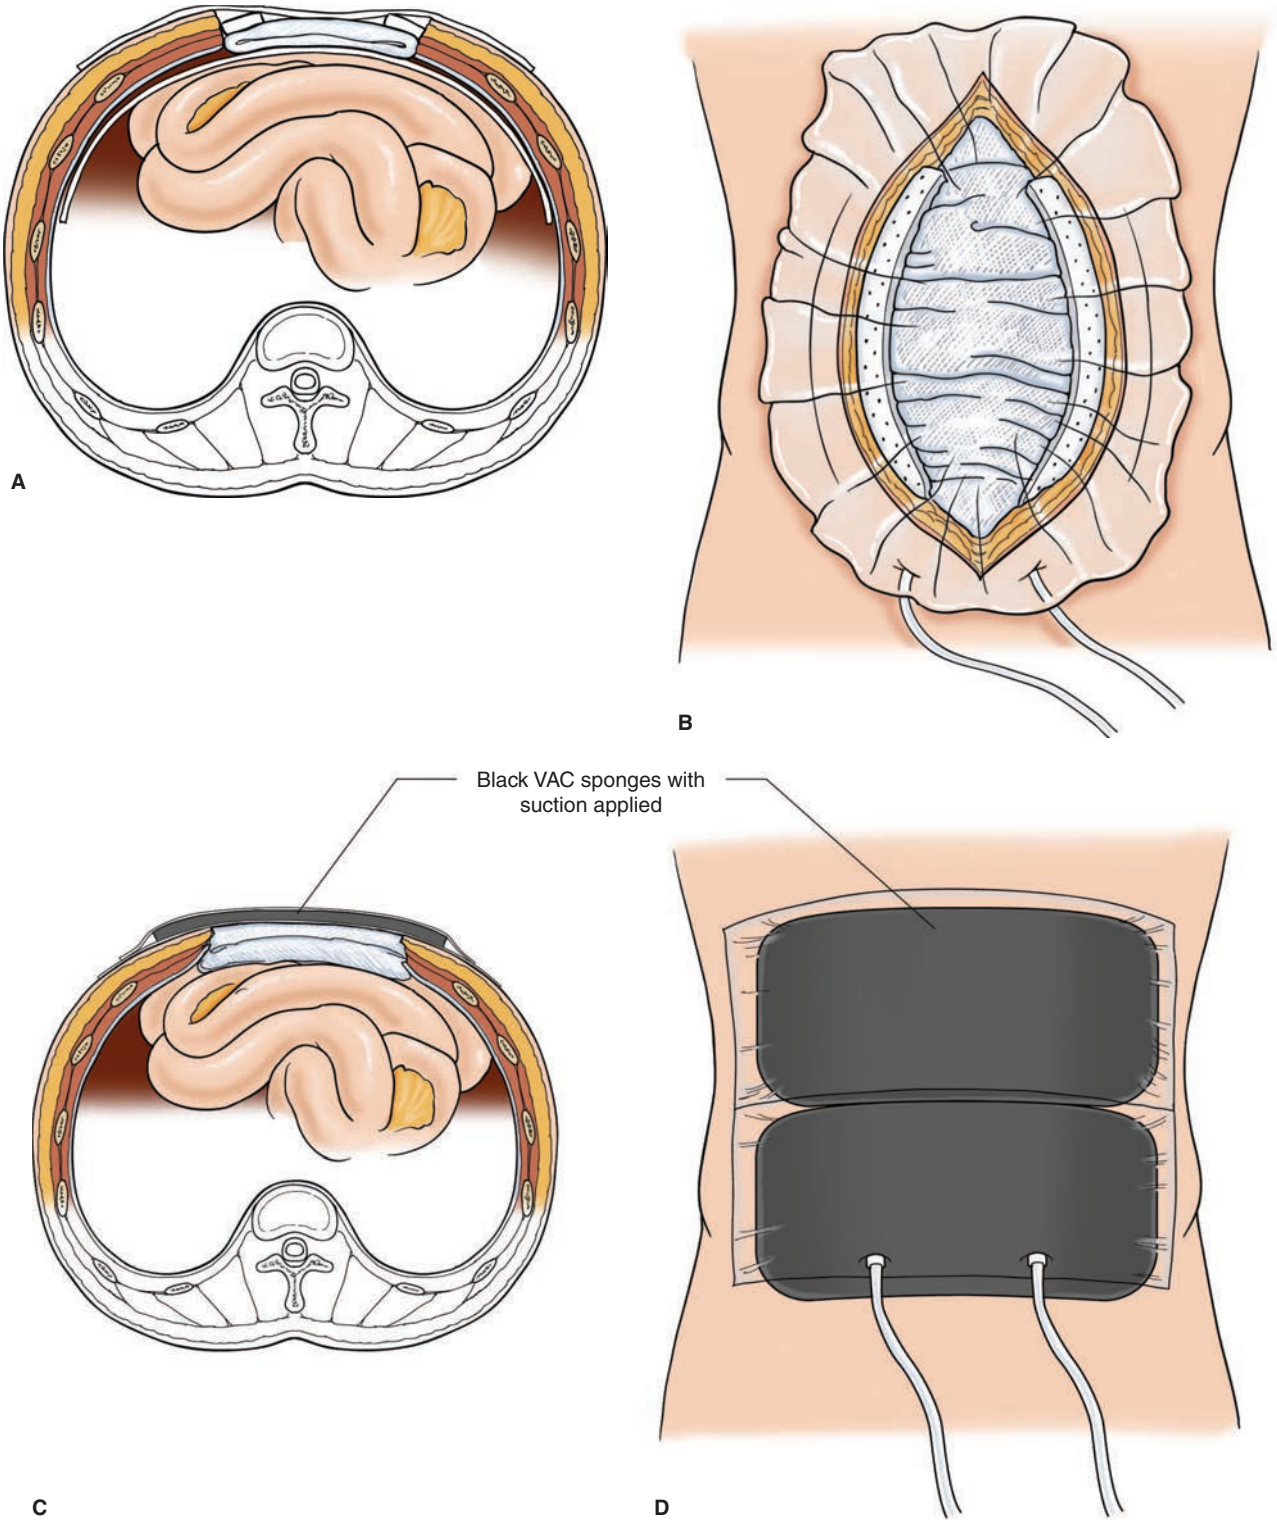

FIGURE 67 Temporary Abdominal Wall Closure Following Damage Control Laparotomy

A. This is the first of a series of drawings demonstrating approaches to management of the abdominal wall after a damage control laparotomy and one in which there is concern for an abdominal compartment syndrome. A transverse depiction of the abdomen is shown with a plastic drape covering the intestines, a series of cloth packings in the middle of the incision, and a plastic drape covering over the entire abdomen, with this drape resting on the skin.

B–D. In **B,** the covering is seen from a frontal view and two suction tubes are seen to emerge from the lower abdomen. Alternatively to the drawings using available pads, plastic sheeting, and suction tubing in every operating room, some surgeons, even at the first operation, might choose to use the same principle, but employ a commercially available device (**C** and **D**). Other surgeons might elect to use such a commercial device at the second or third damage control laparotomy.

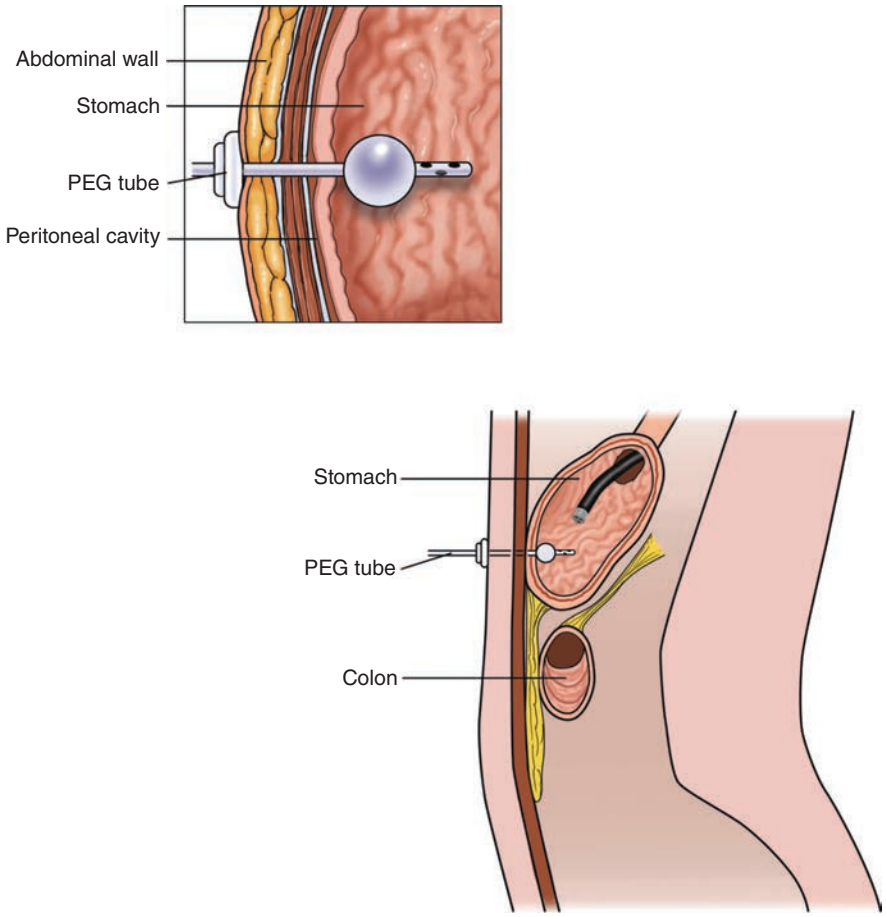

FIGURE 68 PEG (Percutaneous Endoscopic Gastrostomy)
A feeding gastrostomy can be placed with the guidance of a gastroscope to confirm optimal position of the tube. A snare is introduced via the gastroscope to pull a percutaneous wire introduced in the left subcostal region where the stomach transilluminates. The gastrostomy tube is then pulled transorally into the stomach.

EXTREMITY VASCULAR

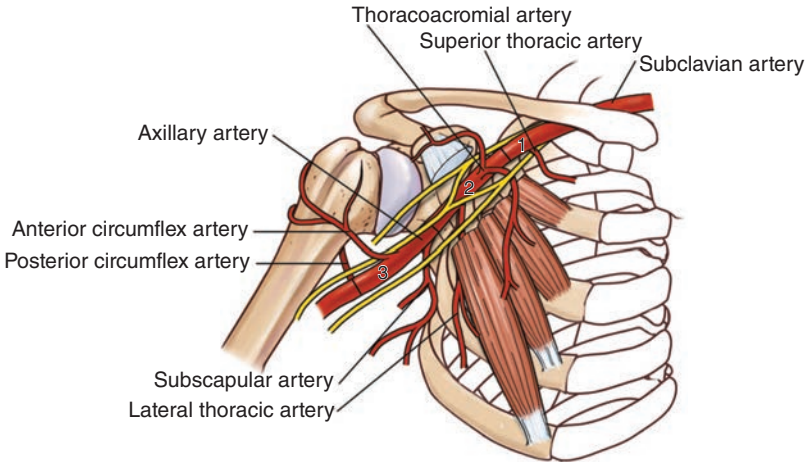

FIGURE 69 Axillary Artery Anatomy
The axillary artery has six branches. The pectoralis major and pectoralis minor muscles, which cover the axilla, are not shown in this drawing.

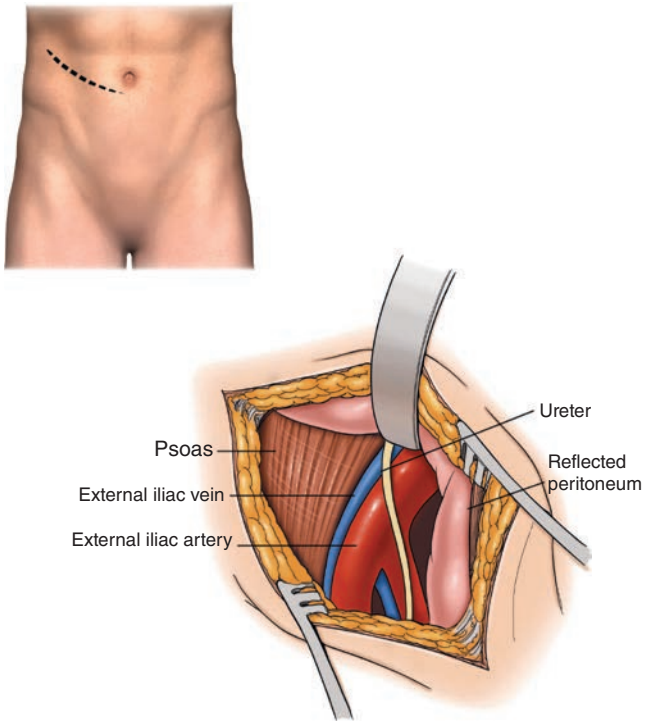

FIGURE 70 Retroperitoneal Exposure of Iliac Artery
This is a lateral lower abdominal incision often used for kidney transplants, which allows for exposure of the retroperitoneal fossa at the bifurcation of the iliac artery. The common, external, and internal iliac arteries are visualized, with the accompanying iliac veins behind the arteries. Note that the ureter crosses anterior to the iliac artery where the iliac artery bifurcates.

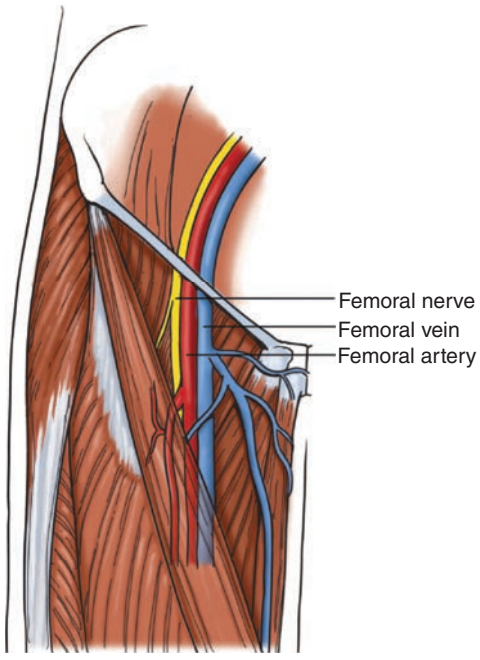

FIGURE 71 Femoral Artery
This is the anatomy of the femoral nerve, artery, and vein, just distal to the inguinal ligament. These anatomical relationships are important to remember when inserting various lines and catheters. Note the arterial branches just proximal to the inguinal ligament. These can produce troublesome bleeding if inadvertently injured during dissection.

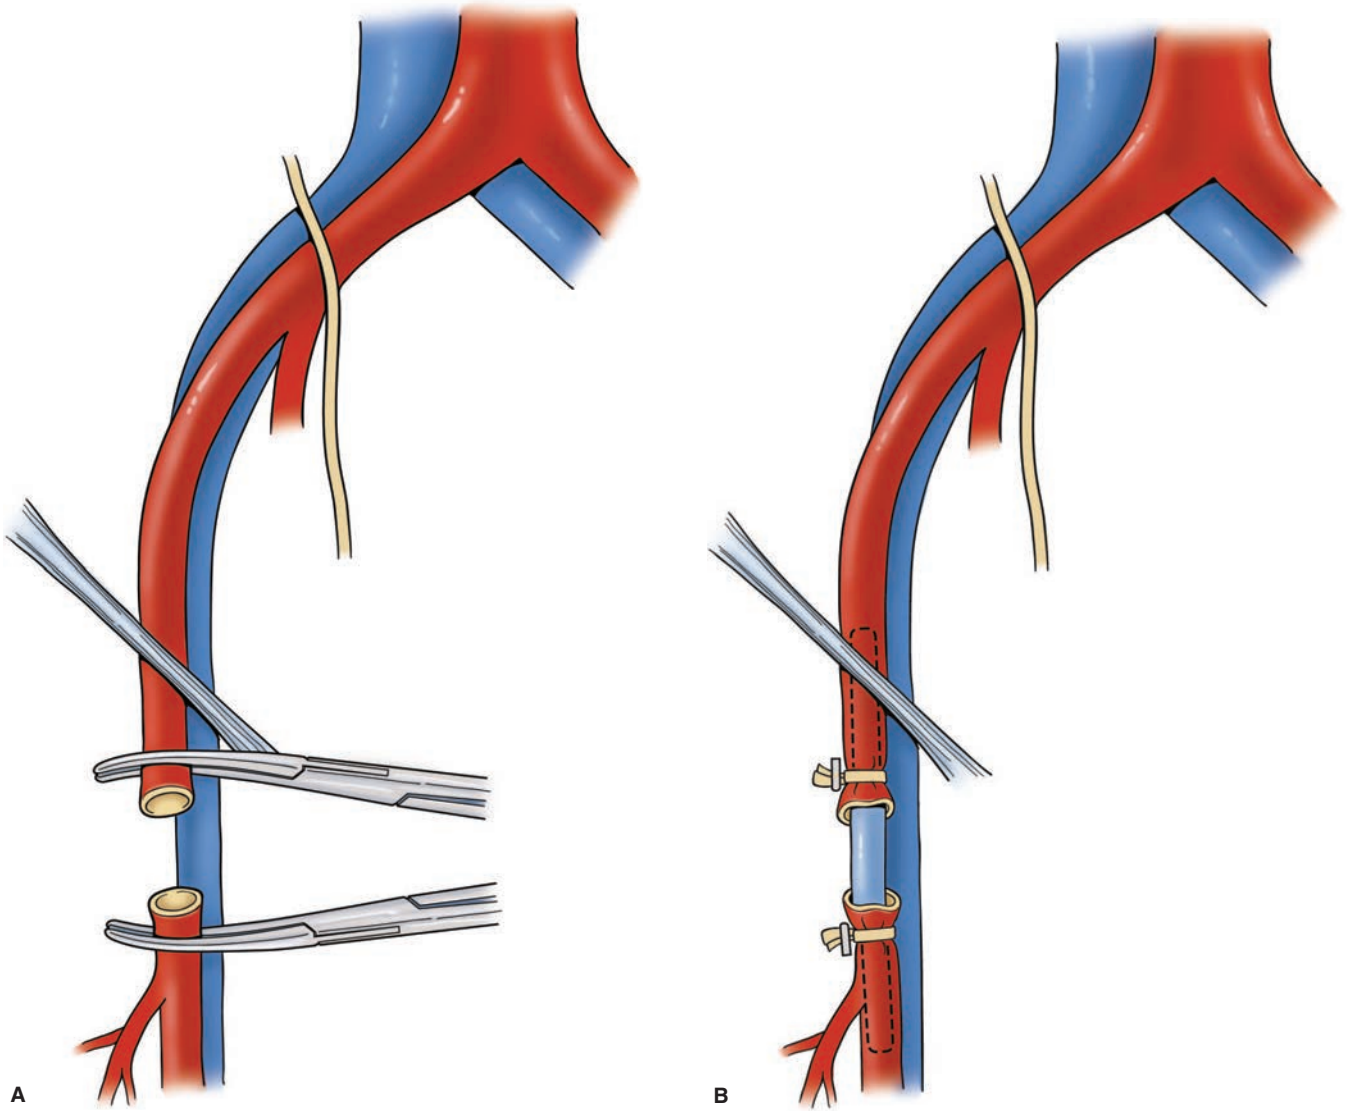

FIGURE 72 Temporary Intraluminal Vascular Shunt

A. Used in most major named vessels of the body, a temporary intravascular shunt is pictured here in the common femoral artery. This vascular damage control tactic provides oxygenated blood distal to a vascular injury, while other injuries are addressed or, if necessary, the patient is transferred for a higher level of care.

B. Using appropriately sized plastic tubing, that is, commercially available carotid shunts, the shunt is secured with encircling tapes.

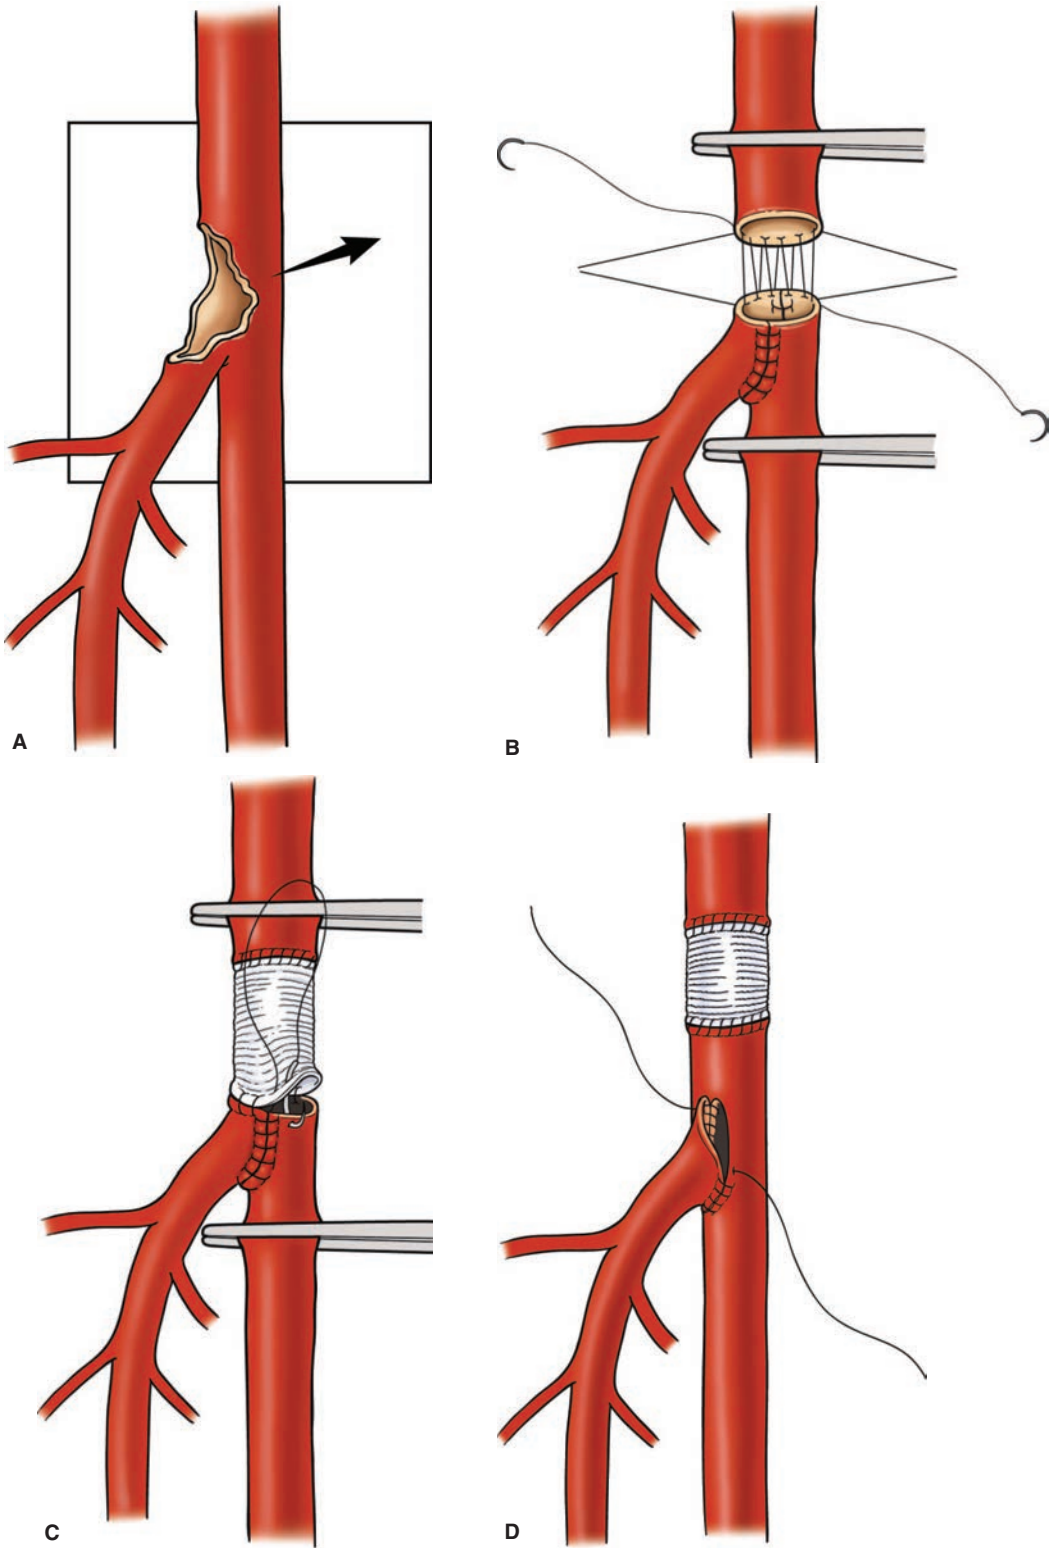

FIGURE 73 Complex Reconstruction of the Femoral Artery

A. Drawing illustrating a complex injury to the femoral artery.

B. The area of injury is debrided, and the sides of the superficial femoral and profunda femoris arteries are sewn together to produce a large single orifice. Depending on the tension, an end-to-end anastomosis can be performed.

C. The artery may also be reconstructed using an interposition graft, here depicted with Dacron.

D. On occasion, a bridge of prosthetic material can be sutured to the proximal superficial femoral artery, with the foreshortened profunda femoris artery sutured end-to-side to a more distal location in the superficial femoral artery.

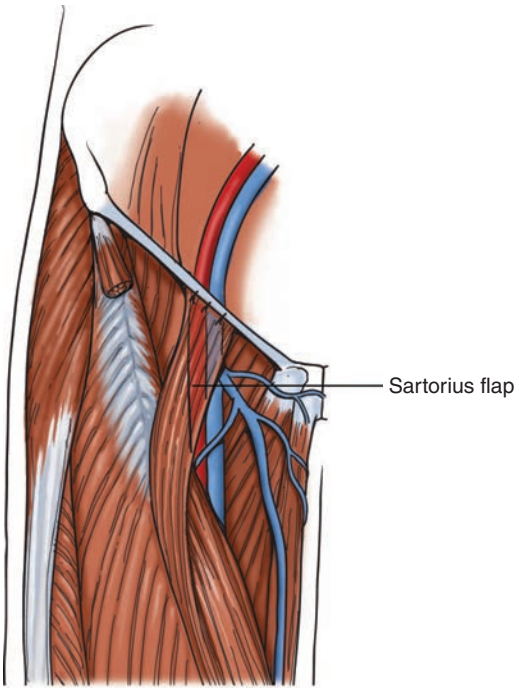

FIGURE 74 Sartorius Muscle Flap in the Groin
This depicts the anatomy of the sartorius muscle, with its accompanying arterial supply. A flap of the sartorius muscle is useful to cover nearby vessels and nerves.

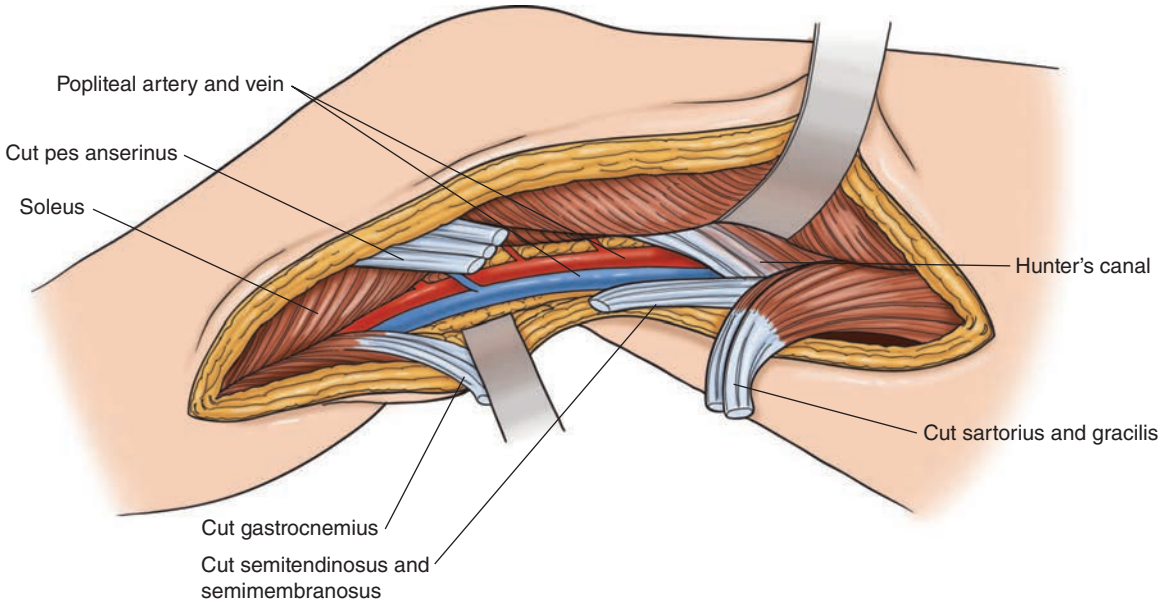

FIGURE 75 Exposure and Repair of Injuries to the Popliteal Artery and Vein
Opening the entire distal medial thigh and proximal medial leg from the area of Hunter's canal proximally to below the area where the popliteal artery divides exposes the popliteal artery and vein. If the injury is directly behind the knee joint, it may be necessary to divide and mark the tendons of the sartorius, gracilis, and semitendinosus muscles approximately 3/8 inch from the bone. After vascular repair, the tendons can be reapproximated with permanent sutures.

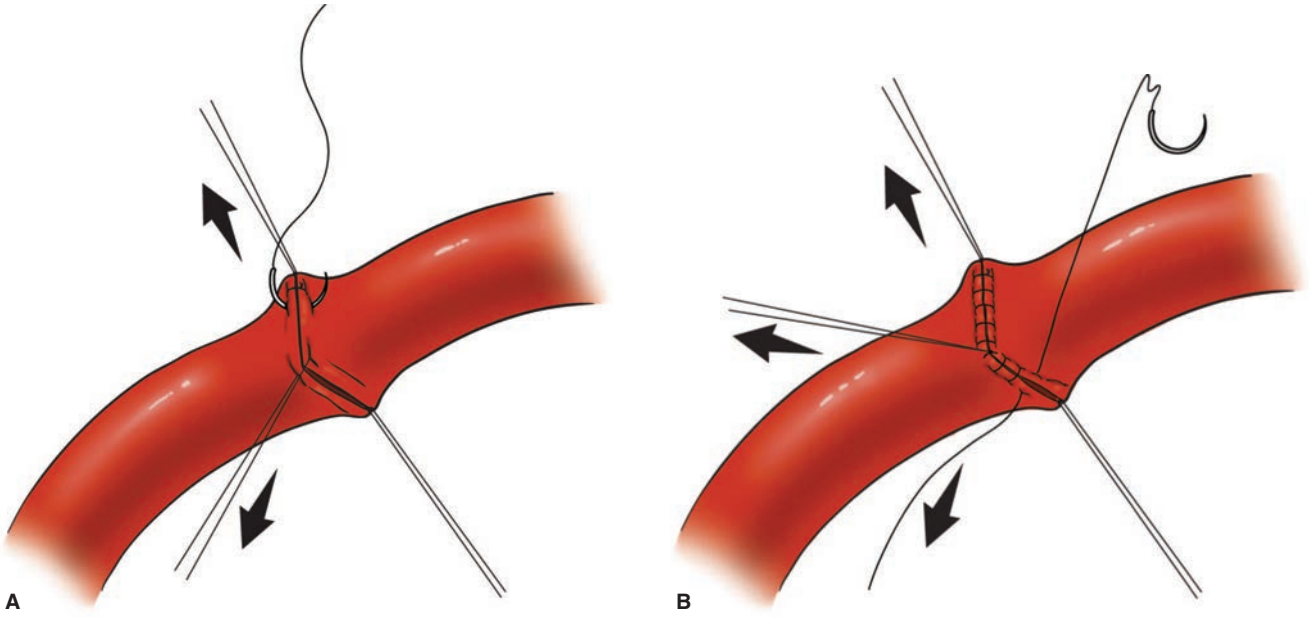

FIGURE 76 Triangulation Technique for End-to-End Anastomosis of Small Vessels

A. A triangulated end-to-end vascular anastomoses, a technique initially described by Alexis Carrel and Charles C. Guthrie.

B. Three temporary stay sutures may be tied as each section of the anastomosis is completed. Some surgeons prefer an interrupted anastomosis (not shown).

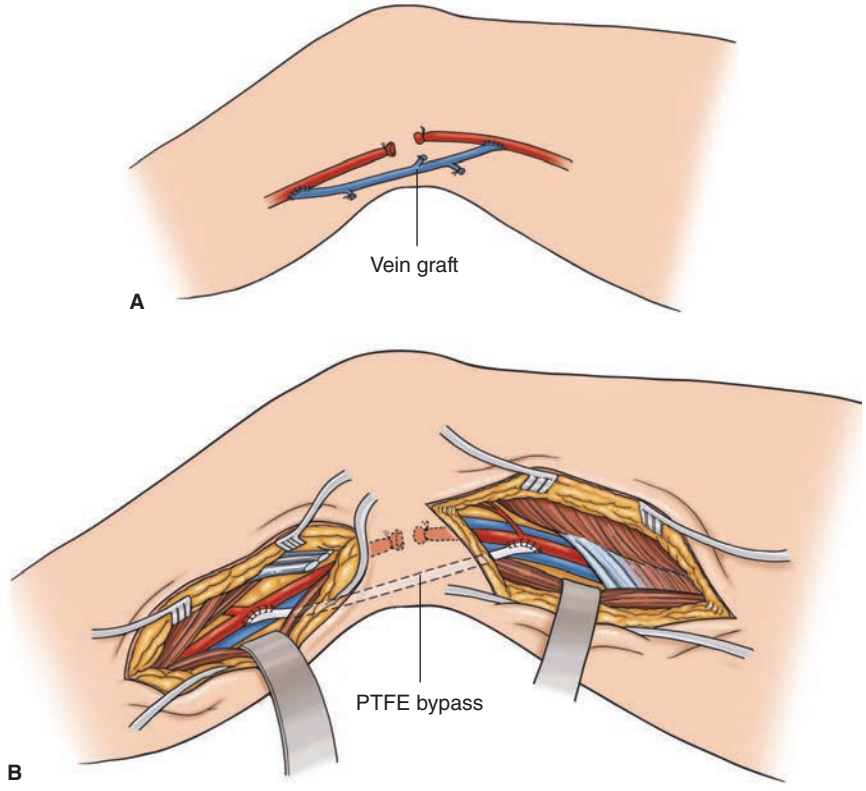

FIGURE 77 Popliteal Artery Injury Behind the Knee

A. Among the several options to reconstruct this injury, ligation of the two ends of the vessel with simple bypass using the saphenous vein from the other leg preserves the muscles and tendons at the medial side of the knee. Depending on presence of associated injuries, the bypass saphenous graft may be passed subcutaneously or deep in the normal traverse of the popliteal artery. Care must be taken to assure the graft does not kink when the knee is flexed.

B. On occasion, when vein is not available, an appropriately sized ringed polytetrafluoroethylene (PTFE) graft is used.

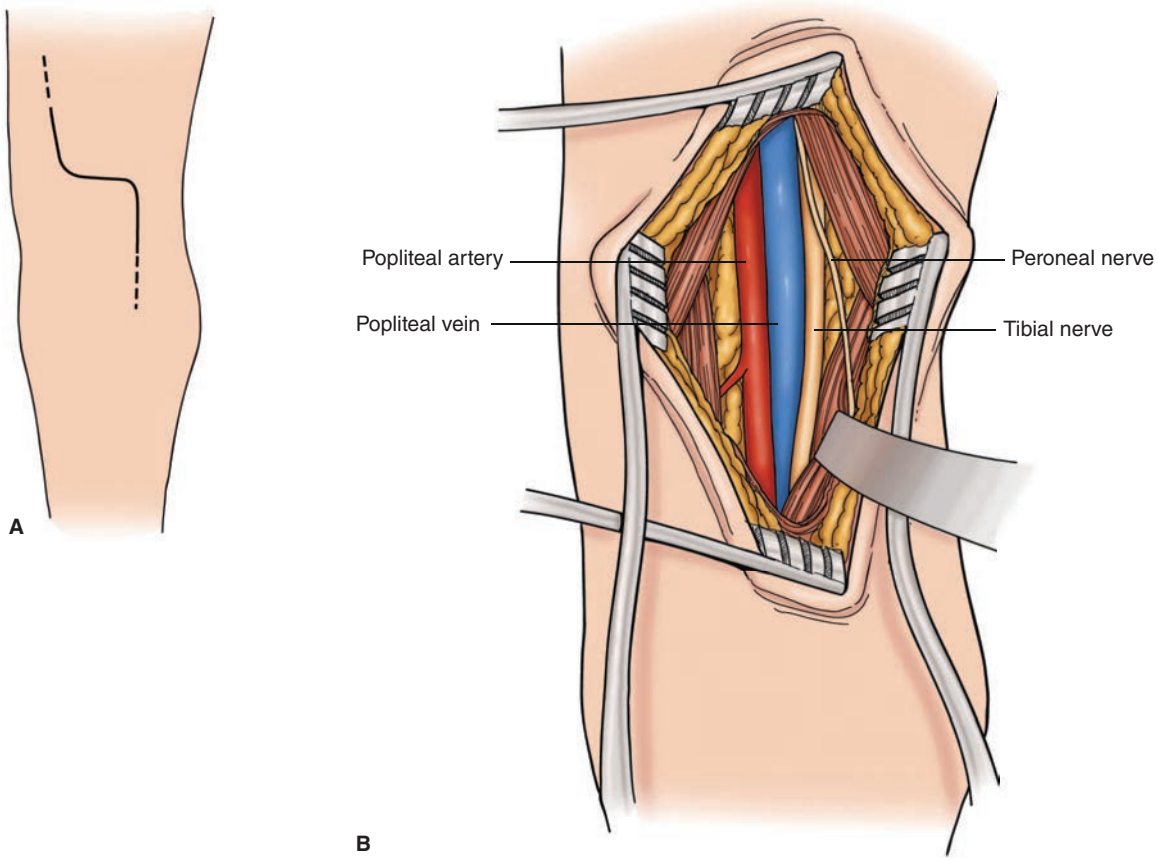

FIGURE 78 Posterior Exposure for Popliteal Artery Injuries

A. On rare occasions, a posterior approach to the popliteal fossa and its vessels may be desired. This approach prevents access to the groin and often reduces the opportunity for salvage of the greater saphenous vein.

B. Anatomy as seen for posterior approach to popliteal space.

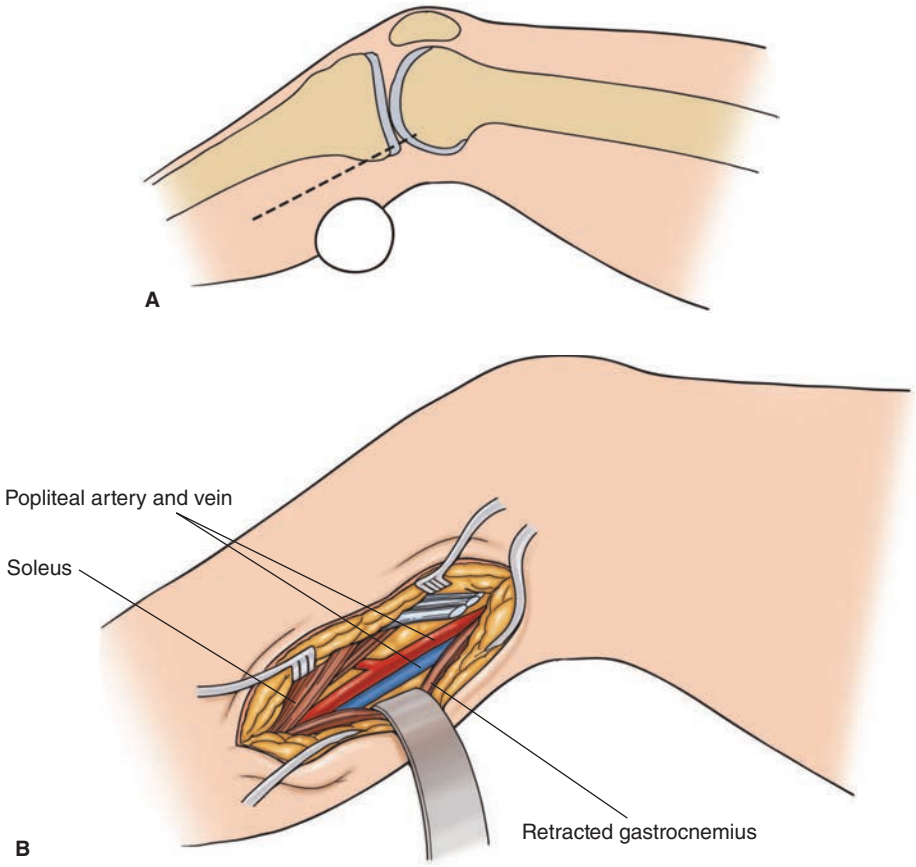

FIGURE 79 Exposure and Repair of Distal Popliteal and "Trifurcation" Injuries

A. Care is taken that the upper portion of this medial incision does not injure the subcutaneous saphenous vein and that it is sufficiently long enough for exposure of the proximal shank arteries.

B. The medial head of the gastrocnemius is taken down and the soleus muscle is exposed. The popliteal artery first gives off the anterior tibial artery, which traverses anteriorly through the interosseous membrane. Once precise vascular control is obtained in the area of the injury, reconstruction can be accomplished.

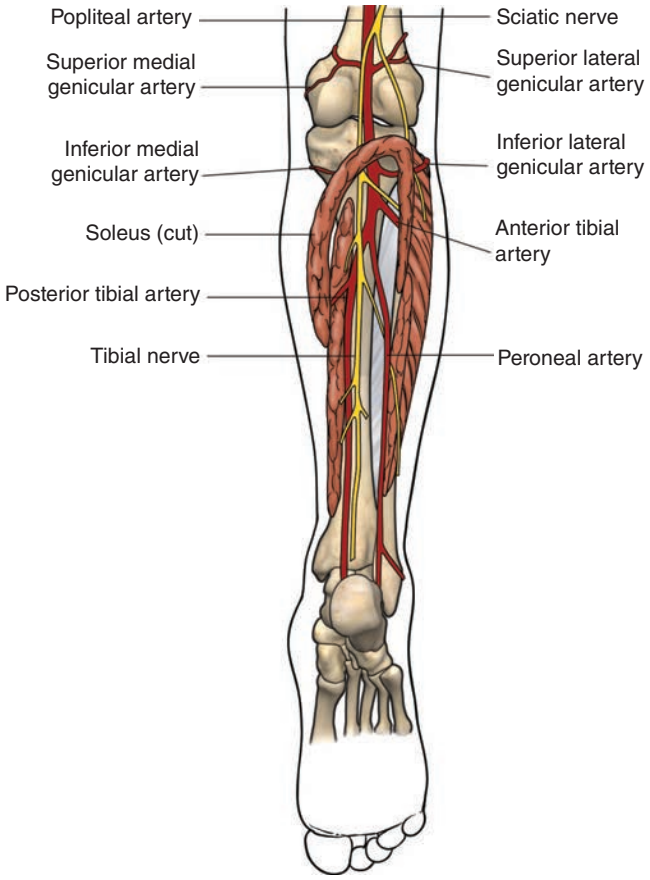

FIGURE 80 Anatomy of the Posterior Leg
Note the course of the popliteal artery and its association with the branches of the sciatic nerve.

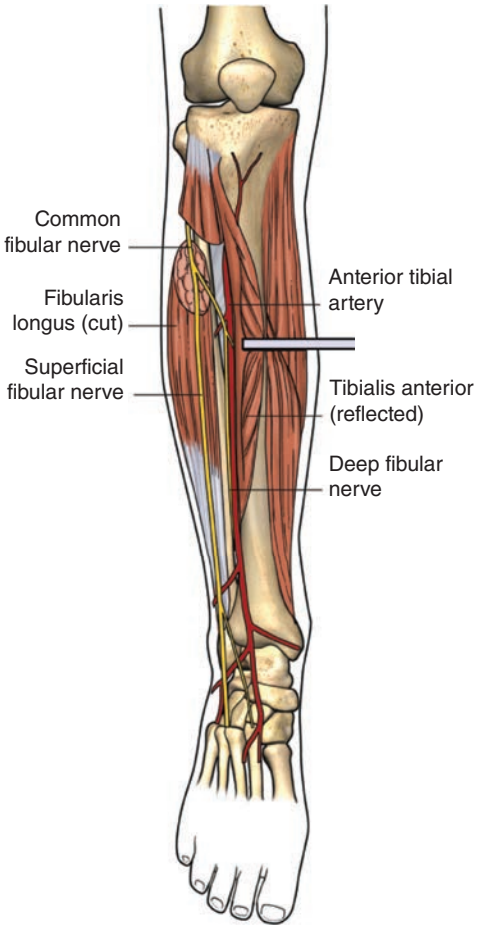

FIGURE 81 Anatomy of the Anterior Leg
The nerves of concern are located laterally, and care is taken during a lateral fasciotomy to prevent iatrogenic injury. Note that the anterior tibial artery has traversed through the interosseous membrane to the anterior compartment.

B

FIGURE 82 Forearm Volar-Ulnar Fasciotomy to Decompress Mobile Wad and Superficial and Deep Volar Compartments

A. A single incision beginning on the radial side of the antecubital area extends transversely to the ulnar side. The incision then curves toward the hand and goes down the ulnar side of the volar forearm aiming for the mid-wrist.

B. The transverse antecubital fascial incision decompresses the mobile wad, while the volar-ulnar fascial incision decompresses the superficial volar compartment. Through this latter incision, the flexor carpi ulnaris and flexor digitorum sublimis muscles are separated, the ulnar artery is avoided, and the muscles in the deep volar compartment are individually decompressed.

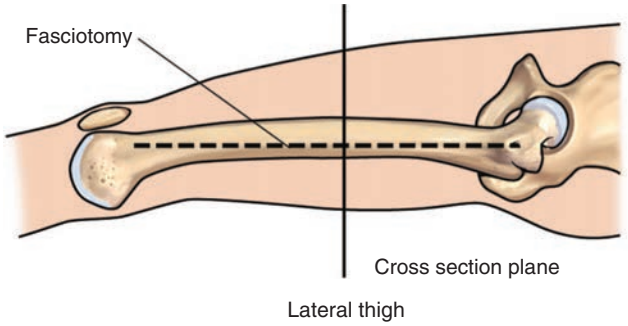

FIGURE 83 Thigh Fasciotomy to Decompress Anterior (Extensor) and Posterior (Flexor) Compartments

One anterolateral thigh skin incision along the iliotibial tract and opening the fascia over the vastus lateralis muscle and mobilizing it superiorly allows for decompression of the extensor and flexor compartments of the thigh.

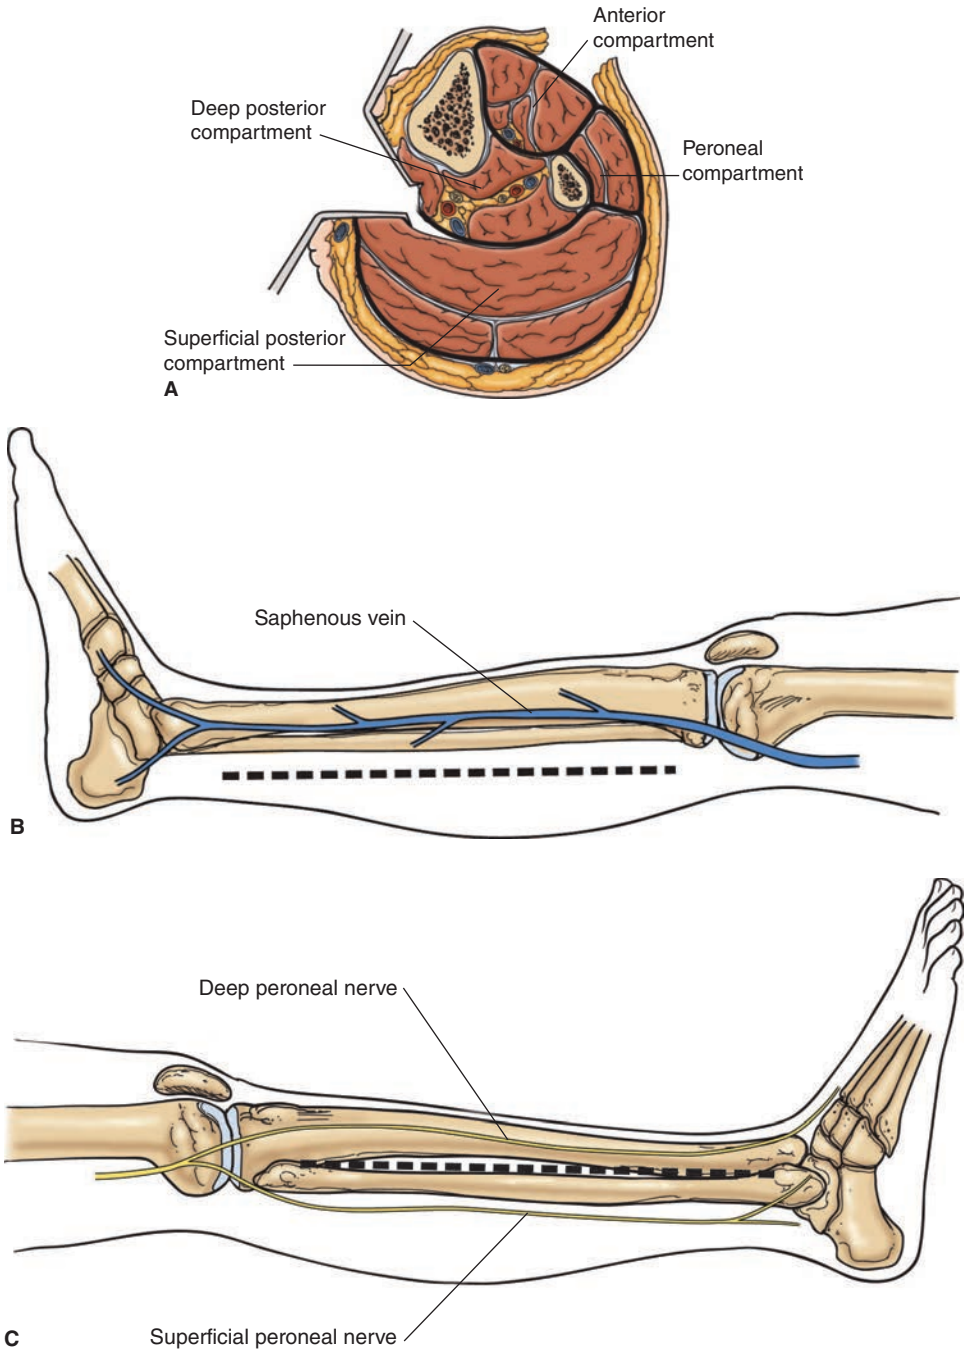

FIGURE 84 Calf Fasciotomy to Decompress Anterior, Peroneal, and Superficial and Deep Posterior Compartments

A. Cross section of the four compartments of the calf.

B. The lateral skin incision is made 2 cm anterior to the superior edge of the fibula curving anteriorly as the incision goes toward the knee to avoid injury to the superficial peroneal nerve. The anterior and peroneal compartments are opened longitudinally (about 4–5 cm apart) through this one lateral skin incision.

C. The medial skin incision is made 2 cm posterior to the inferior edge of the tibia avoiding injury to the greater saphenous vein. Once the superficial posterior compartment is decompressed, the soleus muscle is detached from the lateral tibia to allow for decompression of the deep posterior compartment immediately under the shaft of the tibia.

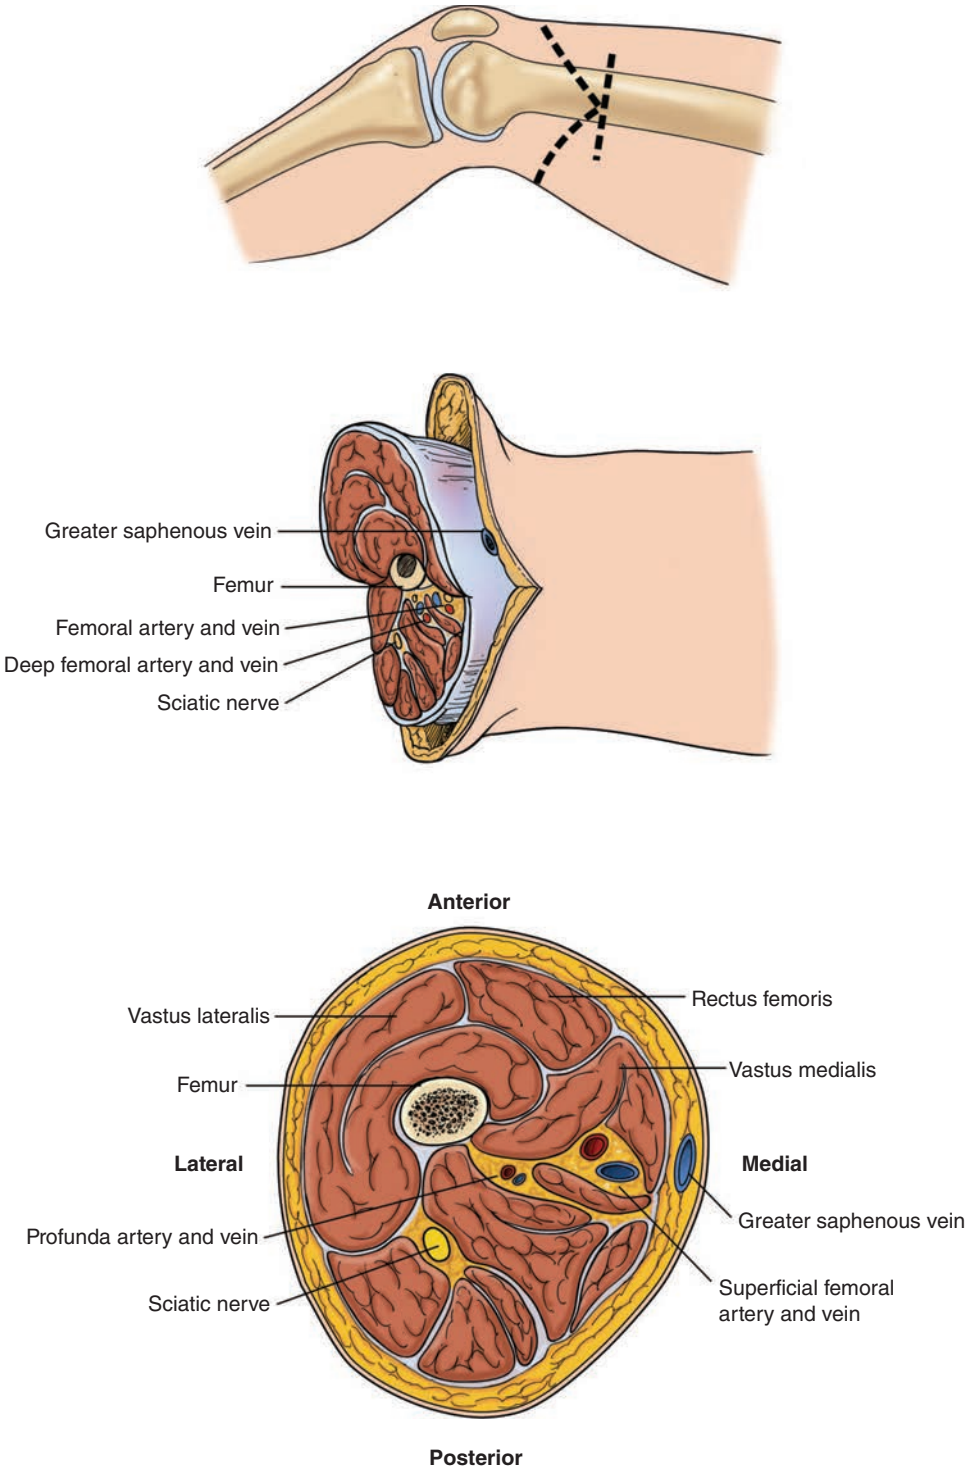

FIGURE 85 Above the Knee Amputation
These drawings illustrate an above the knee amputation. Note that the femur is amputated higher than the skin flaps to achieve tension-free coverage. The regional anatomy is shown.

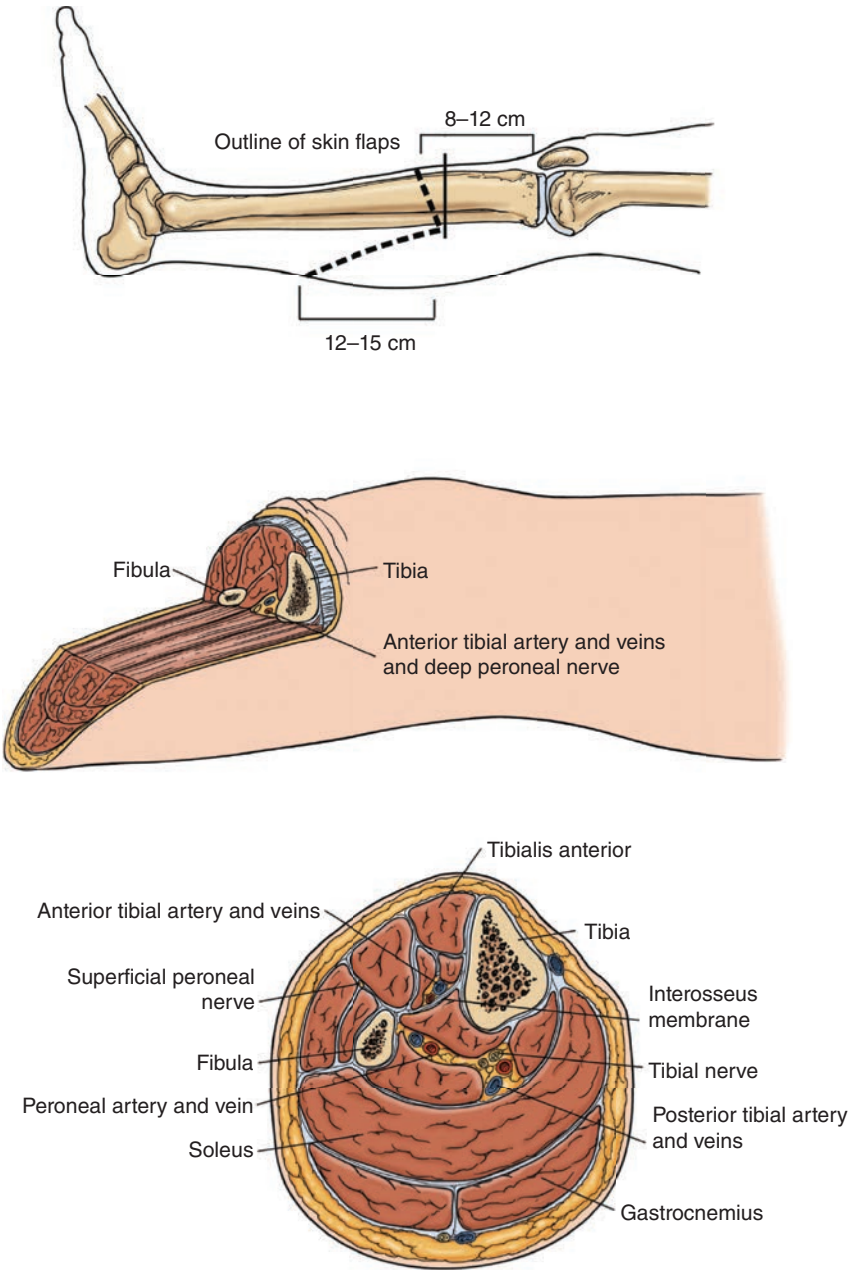

FIGURE 86 Below the Knee Amputation
These drawings illustrate a below the knee amputation. Note the long posterior flap to allow coverage of the amputation stump and provide an adequate cushion for the weight-bearing surface.
